Preface

In an age when the internet is providing numerous options of treatment based on not always properly validated concepts presented by clinicians of sometimes unclear background, the practitioner is left with a confusing image of the profession. The questions of what is right and what is a professional error are becoming increasingly difficult to determine. It is evident that such online education – while occasionally having its undisputed benefits – bears the danger of distributing treatment philosophies that are most likely not scientifically scrutinized and, hence, may even be detrimental to the patient.

Given these facts, one may wonder what the role of a textbook becomes, when everything is so easily accessible through electronic media. Obviously, a textbook still represents a unique source of professional information containing a treatment philosophy that must be based on scientific evidence rather than on trial and error or personal preference. *Clinical Periodontology and Implant Dentistry* has always emphasized the evidence-based treatment approach.

The textbook originated from Scandinavia and documented various treatment procedures with clinical research data. In later years, the authorship became more international, which led to the success of the text throughout the world. In the fourth edition some aspects of implant dentistry were incorporated, and by the time that fifth edition was prepared implant dentistry had become an important part of clinical periodontology. Owing to the increased content, the first of the now two volumes presented the basic aspects, applying biological principles to both periodontal and peri-implant tissues, whereas the second volume was devoted to treatment aspects. It had become evident that periodontology also affects the biology of implants.

Consequently, these two fields of dentistry have become merged and married to each other. The new sixth edition of this textbook incorporates the important topic of the strictly prosthetic aspects of treating mutilated dentition. An essential part of comprehensive therapy is treatment planning according to biological principles, to which special attention has been given. The installation of oral implants and their healing are covered in detail, and novel concepts of tissue integration are also addressed. Last, but not least, clinical experience from latter years has revealed that biological complications occur with oral implants. The sixth edition gives special attention to coping with such adverse events and also to issues related to the maintenance of periodontal and peri-implant health. All in all, the sixth edition represents a thoroughly revised syllabus of contemporary periodontology and implant dentistry.

If a textbook is to maintain its role as a reference source and guide for clinical activities it has to be updated at regular intervals. The sixth edition follows the fifth edition by 7 years, and 90% of the content has been revised in the last 2 years. Several chapters have been reconceived or completely rewritten by a new generation of internationally recognized researchers and master clinicians. As we thank our contributors to this new masterpiece for their enormous effort in keeping the text updated, we hope that the sixth edition of *Clinical Periodontology and Implant Dentistry* will maintain its status as the master text of periodontology and implant dentistry for the entire profession worldwide.

We express our gratitude to the numerous coworkers at Wiley, our publisher, who contributed to the realization of the project, and special thanks go to Nik Prowse (freelance project manager), Lucy Gardner (freelance copy-editor) and Susan Boobis (freelance indexer).

However, most of our thanks go to you, as reader, student, colleague, specialist clinician or researcher in clinical periodontology and implant dentistry. We hope that you enjoy this new edition, with its new clothes and new outline.

Introduction

This chapter provides a brief description of the characteristics of the normal periodontium. It is assumed that the reader has prior knowledge of oral embryology and histology.

The periodontium (peri = around, odontos = tooth) comprises the following tissues: (1) *gingiva* (G), (2) *periodontal ligament* (PL), (3) *root cementum* (RC), and (4) *alveolar bone proper* (ABP) (Fig. 1-1). ABP lines the alveolus of the tooth and is continuous with the alveolar bone; on a radiograph it may appear as *lamina dura*. The *alveolar process* that extends from the basal bone of the maxilla and mandible consists of the alveolar bone and the *alveolar bone proper*.

The main function of the periodontium is to attach the tooth to the bone tissue of the jaws and to maintain the integrity of the surface of the masticatory mucosa of the oral cavity. The periodontium, also called "the attachment apparatus" or "the supporting tissues of the teeth", constitutes a developmental, biologic, and functional unit which undergoes certain changes with age and is, in addition, subjected to morphologic changes related to functional alterations and alterations in the oral environment.

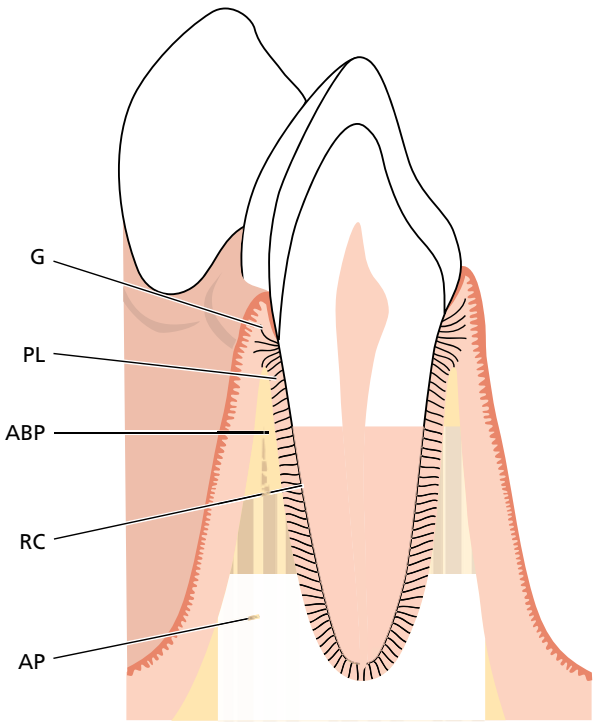

Fig. 1-1

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

The development of the periodontal tissues occurs during the development and formation of teeth. This process starts early in the embryonic phase when cells from the neural crest (from the neural tube of the embryo) migrate into the first branchial arch. In this position, the neural crest cells form a band of *ectomesenchyme* beneath the epithelium of the stomatodeum (the primitive oral cavity). After the uncommitted neural crest cells have reached their location in the jaw space, the epithelium of the stomatodeum releases factors which initiate epithelial–ectomesenchymal interactions. Once these interactions have occurred, the ectomesenchyme takes the dominant role in the further development. Following the formation of the *dental lamina*, a series of processes are initiated (bud stage, cap stage, bell stage with root development) which result in the formation of a tooth and its surrounding periodontal tissues, including the alveolar bone proper. During the cap stage, condensation of ectomesenchymal cells appears in relation to the dental epithelium (the dental organ [DO]), forming the *dental papilla* (DP) that gives rise to the dentin and the pulp, and the *dental follicle* (DF) that gives rise to the periodontal supporting tissues (Fig. 1-2). The decisive role played by the ectomesenchyme in this process is further established by the fact that the tissue of the dental papilla apparently also determines the shape and form of the tooth.

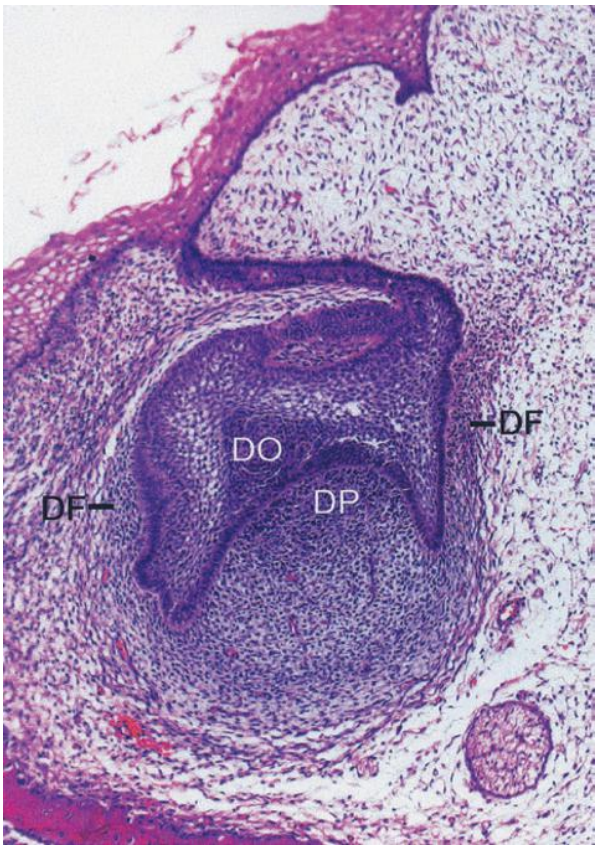

Fig. 1-2

If a tooth germ in the bell stage of development is dissected and transplanted to an ectopic site (e.g. the connective tissue or the anterior chamber of the eye), the tooth formation process continues. The crown and the root are formed, and the supporting structures (i.e. cementum, periodontal ligament, and a thin lamina of alveolar bone proper) also develop. Such experiments document that all information necessary for the formation of a tooth and its attachment apparatus resides within the tissues of the dental organ and the surrounding ectomesenchyme. The dental organ is the formative organ of enamel, the dental papilla is the formative organ of the dentin–pulp complex, and the dental follicle is the formative organ of the attachment apparatus (cementum, periodontal ligament, and alveolar bone proper).

The development of the root and the periodontal supporting tissues follows that of the crown. Epithelial cells of the external and internal dental epithelium (the dental organ) proliferate in an apical direction, forming a double layer of cells called *Hertwig's epithelial root sheath* (RS). The odontoblasts (OBs) forming the dentin of the root differentiate from ectomesenchymal cells in the dental papilla under the inductive influence of the inner epithelial cells (Fig. 1-3). The dentin (D) continues to form in an apical direction, producing the framework of the root. During formation of the root, the periodontal supporting tissues, including the acellular cementum, develop. Some of the events in cementogenesis are still unclear, but the following concept is gradually emerging.

At the start of dentin formation, the inner cells of Hertwig's epithelial root sheath synthesize and secrete enamel-related proteins, probably belonging to the amelogenin family. At the end of this period, the epithelial root sheath becomes fenestrated and ectomesenchymal cells from the dental follicle penetrate through these fenestrations and contact the root surface. The ectomesenchymal cells in contact with the enamel-related proteins differentiate into cementoblasts and start to form cementoid. This cementoid represents the organic matrix of the cementum and consists of a ground substance and collagen fibers, which intermingle with collagen fibers in the not yet fully mineralized outer layer of the dentin. It is assumed that the cementum becomes firmly attached to the dentin through these fiber interactions. The formation of the cellular cementum, which often covers the apical third of the dental roots, differs from that of acellular cementum in that some of the cementoblasts become embedded in the cementum.

The remaining parts of the periodontium are formed by ectomesenchymal cells from the dental follicle lateral to the cementum. Some of them differentiate into periodontal fibroblasts and form the fibers of the periodontal ligament, while

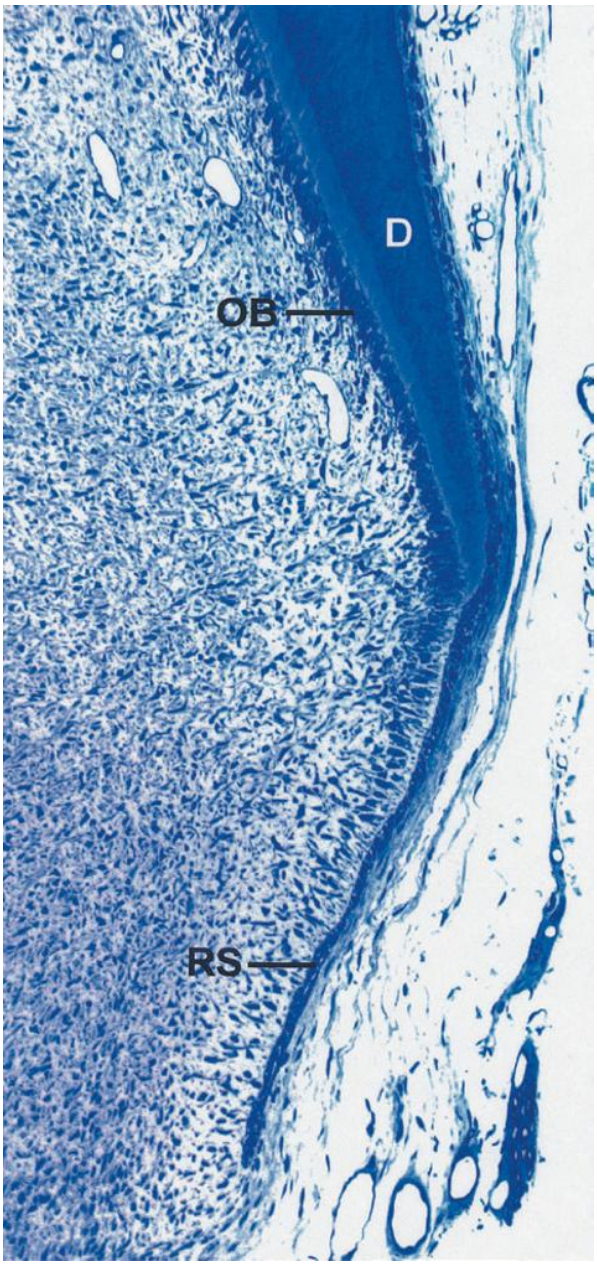

Fig. 1-3

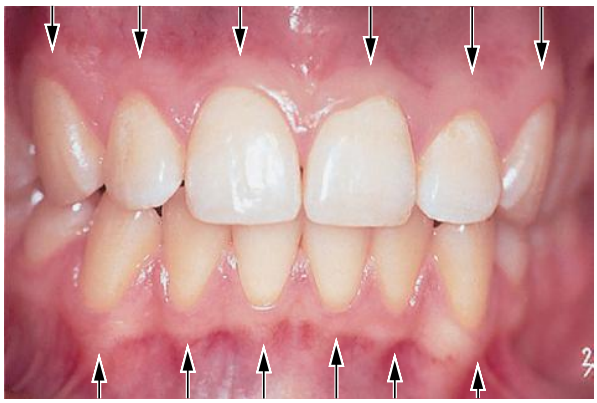

Fig. 1-4

Fig. 1-5

others become osteoblasts and form the alveolar bone proper in which the periodontal fibers are anchored. In other words, the primary alveolar wall is also an ectomesenchymal product. It is likely, but still not conclusively documented, that ectomesenchymal cells remain in the mature periodontium and take part in the turnover of this tissue.

Gingiva

Macroscopic anatomy

The oral mucosa (mucous membrane) is continuous with the skin of the lips and the mucosa of the soft palate and pharynx. The oral mucosa consists of (1) the *masticatory mucosa*, which includes the gingiva and the covering of the hard palate; (2) the *specialized mucosa*, which covers the dorsum of the tongue; and (3) the remaining part, called the *lining mucosa*.

Figure 1-4 The gingiva is that part of the masticatory mucosa which covers the alveolar process and surrounds the cervical portion of the teeth. It consists of an epithelial layer and an underlying connective tissue layer called the *lamina propria*. The gingiva obtains its final shape and texture in conjunction with eruption of the teeth.

In the coronal direction, the coral pink gingiva terminates in the *free gingival margin*, which has a scalloped outline. In the apical direction, the gingiva is continuous with the loose, darker red *alveolar mucosa* (lining mucosa) from which the gingiva is separated by a usually easily recognizable border called either the mucogingival junction (arrows) or the mucogingival line.

Figure 1-5 There is no mucogingival line present in the palate since the hard palate and the maxillary alveolar process are covered by the same type of masticatory mucosa.

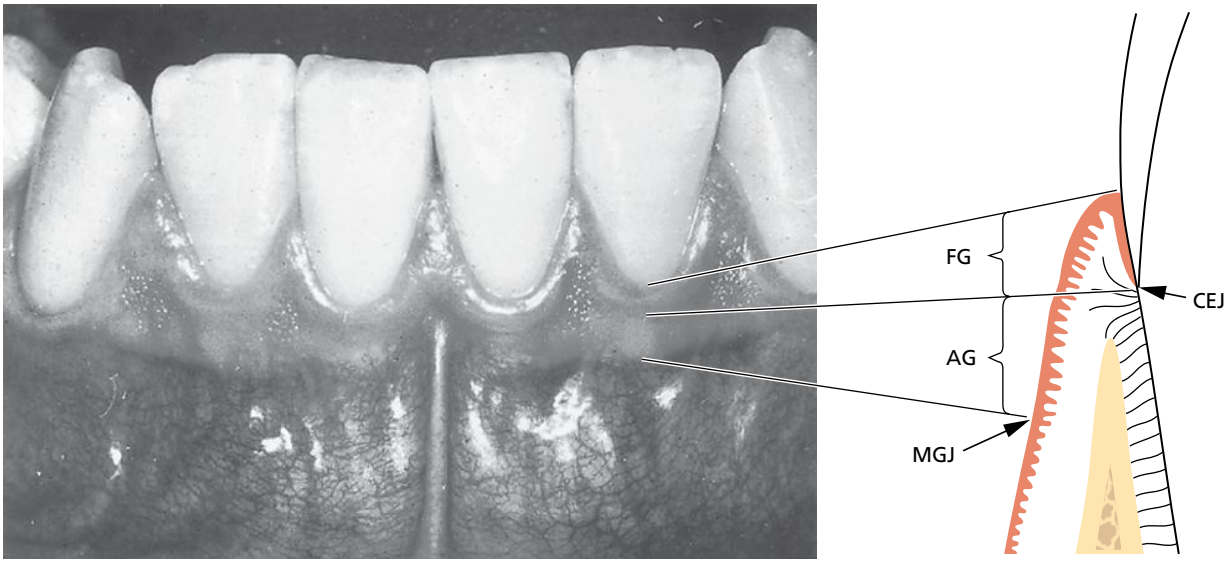

Fig. 1-6

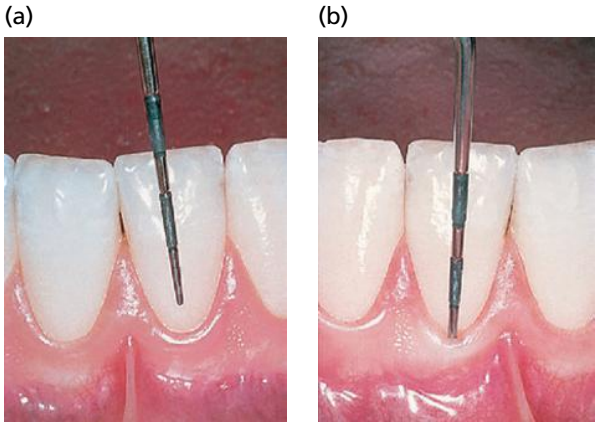

Fig. 1-7

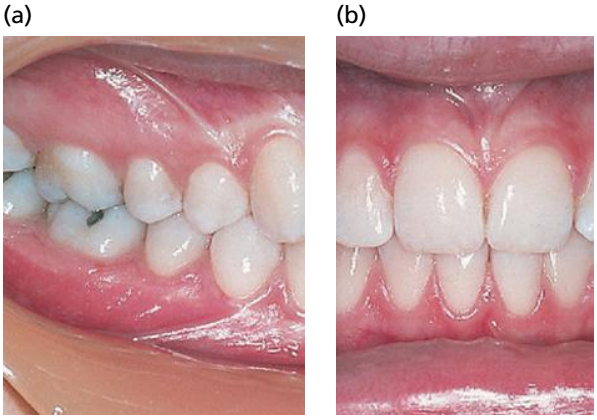

Fig. 1-8

Figure 1-6 Three parts of the gingiva can be identified:

1. Free gingiva (FG)
2. Interdental gingiva
3. Attached gingiva (AG).

The free gingiva is coral pink, has a dull surface and a firm consistency. It comprises the gingival tissue at the vestibular and lingual/palatal aspects of the teeth. On the vestibular and lingual sides of the teeth, the free gingiva extends from the gingival margin in an apical direction to the *free gingival groove*, which is positioned at a level corresponding to the level of the *cementoenamel junction* (CEJ). The attached gingiva is demarcated by the mucogingival junction (MGJ) in the apical direction.

Figure 1-7 The free gingival margin is often rounded in such a way that a small invagination or sulcus is formed between the tooth and the gingiva (Fig. 1-7a).

When a periodontal probe is inserted into this invagination and, further apically, towards the CEJ, the gingival tissue is separated from the tooth and a "*gingival pocket*" or "*gingival crevice*" is artificially opened. Thus, in normal or clinically healthy gingiva there is in fact no "gingival pocket" or "gingival crevice" present, but the gingiva is in close contact with the enamel surface. In Fig. 1-7b, a periodontal probe has been inserted into the tooth–gingiva interface and a "gingival crevice" artificially opened approximately to the level of the CEJ.

After complete tooth eruption, the free gingival margin is located on the enamel surface approximately 1.5–2 mm coronal to the CEJ.

Figure 1-8 The shape of the *interdental gingiva (the interdental papilla)* is determined by the contact relationships between the teeth, the width of the approximal tooth surfaces, and the course of the CEJ. In anterior regions of the dentition, the interdental papilla is of pyramidal form (Fig. 1-8b), while in the molar regions, the papillae are flatter in the buccolingual direction (Fig. 1-8a). Due to the presence of interdental papillae, the free gingival margin follows a more or less accentuated, scalloped course through the dentition.

Figure 1-9 In the premolar/molar regions of the dentition, the teeth have approximal contact surfaces (Fig. 1-9a) rather than contact points. Since the shape of

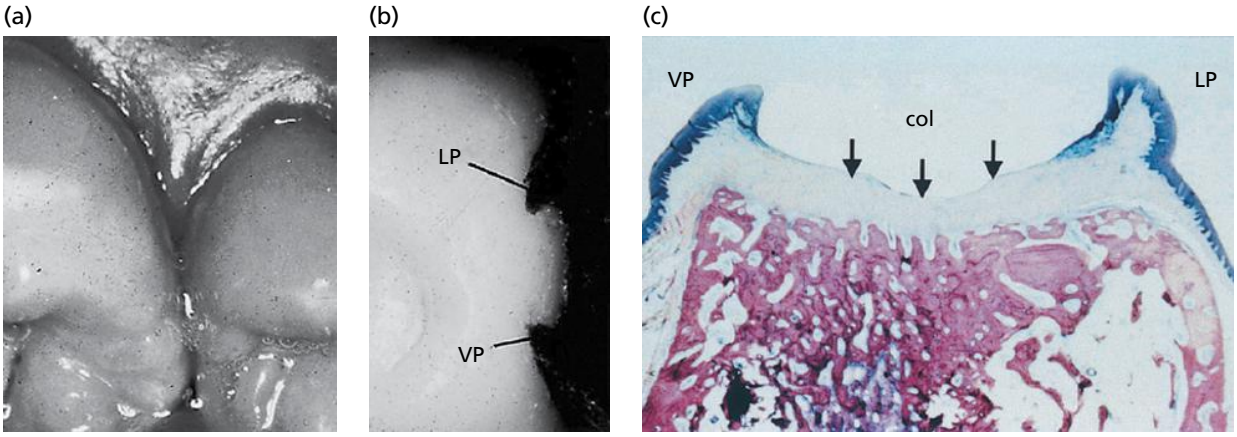

Fig. 1-9

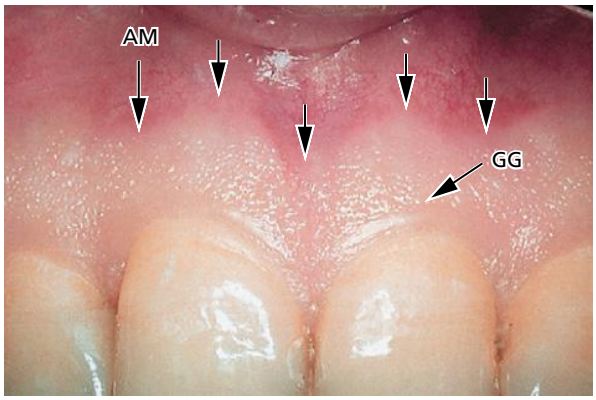

Fig. 1-10

the interdental papilla conforms with the outline of the interdental contact surfaces, a concavity – *a col* – is established in the premolar and molar regions, as demonstrated in Fig. 1-9b, where the distal tooth has been removed. Thus, the interdental papillae in these areas often have one vestibular (VP) and one lingual/palatal portion (LP) separated by the col region. The col region, as demonstrated in the histologic section (Fig. 1-9c), is covered by a thin non-keratinized epithelium (arrows). This epithelium has many features in common with the junctional epithelium (see Fig. 1-34).

Figure 1-10 The attached gingiva is demarcated in the coronal direction by the free gingival groove (GG) or, when such a groove is not present, by a horizontal plane placed at the level of the CEJ. In clinical examinations, it was observed that a free gingival groove is only present in about 30–40% of adults.

The free gingival groove is often most pronounced on the vestibular aspect of the teeth, occurring most frequently in the incisor and premolar regions of the mandible, and least frequently in the mandibular molar and maxillary premolar regions.

The attached gingiva extends in the apical direction to the mucogingival junction (arrows), where it becomes continuous with the alveolar (lining) mucosa (AM). It is of firm texture, coral pink in color, and often shows small depressions on the surface. The depressions, called "stippling", give the appearance of orange peel. The

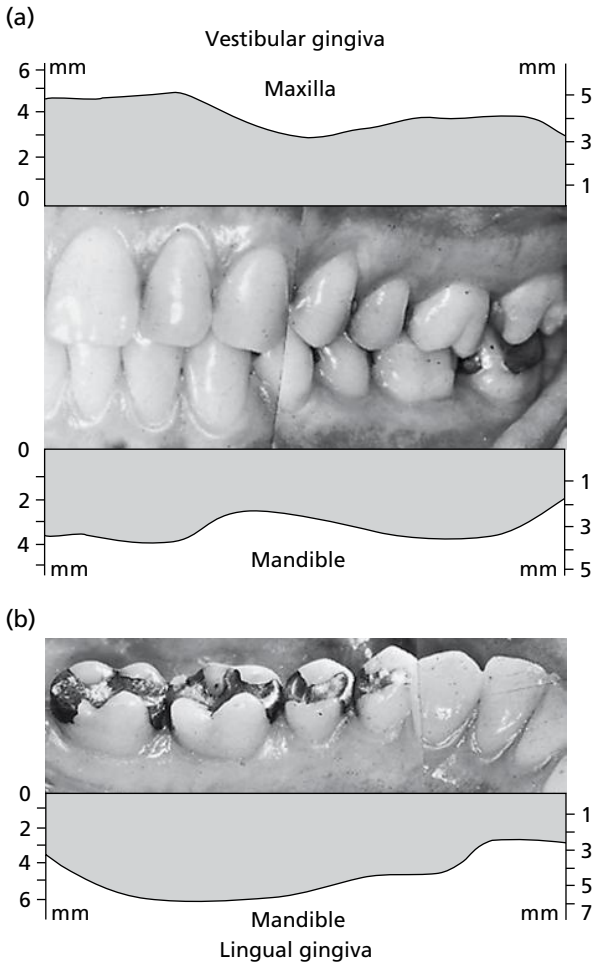

Fig. 1-11

gingiva is firmly attached to the underlying alveolar bone and cementum by connective tissue fibers, and is, therefore, comparatively immobile in relation to the underlying tissue. The darker red alveolar mucosa (AM) located apical to the mucogingival junction, on the other hand, is loosely bound to the underlying bone. Therefore, in contrast to the attached gingiva, the alveolar mucosa is mobile in relation to the underlying tissue.

Figure 1-11 shows how the width of the gingiva varies in different parts of the dentition. In the maxilla

(Fig. 1-11a), the vestibular gingiva is generally widest in the area of the incisors and narrowest adjacent to the premolars. In the mandible (Fig. 1-11b), the gingiva on the lingual aspect is particularly narrow in the area of the incisors and wide in the molar region. The range of variation is 1–9 mm.

Fig. 1-12

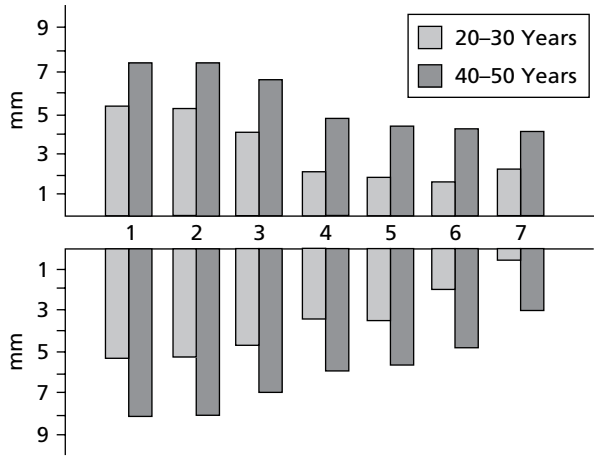

Fig. 1-13

Figure 1-12 illustrates an area in the mandibular premolar region where the gingiva is extremely narrow. The arrows indicate the location of the mucogingival junction. The mucosa has been stained with an iodine solution in order to distinguish more accurately between the gingiva and the alveolar mucosa.

Figure 1-13 depicts the result of a study in which the width of the attached gingiva was assessed and related to the age of the patients examined. It was found that the gingiva in 40–50-year olds was significantly wider than that in 20–30-year olds. This observation indicates that the width of the gingiva tends to increase with age. Since the mucogingival junction remains stable throughout life in relation to the lower border of the mandible, the increasing width of the gingiva may suggest that the teeth, as a result of occlusal wear, erupt slowly throughout life.

Microscopic anatomy

Oral epithelium

Figure 1-14a A schematic drawing of a histologic section (see Fig. 1-14b) describing the composition of the gingiva and the contact area between the gingiva and the enamel (E).

Figure 1-14b The free gingiva comprises all epithelial and connective tissue structures (CT) located coronal to a horizontal line placed at the level of the cementoenamel junction (CEJ). The epithelium covering the free gingiva may be differentiated as follows:

- *Oral epithelium* (OE), which faces the oral cavity
- *Oral sulcular epithelium* (OSE), which faces the tooth without being in contact with the tooth surface

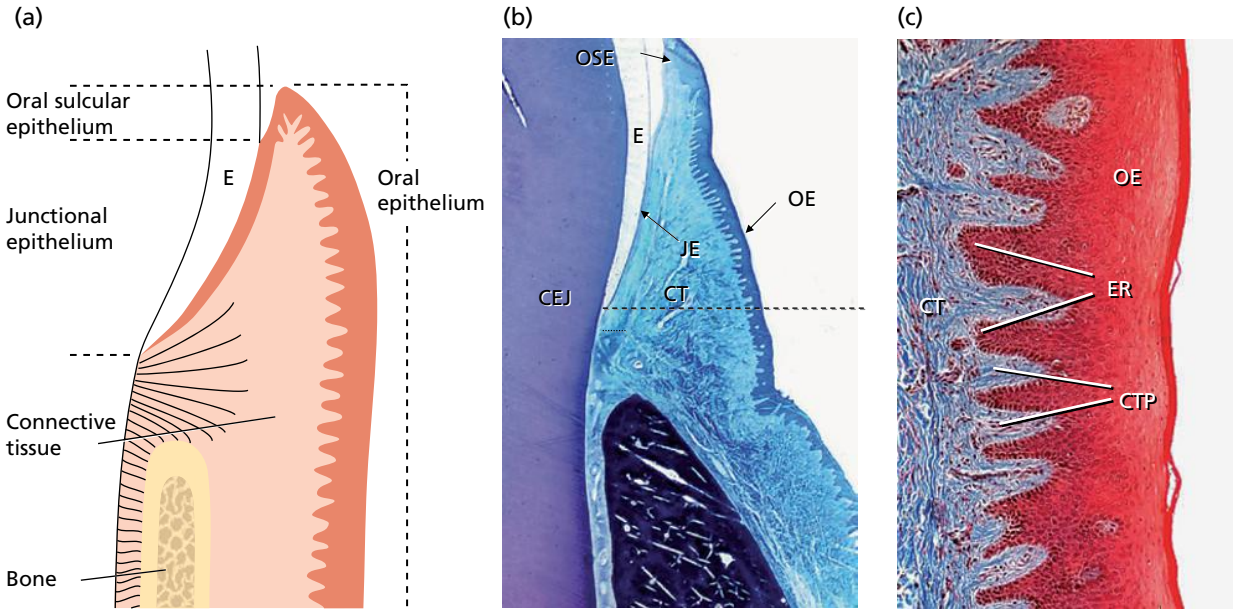

Fig. 1-14

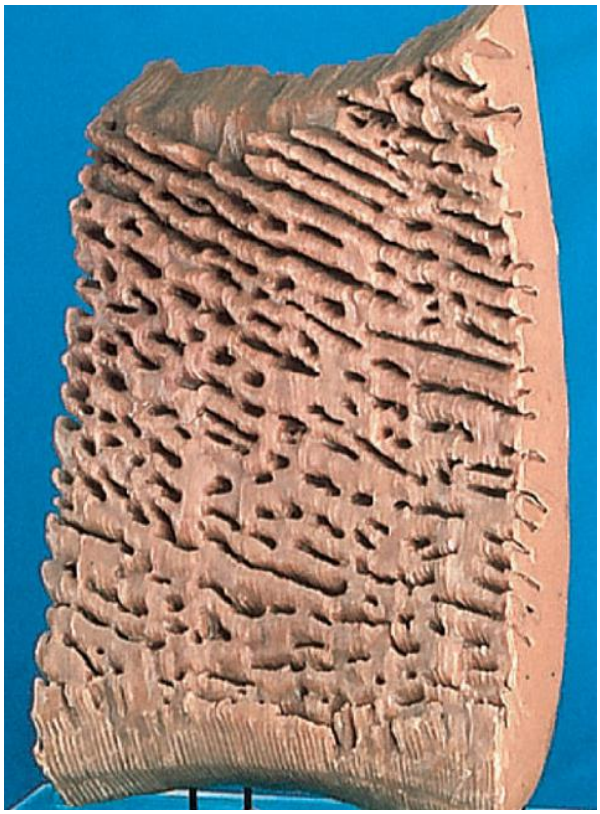

Fig. 1-15

- *Junctional epithelium* (JE), which provides the contact between the gingiva and the tooth.

Figure 1-14c The boundary between the oral epithelium (OE) and underlying connective tissue (CT) has a wavy course. The connective tissue portions which project into the epithelium are called *connective tissue papillae* (CTP) and are separated from each other by *epithelial ridges* – so-called *rete pegs* (ER). In normal, non-inflamed gingiva, rete pegs and connective tissue papillae are lacking at the boundary between the junctional epithelium and its underlying connective tissue (Fig. 1-14b). Thus, a characteristic morphologic feature of the oral epithelium and the oral sulcular epithelium is the presence of rete pegs: these structures are lacking in the junctional epithelium.

Figure 1-15 presents a model, constructed on the basis of magnified serial histologic sections, showing the subsurface of the oral epithelium of the gingiva after the connective tissue has been removed. The subsurface of the oral epithelium (i.e. the surface of the epithelium facing the connective tissue) exhibits several depressions corresponding to the connective tissue papillae (see Fig. 1-16) which project into the epithelium. It can be seen that the epithelial projections, which in histologic sections separate the connective tissue papillae, constitute a continuous system of epithelial ridges.

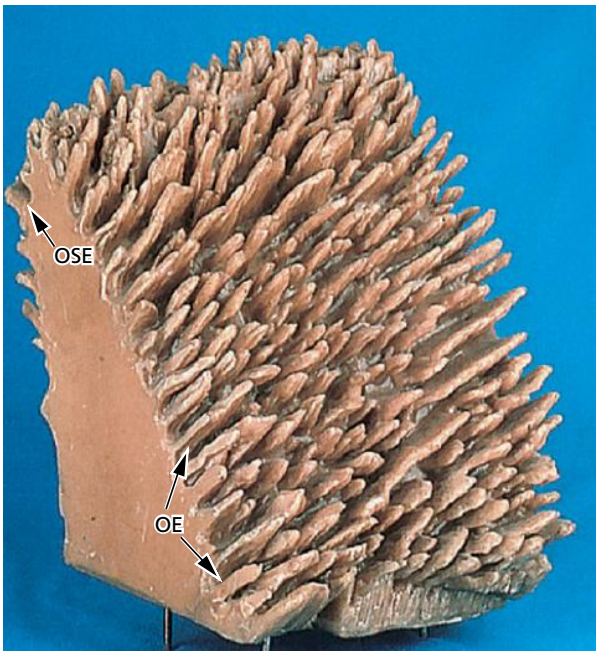

Fig. 1-16

Figure 1-16 presents a model of the connective tissue, corresponding to the model of the epithelium shown in Fig. 1-15. The epithelium has been removed, thereby making the vestibular aspect of the gingival connective tissue visible. Note the connective tissue papillae which project into the space that was occupied by the oral epithelium (OE) in Fig. 1-15 and by the oral sulcular epithelium (OSE) at the back of the model.

Figure 1-17a In most adults the attached gingiva shows a stippling on the surface. The photograph shows a case where this stippling is conspicuous (see also Fig. 1-10).

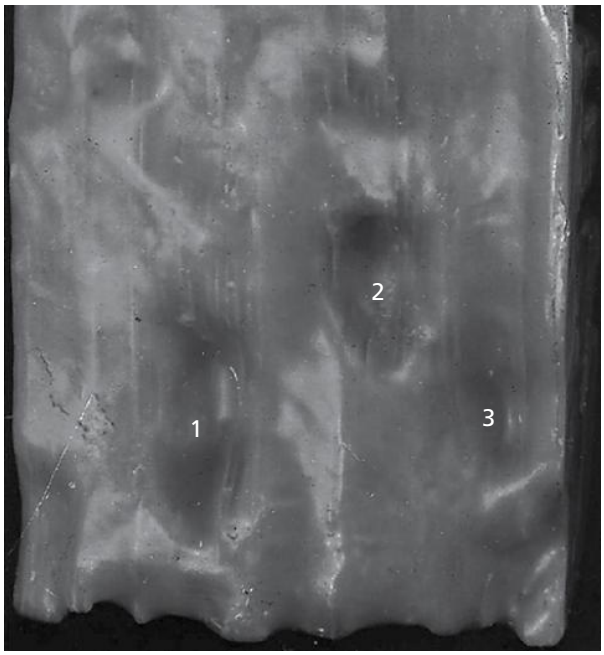
Figure 1-17b presents a magnified model of the outer surface of the oral epithelium of the attached gingiva. The surface exhibits the minute depressions (1–3) which give the gingiva its characteristic stippled appearance.

Figure 1-17c shows a photograph of the subsurface (i.e. the surface of the epithelium facing the connective tissue) of the model shown in Fig. 1-17b. The subsurface of the epithelium is characterized by the presence of epithelial ridges which merge at various locations (1–3). The depressions seen on the outer surface of the epithelium (1–3 in Fig. 1-17b) correspond to these fusion sites (1–3) between the epithelial ridges. Thus, the depressions on the surface of the gingiva occur in the areas of fusion between various epithelial ridges.

Figure 1-18 (a) A portion of the oral epithelium covering the free gingiva is illustrated in this photomicrograph. The oral epithelium is a *keratinized*, *stratified*,

(a)

(b)



(c)

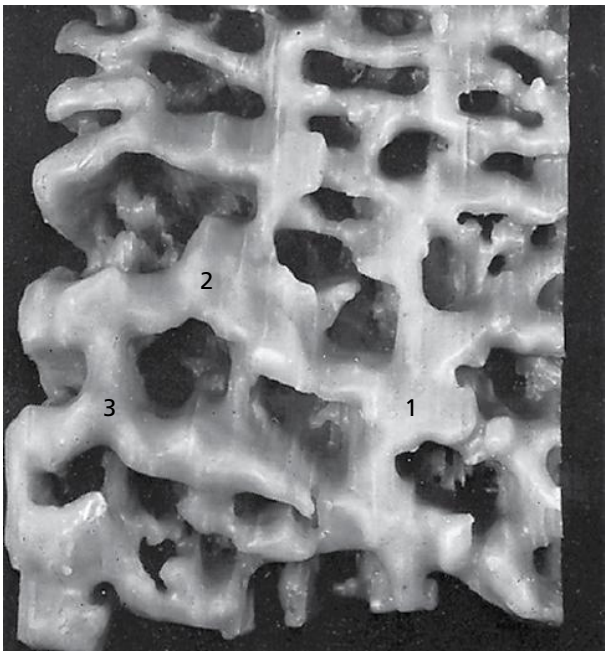


Fig. 1-17

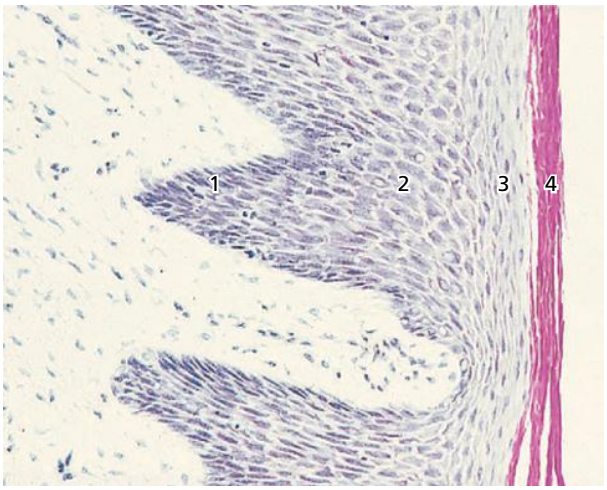
(a)



(b)

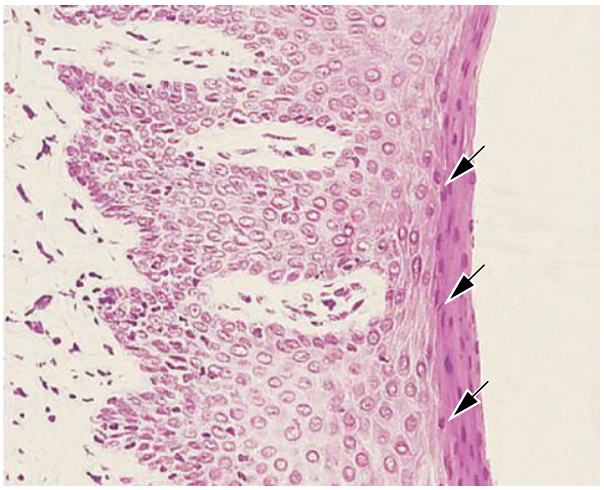


Fig. 1-18

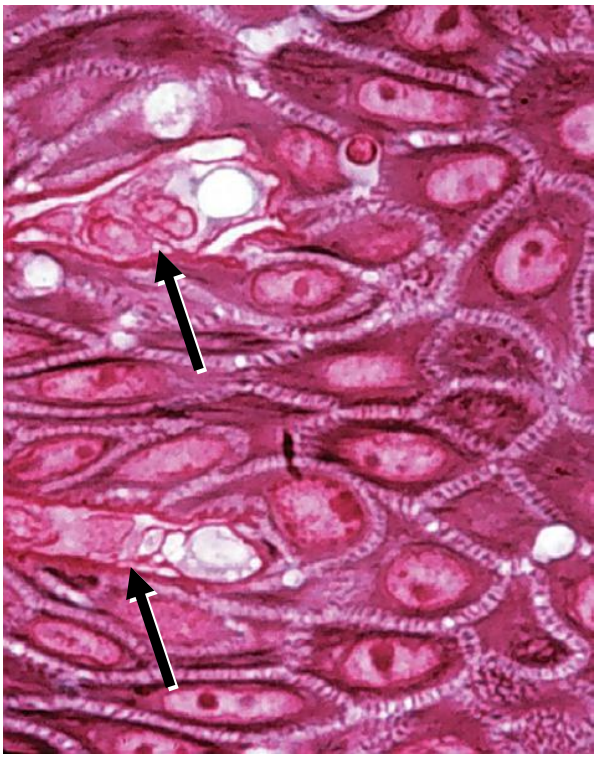

Fig. 1-19

squamous epithelium which, on the basis of the degree to which the keratin-producing cells are differentiated, can be divided into the following cell layers:

1. *Basal layer* (stratum basale or stratum germinativum)
2. *Prickle cell layer* (stratum spinosum)
3. *Granular cell layer* (stratum granulosum)
4. *Keratinized cell layer* (stratum corneum).

It should be observed that in this section, cell nuclei are lacking in the outer cell layers. Such an epithelium is denoted *orthokeratinized*. Often, however, the cells of the stratum corneum of the epithelium of human gingiva contain remnants of the nuclei as seen in Fig. 1-18b (arrows). In such a case, the epithelium is denoted *parakeratinized*.

Figure 1-19 In addition to the keratin-producing cells, which comprise about 90% of the total cell population, the oral epithelium contains the following types of cell:

- *Melanocytes*
- *Langerhans cells*
- *Merkel's cells*
- *Inflammatory cells.*

These cell types are often stellate and have cytoplasmic extensions of various size and appearance. They are also called "clear cells" since in histologic sections, the zone around their nuclei appears lighter than that in the surrounding keratin-producing cells.

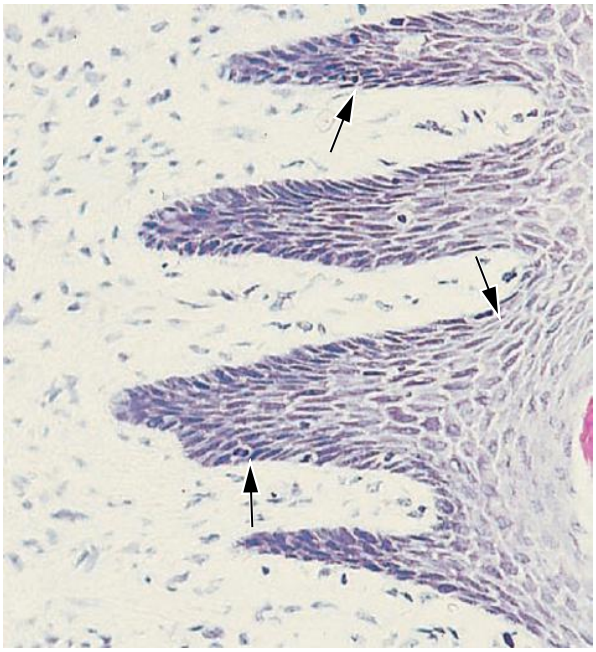

Fig. 1-20

The photomicrograph shows "clear cells" (arrows) located in or near the stratum basale of the oral epithelium. With the exception of the Merkel's cells, these "clear cells", which do not produce keratin, lack desmosomal attachment to adjacent cells. The melanocytes are pigment-synthesizing cells and are responsible for the melanin pigmentation occasionally seen on the gingiva. However, both lightly and darkly pigmented individuals have melanocytes in the epithelium.

The Langerhans cells are believed to play a role in the defense mechanism of the oral mucosa. It has been suggested that the Langerhans cells react with antigens which are in the process of penetrating the epithelium. An early immunologic response is thereby initiated, inhibiting or preventing further antigen penetration of the tissue. The Merkel's cells have been suggested to have a sensory function.

Figure 1-20 The cells in the basal layer are either cylindric or cuboid, and are in contact with the *basement membrane* that separates the epithelium and the connective tissue. The basal cells possess the ability to divide, that is undergo mitotic cell division. The cells marked with arrows in the photomicrograph are in the process of dividing. It is in the basal layer that the epithelium is renewed. Therefore, this layer is also termed *stratum germinativum*, and can be considered the *progenitor cell compartment* of the epithelium.

Figure 1-21 When two daughter cells (D) have been formed by cell division, an adjacent "older" basal cell (OB) is pushed into the spinous cell layer and starts, as a *keratinocyte*, to traverse the epithelium. It takes approximately 1 month for a keratinocyte to reach the outer epithelial surface, where it is shed from the stratum corneum. Within a given time, the

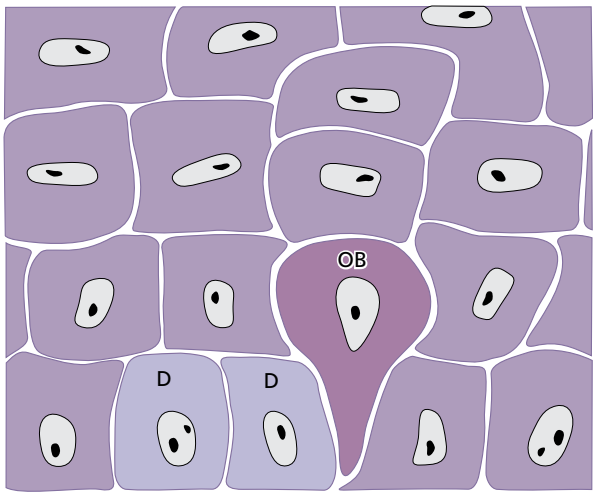

Fig. 1-21

Fig. 1-22

number of cells which divide in the basal layer equals the number of cells which are shed from the surface. Thus, under normal conditions there is equilibrium between cell renewal and cell loss so that the epithelium maintains a constant thickness. As the basal cell migrates through the epithelium, it becomes flattened with its long axis parallel to the epithelial surface.

Figure 1-22 The basal cells are found immediately adjacent to the connective tissue and are separated from this tissue by the basement membrane, probably produced by the basal cells. Under the light microscope this membrane appears as a structureless zone approximately 1–2 µm wide (arrows) and reacts positively to a periodic acid-Schiff (PAS) stain. This positive reaction demonstrates that the basement membrane contains carbohydrate (glycoproteins). The epithelial cells are surrounded by an extracellular substance which also contains protein–polysaccharide complexes. At the ultrastructural level, the basement membrane has a complex composition.

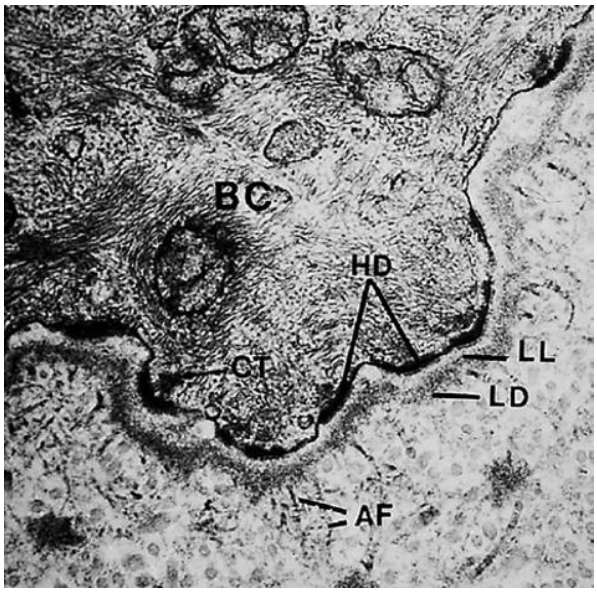

Fig. 1-23

Figure 1-23 is an electron micrograph (magnification × 70 000) of an area including part of a basal cell, the basement membrane, and part of the adjacent connective tissue. The basal cell (BC) occupies the upper portion of the micrograph. Immediately beneath the basal cell, an approximately 400-Å wide electron-lucent zone can be seen, which is called the *lamina lucida* (LL). Beneath the lamina lucida, an electron-dense zone of approximately the same thickness can be observed. This zone is called *lamina densa* (LD). From the lamina densa so-called *anchoring fibers* (AF) project in a fan-shaped fashion into the connective tissue. The anchoring fibers are approximately 1 µm in length and terminate freely in the connective tissue. The basement membrane, which under the light microscope appears as an entity, thus, in the electron micrograph, appears to comprise one lamina lucida and one lamina densa with adjacent connective tissue fibers (anchoring fibers). The cell membrane of the epithelial cells facing the lamina lucida harbors a number of electron-dense, thicker zones appearing at various intervals along the cell membrane. These structures are called *hemidesmosomes* (HD). The cytoplasmic *tonofilaments* (CT) in the cell converge towards the hemidesmosomes. The hemidesmosomes are involved in the attachment of the epithelium to the underlying basement membrane.

Figure 1-24 illustrates an area of stratum spinosum in the gingival oral epithelium. Stratum spinosum consists of 10–20 layers of relatively large, polyhedral cells, equipped with short cytoplasmic processes resembling spines. The cytoplasmic processes (arrows) occur at regular intervals and give the cells a prickly appearance. Together with intercellular protein–carbohydrate complexes, cohesion between the cells is provided by numerous "desmosomes" (pairs of hemidesmosomes) which are located between the cytoplasmic processes of adjacent cells.

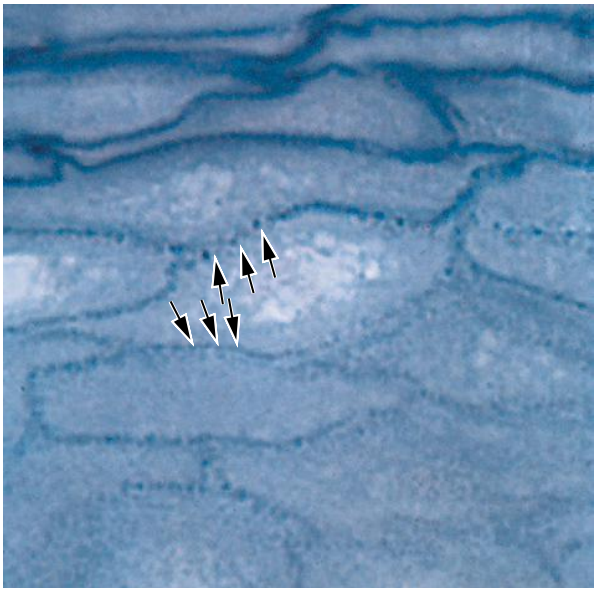

Fig. 1-24

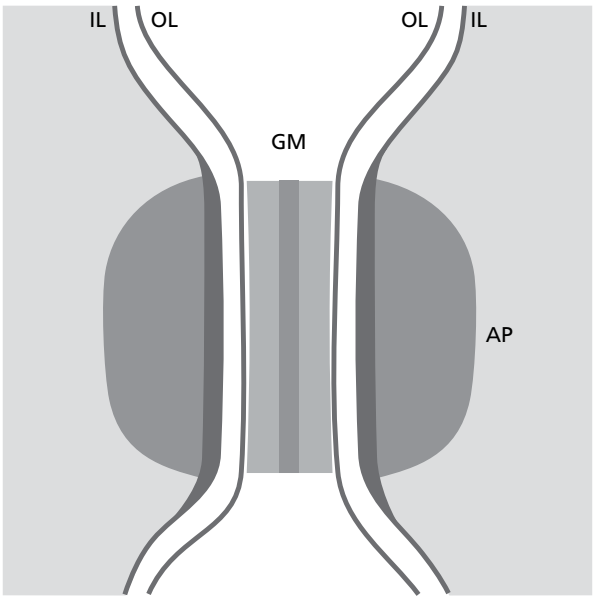

Fig. 1-26

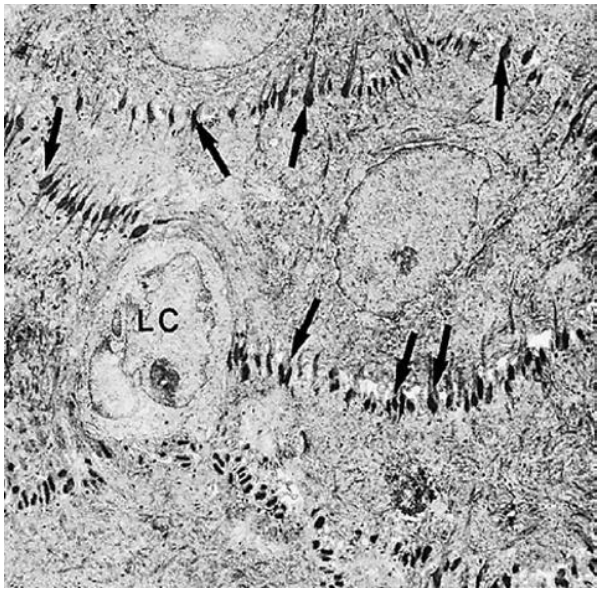

Fig. 1-25

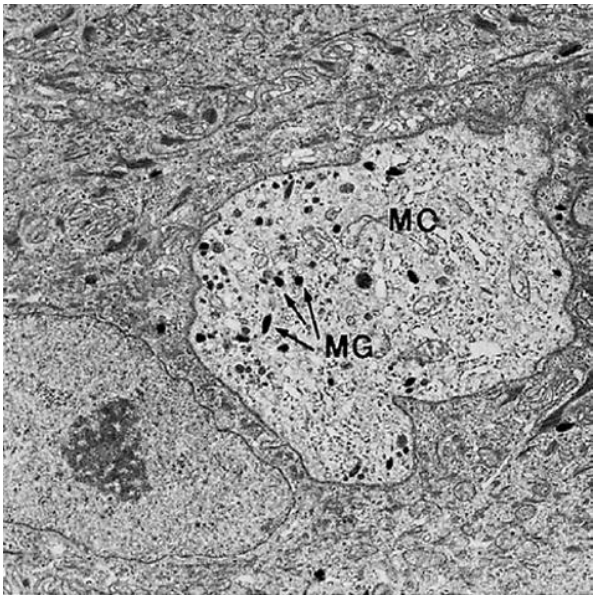

Fig. 1-27

Figure 1-25 shows an area of stratum spinosum in an electron micrograph. The dark-stained structures between the individual epithelial cells represent the *desmosomes* (arrows). A desmosome may be considered to be two hemidesmosomes facing one another. The presence of a large number of desmosomes indicates that the cohesion between the epithelial cells is solid. The light cell (LC) in the center of the micrograph harbors no hemidesmosomes and is, therefore, not a keratinocyte but rather a "clear cell" (see also Fig. 1-19).

Figure 1-26 is a schematic drawing showing the composition of a desmosome. A desmosome can be considered to consist of two adjoining hemidesmosomes separated by a zone containing electron-dense granulated material (GM). Thus, a desmosome comprises the following structural components: (1) the *outer leaflets* (OL) of the cell membranes of two adjoining cells, (2) the thick *inner leaflets* (IL) of the cell membranes, and (3) the *attachment plaques* (AP), which represent granular and fibrillar material in the cytoplasm.

Figure 1-27 As mentioned previously, the oral epithelium also contains melanocytes, which are responsible for the production of the pigment melanin. Melanocytes are present in individuals with marked pigmentation of the oral mucosa as well as in individuals in whom no clinical signs of pigmentation can be seen. In this electron micrograph, a melanocyte (MC) is present in the lower portion of the stratum spinosum. In contrast to the keratinocytes, this cell contains melanin granules (MG) and has no tonofilaments or hemidesmosomes. Note the large number of tonofilaments in the cytoplasm of the adjacent keratinocytes.

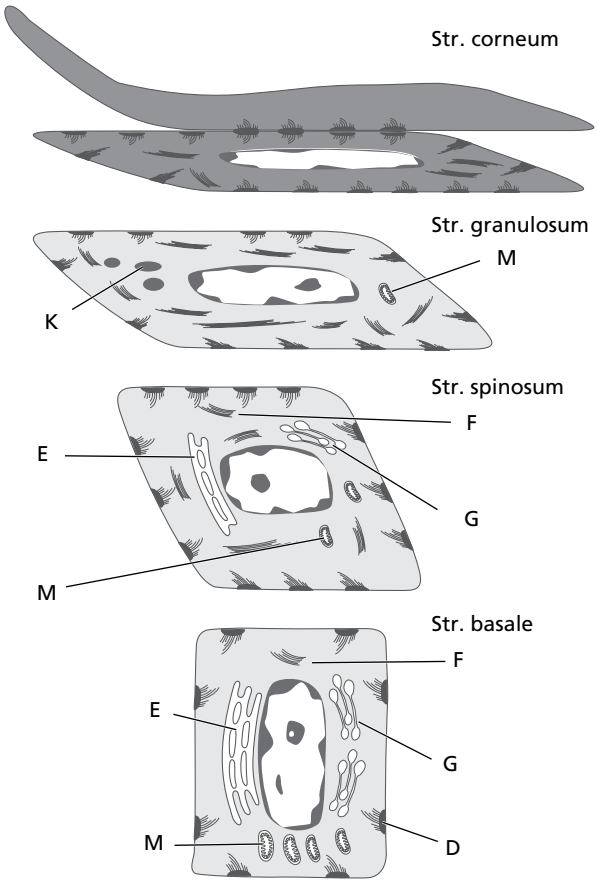

Fig. 1-28

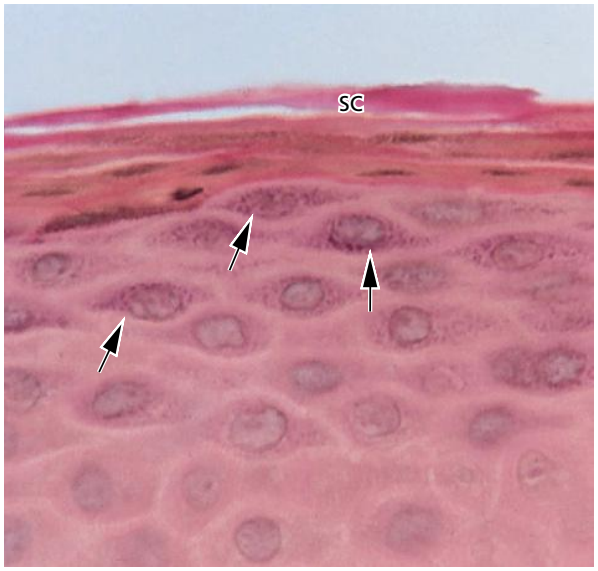

Fig. 1-29

Figure 1-28 When traversing the epithelium from the basal layer to the epithelial surface, the keratinocytes undergo continuous differentiation and specialization. The many changes which occur during this process are indicated in this diagram of a keratinized stratified squamous epithelium. From the basal layer (stratum basale) to the granular layer (stratum granulosum) both the number of tonofilaments (F) in the cytoplasm and the number of desmosomes (D) increase. In contrast, the number of organelles, such as mitochondria (M), lamellae of rough endoplasmic reticulum (E), and Golgi complexes (G) decrease in the keratinocytes on their way from the basal layer towards the surface. In the stratum granulosum, electron-dense *keratohyalin bodies* (K) and clusters of glycogen-containing granules start to appear. Such granules are believed to be related to the synthesis of keratin.

Figure 1-29 is a photomicrograph of the stratum granulosum and stratum corneum. Keratohyalin granules (arrows) are seen in the stratum granulosum. There is an abrupt transition of the cells from the stratum granulosum to the stratum corneum. This is indicative of a very sudden keratinization of the cytoplasm of the keratinocyte and its conversion into a horny squame. The cytoplasm of the cells in the stratum corneum (SC) is filled with keratin and the entire apparatus for protein synthesis and energy production, that is the nucleus, the mitochondria, the endoplasmic reticulum, and the Golgi complex, is lost. In a parakeratinized epithelium, however, the cells of the stratum corneum contain remnants of nuclei. Keratinization is considered a process of differentiation rather than degeneration. It is a process of protein synthesis which requires energy and is dependent on functional cells, that is cells containing a nucleus and a normal set of organelles.

Summary: The keratinocyte undergoes continuous differentiation on its way from the basal layer to the surface of the epithelium. Thus, once the keratinocyte has left the basement membrane it can no longer divide, but maintains a capacity for production of protein (tonofilaments and keratohyalin granules). In the granular layer, the keratinocyte is deprived of its energy- and protein-producing apparatus (probably by enzymatic breakdown) and is abruptly converted into a keratin-filled cell which, via the stratum corneum, is shed from the epithelial surface.

Figure 1-30 illustrates a portion of the epithelium of the alveolar (lining) mucosa. In contrast to the epithelium of the gingiva, the lining mucosa has no stratum corneum. Note that cells containing nuclei can be identified in all layers, from the basal layer to the surface of the epithelium.

Dentogingival epithelium

The tissue components of the dentogingival region achieve their final structural characteristics in conjunction with the eruption of the teeth. This is illustrated in Fig. 1-31a–d.

Figure 1-31a When the enamel of the tooth is fully developed, the enamel-producing cells (ameloblasts) become reduced in height, produce a basal lamina, and form, together with cells from the outer enamel epithelium, the so-called reduced dental epithelium

(RE). The basal lamina (epithelial attachment lamina [EAL]) lies in direct contact with the enamel. The contact between this lamina and the epithelial cells is maintained by hemidesmosomes. The reduced enamel epithelium surrounds the crown of the tooth from the moment the enamel is properly mineralized until the tooth starts to erupt.

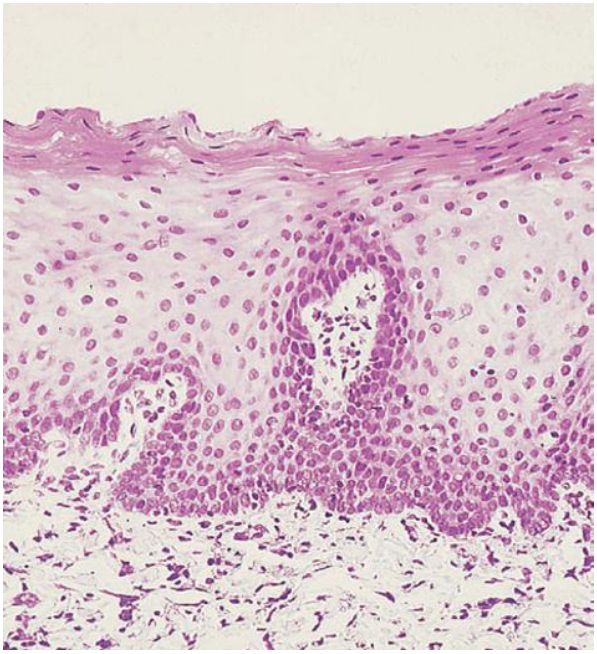

Fig. 1-30

Figure 1-31b As the erupting tooth approaches the oral epithelium, the cells of the outer layer of the reduced dental epithelium (RE), as well as the cells of the basal layer of the oral epithelium (OE), show increased mitotic activity (arrows) and start to migrate into the underlying connective tissue. The migrating epithelium produces an epithelial mass between the oral epithelium and the reduced dental epithelium so that the tooth can erupt without bleeding. The former ameloblasts do not divide.

Figure 1-31c When the tooth has penetrated into the oral cavity, large portions immediately apical to the incisal area of the enamel are covered by a junctional epithelium (JE) containing only a few layers of cells. The cervical region of the enamel, however, is still covered by ameloblasts (AB) and outer cells of the reduced dental epithelium.

Figure 1-31d During the later phases of tooth eruption, all cells of the reduced enamel epithelium are replaced by a junctional epithelium (JE). This epithelium is continuous with the oral epithelium and

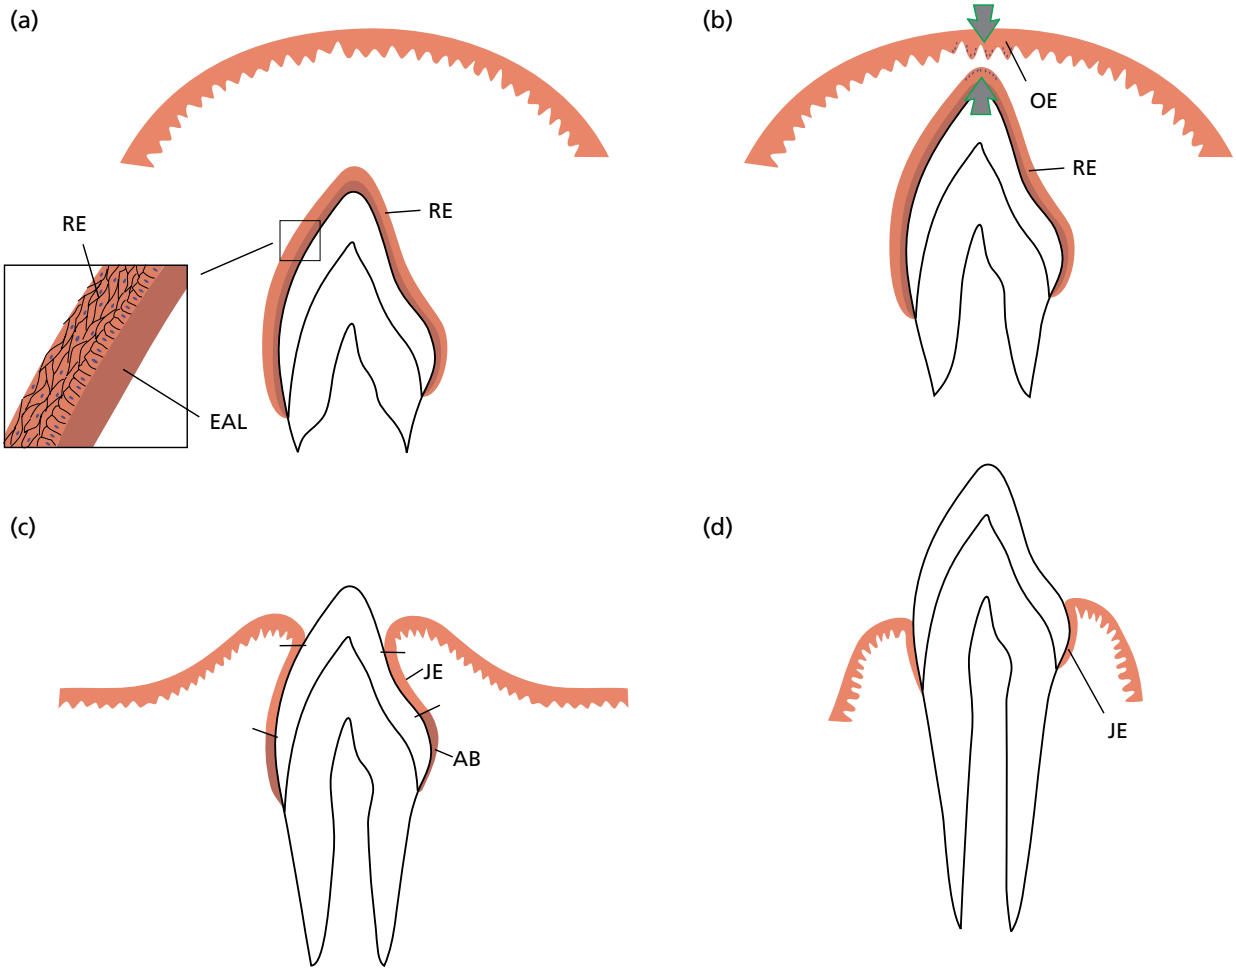

Fig. 1-31

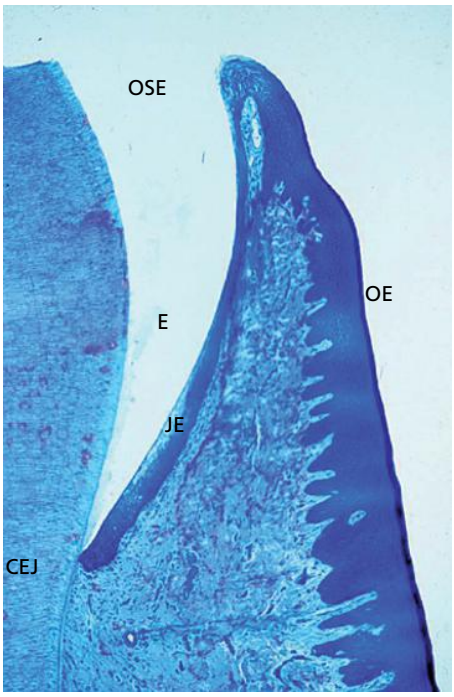

Fig. 1-32

provides the attachment between the tooth and the gingiva. If the free gingiva is excised after the tooth has fully erupted, a new junctional epithelium, indistinguishable from that found following tooth eruption, will develop during healing. The fact that this new junctional epithelium has developed from the oral epithelium indicates that the cells of the oral epithelium possess the ability to differentiate into cells of the junctional epithelium.

Figure 1-32 is a histologic section through the border area between the tooth and the gingiva, that is the *dentogingival region*. The enamel (E) is to the left. To the right are the *junctional epithelium* (JE), the *oral sulcular epithelium* (OSE), and the *oral epithelium* (OE). The oral sulcular epithelium covers the shallow groove, the gingival sulcus, located between the enamel and the top of the free gingiva. The junctional epithelium differs morphologically from the oral sulcular epithelium and oral epithelium, while the latter two are structurally very similar. Although individual variation may occur, the junctional epithelium is usually widest in its coronal portion (about 15–20 cells), but becomes thinner (3–4 cells) towards the cementoenamel junction (CEJ). The borderline between the junctional epithelium and the underlying connective tissue does not have epithelial rete pegs, except when inflamed.

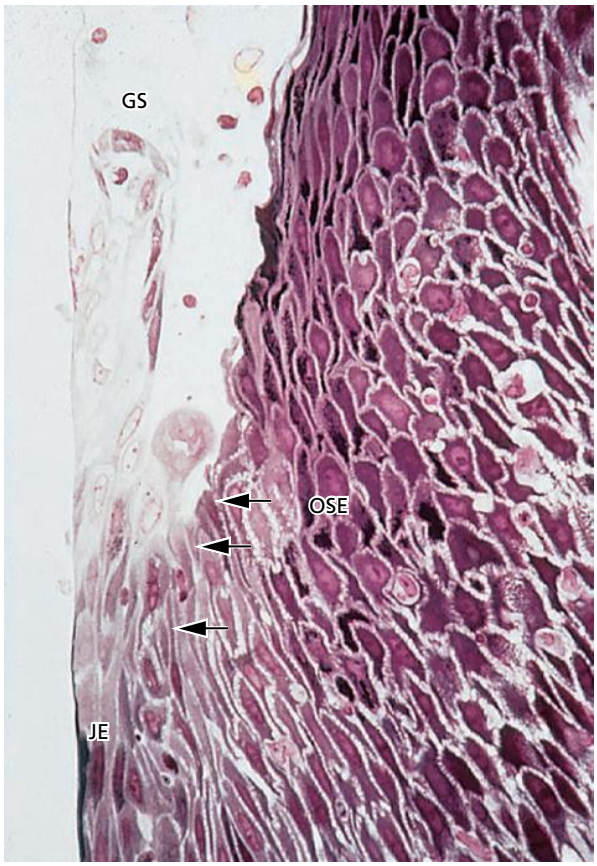

Fig. 1-33

Figure 1-33 The junctional epithelium has a free surface at the bottom of the *gingival sulcus* (GS). Like the oral sulcular epithelium and the oral epithelium, the junctional epithelium is continuously renewed through cell division in the basal layer. The cells migrate to the base of the gingival sulcus from where they are shed. The border between the junctional epithelium (JE) and the oral sulcular epithelium (OSE) is indicated by arrows. The cells of the oral sulcular epithelium are cuboidal and the surface of this epithelium is non-keratinized.

Figure 1-34 illustrates different characteristics of the junctional epithelium. As can be seen in Fig. 1-34a, the cells of the junctional epithelium (JE) are arranged into one basal layer (BL) and several suprabasal layers (SBL). Fig. 1-34b demonstrates that the basal cells as well as the suprabasal cells are flattened with their long axis parallel to the tooth surface. (CT, connective tissue; E, enamel space.)

There are distinct differences between the oral sulcular epithelium, the oral epithelium, and the junctional epithelium:

- The size of the cells in the junctional epithelium is, relative to the tissue volume, larger than in the oral epithelium.
- The intercellular space in the junctional epithelium is, relative to the tissue volume, comparatively wider than in the oral epithelium.
- The number of desmosomes is smaller in the junctional epithelium than in the oral epithelium.

Note the comparatively wide intercellular spaces between the oblong cells of the junctional epithelium, and the presence of two neutrophilic granulocytes (PMN) which are traversing the epithelium.

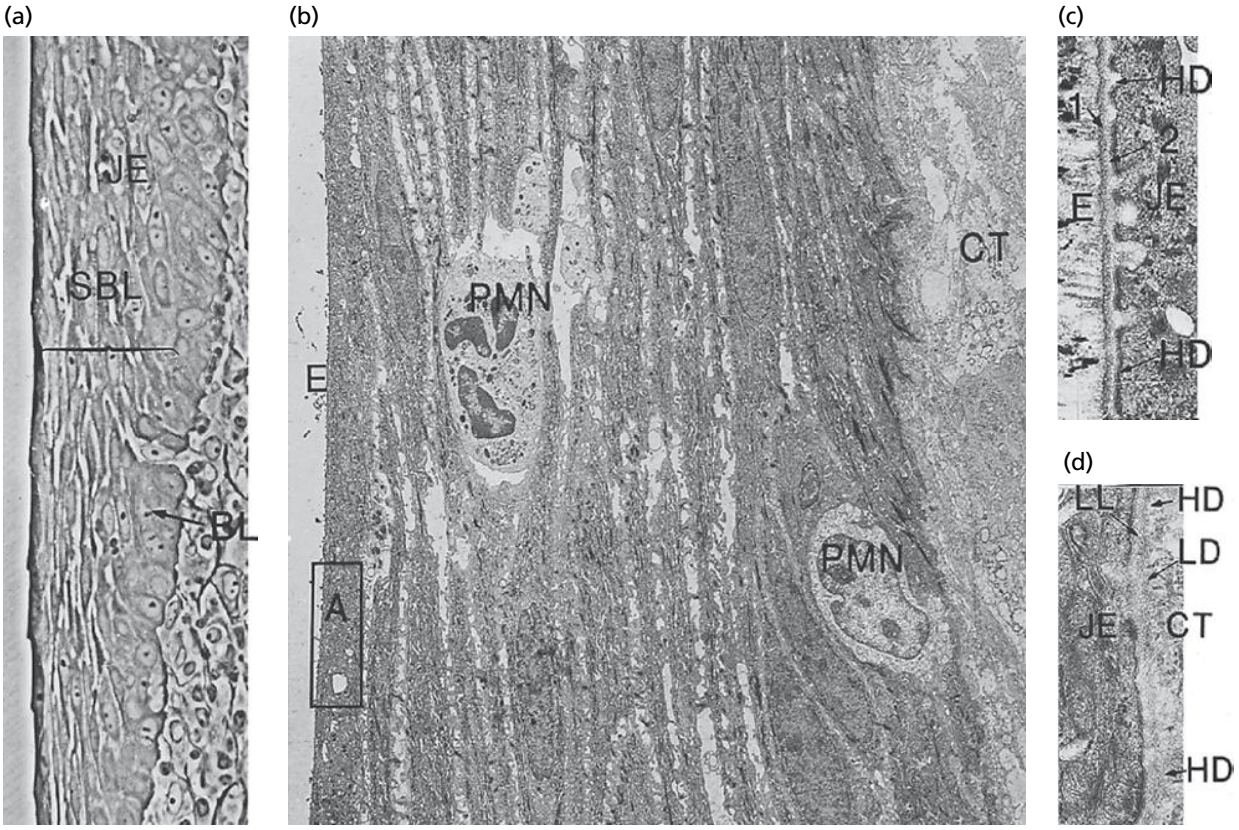

Fig. 1-34

The framed area (A) is shown in a higher magnification in Fig. 1-34c, from which it can be seen that the basal cells of the junctional epithelium are not in direct contact with the enamel (E). Between the enamel and the epithelium (JE), one electron-dense zone (1) and one electron-lucent zone (2) can be seen. The electron-lucent zone is in contact with the cells of the junctional epithelium (JE). These two zones have a structure very similar to that of the lamina densa (LD) and lamina lucida (LL) in the basement membrane area (i.e. the epithelium [JE]–connective tissue [CT] interface) described in Fig. 1-23. Furthermore, as seen in Fig. 1-34d, the cell membrane of the junctional epithelial cells harbors hemidesmosomes (HD) towards the enamel and towards the connective tissue. Thus, the interface between the enamel and the junctional epithelium is similar to the interface between the epithelium and the connective tissue.

Figure 1-35 is a schematic drawing of the most apically positioned cell in the junctional epithelium. The enamel (E) is depicted to the left. It can be seen that the electron-dense zone (1) between the junctional epithelium and the enamel can be considered a continuation of the lamina densa (LD) in the basement membrane of the connective tissue side. Similarly, the electron-lucent zone (2) can be considered a continuation of the lamina lucida (LL). It should be noted, however, that at variance with the epithelium–connective tissue interface, there are no anchoring fibers (AF) attached to the lamina densa-like structure

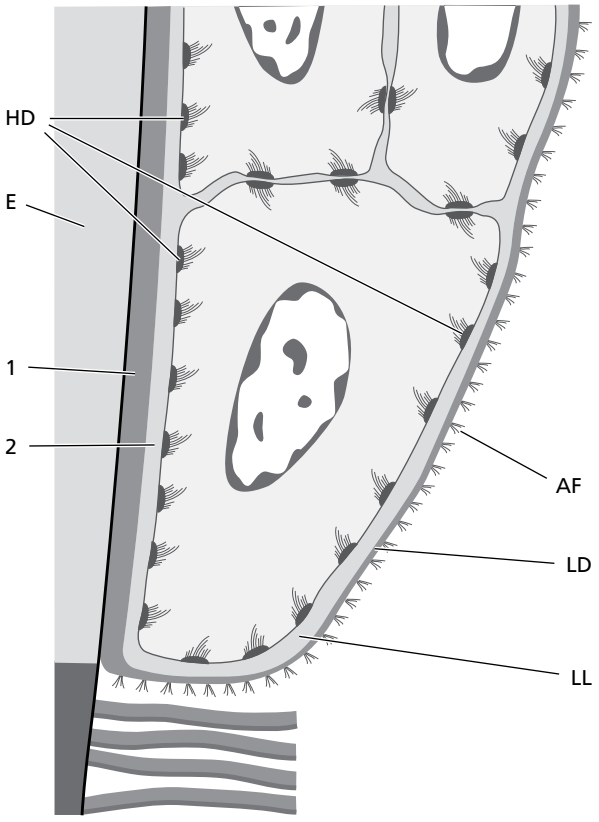

Fig. 1-35

(1) adjacent to the enamel. On the other hand, like the basal cells adjacent to the basement membrane (at the connective tissue interface), the cells of the junctional epithelium facing the lamina lucida-like structure

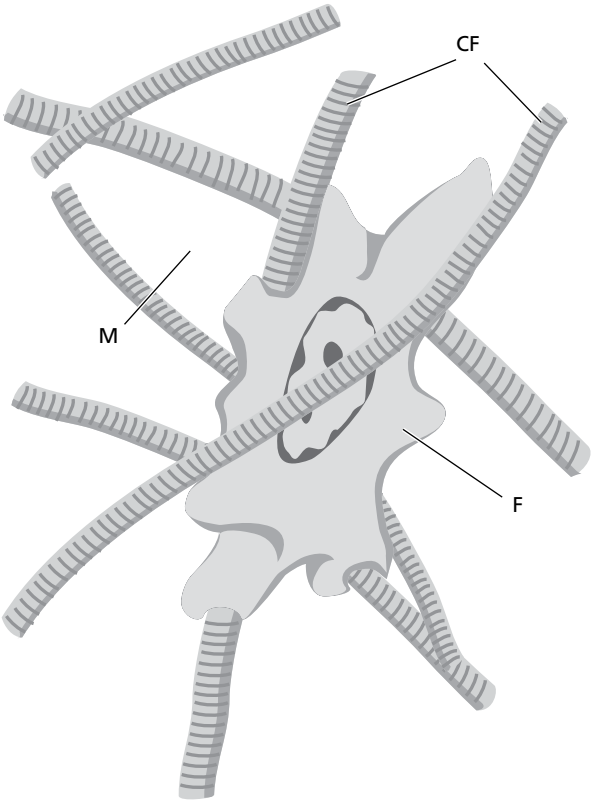

Fig. 1-36

(2) harbor hemidesmosomes (HD). Thus, the interface between the junctional epithelium and the enamel is structurally very similar to the epithelium–connective tissue interface, which means that the junctional epithelium is not only in contact with the enamel but is actually physically attached to the tooth via hemidesmosomes.

Lamina propria

The predominant tissue component of the gingiva is the connective tissue (lamina propria). The major components of the connective tissue are *collagen fibers* (around 60% of connective tissue volume), *fibroblasts* (around 5%), *vessels and nerves* (around 35%), which are embedded in an amorphous ground substance (matrix).

Figure 1-36 The drawing illustrates a fibroblast (F) residing in a network of connective tissue fibers (CF). The intervening space is filled with matrix (M), which constitutes the "environment" for the cell.

Cells

The different types of cell present in the connective tissue are: (1) *fibroblasts*, (2) *mast cells*, (3) *macrophages*, and (4) *inflammatory cells*.

Figure 1-37 The *fibroblast* is the predominant connective tissue cell (65% of the total cell population). The fibroblast is engaged in the production of various types of fibers found in the connective tissue, but is also instrumental in the synthesis of the connective

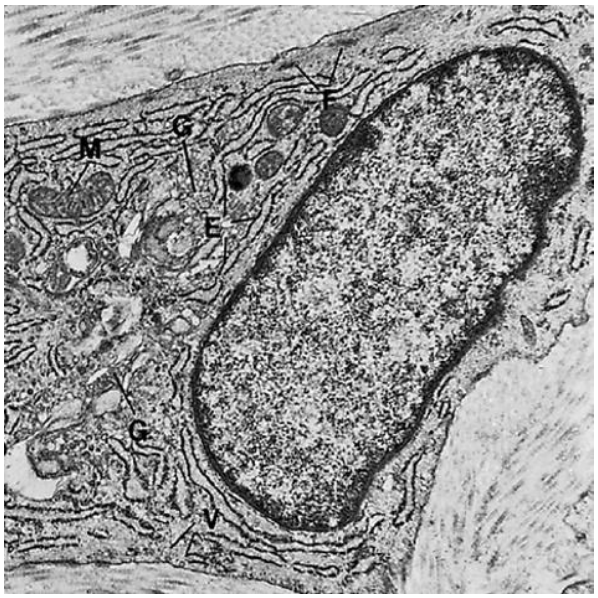

Fig. 1-37

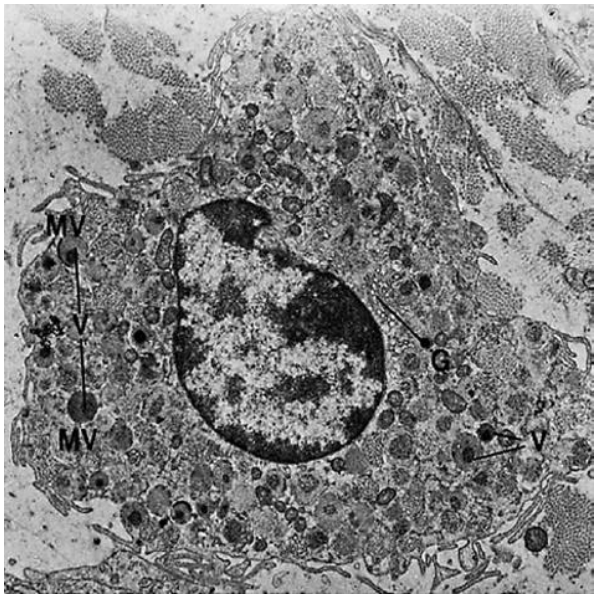

Fig. 1-38

tissue matrix. The fibroblast is a spindle-shaped or stellate cell with an oval-shaped nucleus containing one or more nucleoli. A part of a fibroblast is shown in electron microscopic magnification. The cytoplasm contains a well-developed granular endoplasmic reticulum (E) with ribosomes. The Golgi complex (G) is usually of considerable size and the mitochondria (M) are large and numerous. Furthermore, the cytoplasm contains many fine tonofilaments (F). Adjacent to the cell membrane, all along the periphery of the cell, a large number of vesicles (V) can be seen.

Figure 1-38 The *mast cell* is responsible for the production of certain components of the matrix. This cell also produces vasoactive substances, which can affect the function of the microvascular system and control the flow of blood through the tissue. A mast cell is

presented in electron microscopic magnification. The cytoplasm is characterized by the presence of a large number of vesicles (V) of varying size. These vesicles contain biologically active substances such as proteolytic enzymes, histamine, and heparin. The Golgi complex (G) is well developed, while granular endoplasmic reticulum structures are scarce. A large number of small cytoplasmic projections, that is microvilli (MV), can be seen along the periphery of the cell.

Figure 1-39 The *macrophage* has a number of different phagocytic and synthetic functions in the tissue. A macrophage is shown in electron microscopic magnification. The nucleus is characterized by numerous invaginations of varying size. A zone of electron-dense chromatin condensations can be seen along the periphery of the nucleus. The Golgi complex (G) is well developed and numerous vesicles (V) of varying size are present in the cytoplasm. Granular endoplasmic reticulum (E) is scarce, but a certain number of free ribosomes (R) are evenly distributed in the cytoplasm. Remnants of phagocytosed material are often found in lysosomal vesicles: phagosomes (PH). In the periphery of the cell, a large number of microvilli of varying size can be seen. Macrophages are particularly numerous in inflamed tissue. They are derived from circulating blood monocytes which migrate into the tissue.

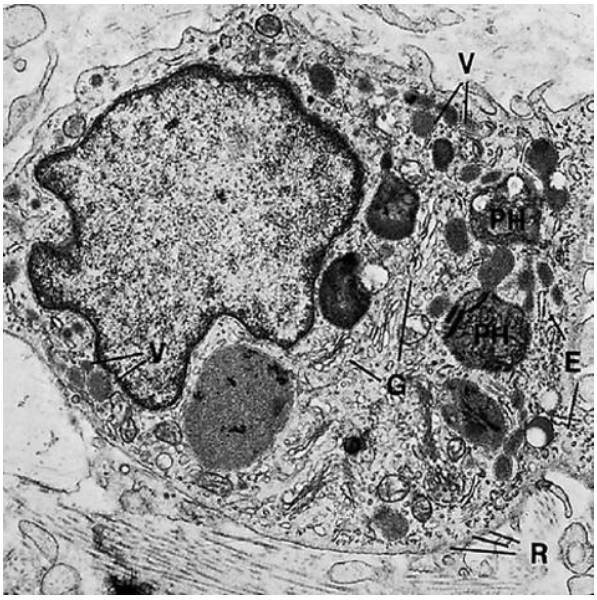

Fig. 1-39

Figure 1-40 Besides fibroblasts, mast cells, and macrophages, the connective tissue also harbors *inflammatory cells* of various types, for example neutrophilic granulocytes, lymphocytes, and plasma cells.

The *neutrophilic granulocytes*, also called *polymorphonuclear leukocytes*, have a characteristic appearance (Fig. 1-40a). The nucleus is lobulated and numerous lysosomes (L), containing lysosomal enzymes, are found in the cytoplasm.

The *lymphocytes* (Fig. 1-40b) are characterized by an oval to spherical nucleus containing localized areas of electron-dense chromatin. The narrow border of cytoplasm surrounding the nucleus contains numerous free ribosomes, a few mitochondria (M), and, in localized areas, endoplasmic reticulum with fixed ribosomes. Lysosomes are also present in the cytoplasm.

The *plasma cells* (Fig. 1-40c) contain an eccentrically located spherical nucleus with radially deployed electron-dense chromatin. Endoplasmic reticulum (E) with numerous ribosomes is found randomly distributed in the cytoplasm. In addition, the cytoplasm contains numerous mitochondria (M) and a well-developed Golgi complex.

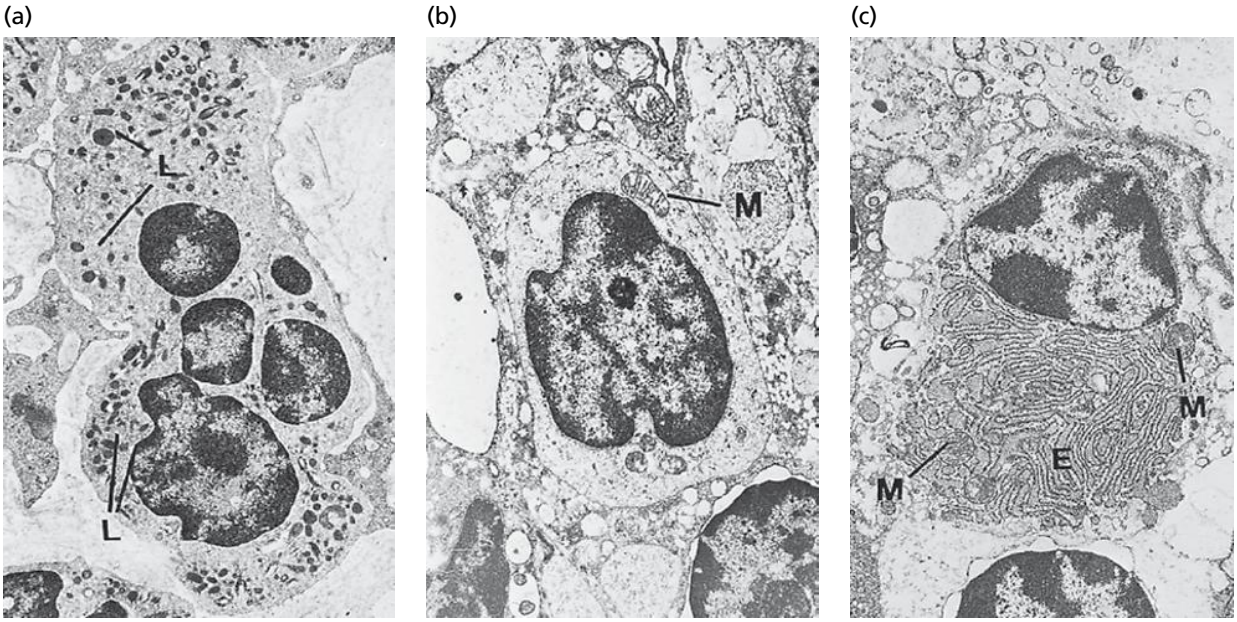

Fig. 1-40

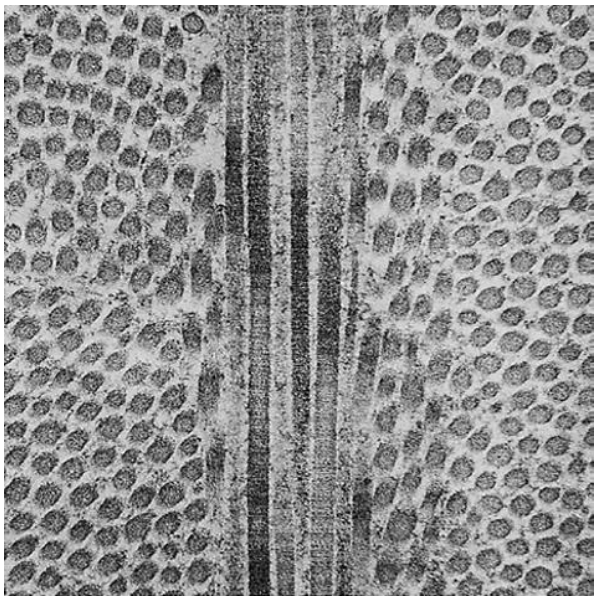

Fig. 1-41

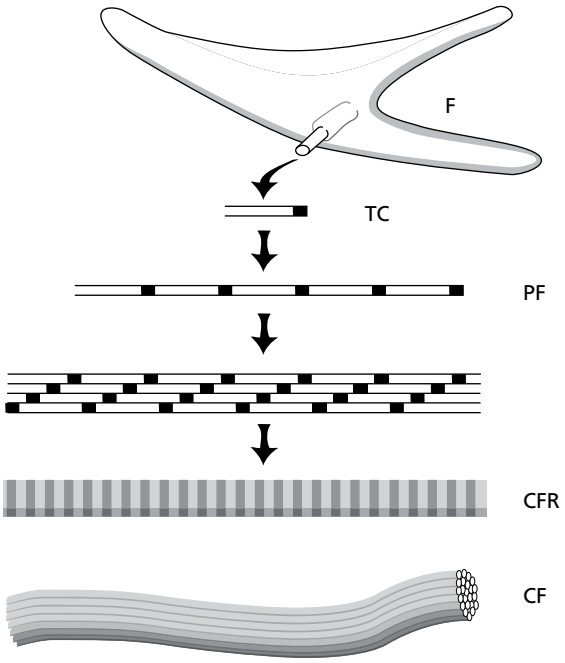

Fig. 1-42

Fibers

The connective tissue fibers are produced by the fibroblasts and can be divided into: (1) *collagen fibers*, (2) *reticulin fibers*, (3) *oxytalan fibers*, and (4) *elastic fibers*.

Figure 1-41 The *collagen fibers* predominate in the gingival connective tissue and constitute the most essential components of the periodontium. The electron micrograph shows cross-sections and longitudinal sections of collagen fibers. The collagen fibers have a characteristic cross-banding with a periodicity of 700 Å between the individual dark bands.

Figure 1-42 illustrates some important features of the synthesis and the composition of collagen fibers produced by fibroblasts (F). The smallest unit, the collagen molecule, is often referred to as *tropocollagen*. A tropocollagen molecule (TC), which is seen in the upper portion of the drawing, is approximately 3000 Å long and has a diameter of 15 Å. It consists of three polypeptide chains intertwined to form a helix. Each chain contains about 1000 amino acids. One-third of these are glycine and about 20% proline and hydroxyproline, the latter being found almost exclusively in collagen. Tropocollagen synthesis takes place inside the fibroblast from which the tropocollagen molecule is secreted into the extracellular space. Thus, the polymerization of tropocollagen molecules to collagen fibers takes place in the extracellular compartment. First, tropocollagen molecules are aggregated longitudinally to form *protofibrils* (PF), which are subsequently laterally aggregated parallel to *collagen fibrils* (CFR), with the tropocollagen molecules overlapping by about 25% of their length. Due to the fact that special refraction conditions develop after staining at the sites where the tropocollagen molecules adjoin, a cross-banding with a periodicity of approximately 700 Å is seen under light microscopy. The *collagen fibers* (CF) are bundles of collagen fibrils, aligned in such a way that the fibers also exhibit a cross-banding with a periodicity of 700 Å. In the tissue, the fibers are usually arranged in bundles. As the collagen fibers mature, covalent cross-links are formed between the tropocollagen molecules, resulting in an age-related reduction in collagen solubility.

Cementoblasts and *osteoblasts* are cells which also possess the ability to produce collagen.

Figure 1-43 *Reticulin fibers*, as seen in this photomicrograph, exhibit argyrophilic staining properties and are numerous in the tissue adjacent to the basement membrane (arrows). However, reticulin fibers also occur in large numbers in the loose connective tissue surrounding the blood vessels. Thus, reticulin fibers are present at the epithelium–connective tissue and the endothelium–connective tissue interfaces.

Figure 1-44 *Oxytalan fibers* are scarce in the gingiva but numerous in the periodontal ligament. They are composed of long thin fibrils with a diameter of approximately 150 Å. These connective tissue fibers can be demonstrated under light microscopy only after previous oxidation with peracetic acid. The photomicrograph illustrates oxytalan fibers (arrows) in the periodontal ligament, where they have a course mainly parallel to the long axis of the tooth. The function of these fibers is as yet unknown. The cementum is seen to the left and the alveolar bone to the right.

Figure 1-45 *Elastic fibers* in the connective tissue of the gingiva and periodontal ligament are only present in association with blood vessels. However, as seen in this photomicrograph, the lamina propria and submucosa of the alveolar (lining) mucosa contain

Fig. 1-43

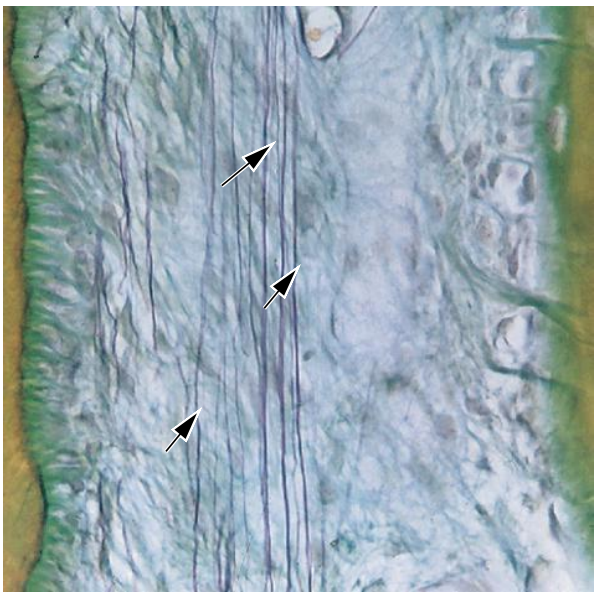

Fig. 1-44

numerous elastic fibers (arrows). The gingiva (G) seen coronal to the mucogingival junction (MGJ) contains no elastic fibers except in association with the blood vessels.

Figure 1-46 Although many of the collagen fibers in the gingiva and the periodontal ligament are irregularly or randomly distributed, most tend to be arranged in groups of bundles with a distinct orientation. According to their insertion and course in the tissue, the oriented bundles in the gingiva can be divided into the following groups:

Fig. 1-45

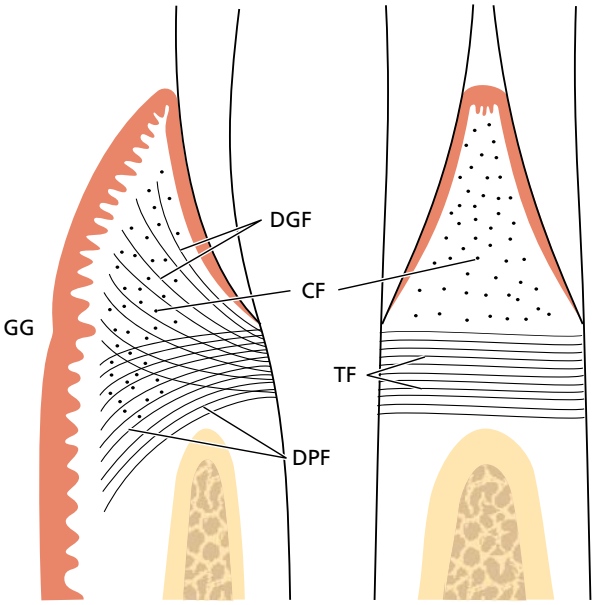

Fig. 1-46

1. *Circular fibers* (CF) are fiber bundles which run their course in the free gingiva and encircle the tooth in a cuff- or ring-like fashion.
2. *Dentogingival fibers* (DGF) are embedded in the cementum of the supra-alveolar portion of the root and project out from the cementum in a fan-like configuration into the free gingival tissue of the facial, lingual, and interproximal surfaces.
3. *Dentoperiosteal fibers* (DPF) are embedded in the same portion of the cementum as the dentogingival fibers, but run their course apically over the

vestibular and lingual bone crest and terminate in the tissue of the attached gingiva. In the border area between the free and attached gingiva, the epithelium often lacks support from underlying oriented collagen fiber bundles. In this area, the free gingival groove (GG) is often present.

4. *Trans-septal fibers* (TF), seen on the drawing to the right, extend between the supra-alveolar cementum of approximating teeth. The trans-septal fibers run straight across the interdental septum and are embedded in the cementum of adjacent teeth.

Figure 1-47 illustrates in a histologic section the orientation of the trans-septal fiber bundles (asterisks) in the supra-alveolar portion of the interdental area. It should be observed that, besides connecting the cementum (C) of adjacent teeth, the trans-septal fibers also connect the supra-alveolar cementum (C) with the crest of the alveolar bone (AB). The four groups of collagen fiber bundles shown in Fig. 1-46 reinforce the gingiva and provide the resilience and tone which is necessary for maintaining its architectural form and the integrity of the dentogingival attachment.

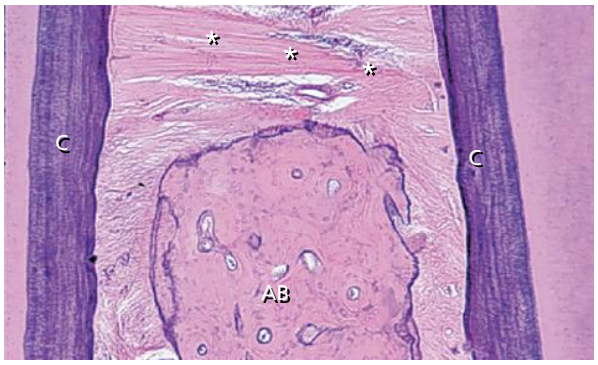

Fig. 1-47

Matrix

The *matrix* of the connective tissue is produced mainly by the fibroblasts, although some constituents are produced by mast cells and others are derived from the blood. The matrix is the medium in which the connective tissue cells are embedded and it is essential for the maintenance of the normal function of the connective tissue. Thus, the transportation of water, electrolytes, nutrients, metabolites, etc., to and from the individual connective tissue cells occurs within the matrix. The main constituents of the connective tissue matrix are protein–carbohydrate macromolecules. These complexes are normally divided into *proteoglycans* and *glycoproteins*. The proteoglycans contain *glycosaminoglycans* as the carbohydrate units (hyaluronan sulfate, heparan sulfate, etc.), which are attached to one or more protein chains via covalent bonds. The carbohydrate component is always predominant in the proteoglycans. The glycosaminoglycan, called hyaluronan or "hyaluronic acid", is probably not bound to protein. The glycoproteins (fibronectin, osteonectin, etc.) also contain polysaccharides, but these macromolecules are different from glycosaminoglycans. The protein component predominates in glycoproteins. In the macromolecules, mono- or oligo-saccharides are connected to one or more protein chains via covalent bonds.

Figure 1-48 Normal function of the connective tissue depends on the presence of proteoglycans and glycosaminoglycans. The carbohydrate moieties of the proteoglycans, the glycosaminoglycans (), are large, flexible, chains of negatively charged molecules, each of which occupies a rather large space (Fig. 1-48a). In such a space, smaller molecules, for example water and electrolytes, can be incorporated, while larger molecules are prevented from entering (Fig. 1-48b).

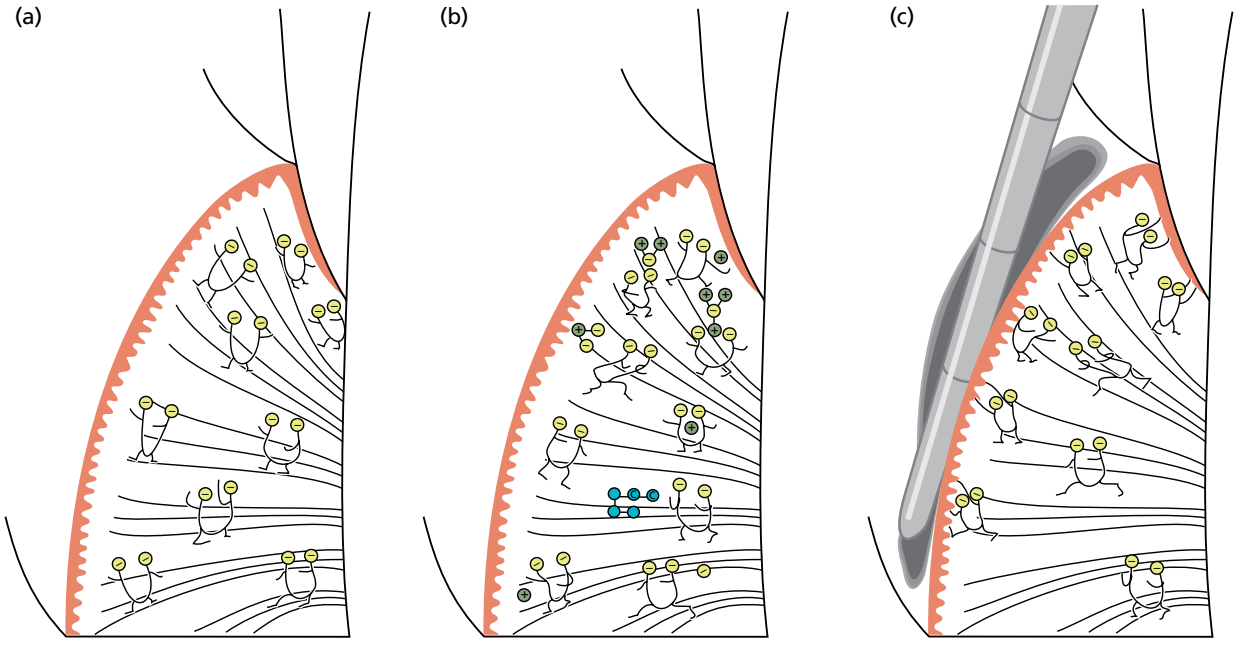

Fig. 1-48

The proteoglycans thereby regulate diffusion and fluid flow through the matrix and are important determinants for the fluid content of the tissue and the maintenance of the osmotic pressure. In other words, the proteoglycans act as a molecule filter and, in addition, play an important role in the regulation of cell migration (movement) in the tissue. Due to their structure and hydration, the macromolecules resist deformation, thereby serving as regulators of the consistency of the connective tissue (Fig. 1-48c). If the gingiva is suppressed, the macromolecules become deformed. When the pressure is eliminated, the macromolecules regain their original form. Thus, the macromolecules are important for the resilience of the gingiva.

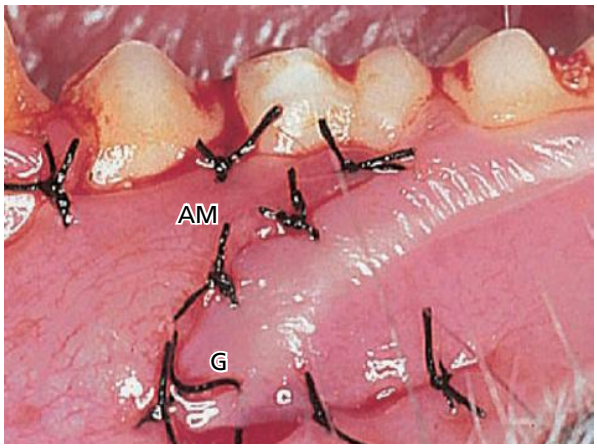

Fig. 1-49

Epithelial–mesenchymal interaction

During the embryonic development of various organs, a mutual inductive influence occurs between the epithelium and the connective tissue. The development of the teeth is a characteristic example of this phenomenon. The connective tissue is, on the one hand, a determining factor for normal development of the tooth bud while, on the other, the enamel epithelia exert a definite influence on the development of the mesenchymal components of the teeth.

It has been suggested that tissue differentiation in the adult organism can be influenced by environmental factors. The skin and mucous membranes, for instance, often display increased keratinization and hyperplasia of the epithelium in areas which are exposed to mechanical stimulation. Thus, the tissues seem to adapt to environmental stimuli. The presence of keratinized epithelium on the masticatory mucosa has been considered to represent an adaptation to mechanical irritation released by mastication. However, research has demonstrated that the characteristic features of the epithelium in such areas are genetically determined. Some pertinent observations are reported in the following images.

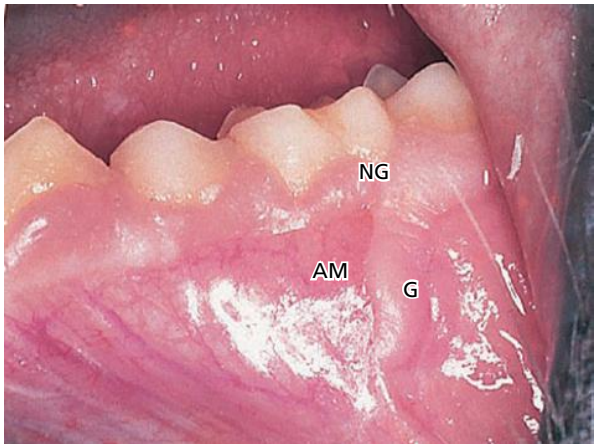

Fig. 1-50

Figure 1-49 shows an area in a monkey where the gingiva (G) and the alveolar mucosa (AM) have been transposed by a surgical procedure. The alveolar mucosa is placed in close contact with the teeth, while the gingiva is positioned in the area of the alveolar mucosa.

Figure 1-50 shows the same area as seen in Fig. 1-49, 4 months later. Despite the fact that the transplanted gingiva (G) is mobile in relation to the underlying bone, like the alveolar mucosa (AM), it has retained its characteristic morphologic features of a masticatory mucosa. A narrow zone of new keratinized gingiva (NG) has formed between the alveolar mucosa and the teeth.

Figure 1-51 shows a histologic section through the transplanted gingiva seen in Fig. 1-50. Since elastic fibers are lacking in the gingival connective tissue

Fig. 1-51

Fig. 1-52

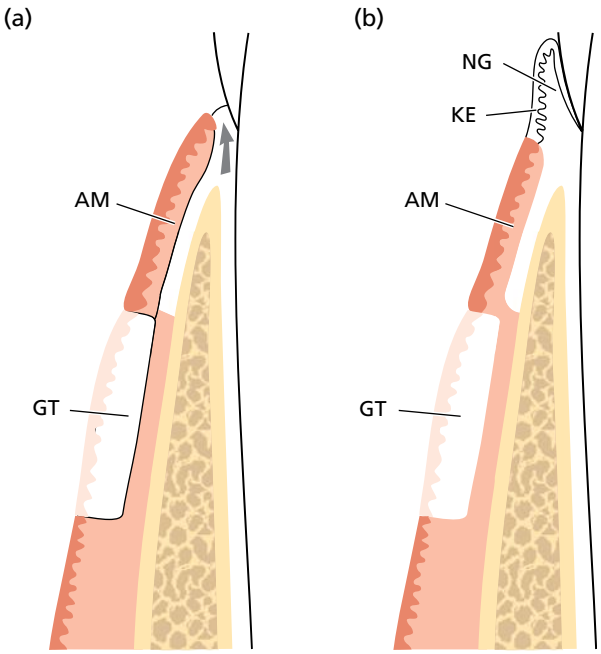

Fig. 1-53

(G), but are numerous (small arrows) in the connective tissue of the alveolar mucosa (AM), the transplanted gingival tissue can readily be identified. The epithelium covering the transplanted gingival tissue exhibits a distinct keratin layer (between arrowheads) on the surface, and the configuration of the epithelium–connective tissue interface (i.e. rete pegs and connective tissue papillae) is similar to that of normal non-transplanted gingiva. Thus, the heterotopically located gingival tissue has maintained its original specificity. This observation demonstrates that the characteristics of the gingiva are genetically determined rather than being the result of functional adaptation to environmental stimuli.

Figure 1-52 shows a histologic section through the coronal portion of the area of transplantation shown in Fig. 1-50. The transplanted gingival tissue (G) shown in Fig. 1-51 can be seen in the lower portion of the photomicrograph. The alveolar mucosa transplant (AM) is seen between the arrowheads in the middle of the micrograph. After surgery, the alveolar mucosa transplant was positioned in close contact with the teeth, as seen in Fig. 1-49. After healing, a narrow zone of keratinized gingiva (NG) developed coronal to the alveolar mucosa transplant (see Fig. 1-50). This new zone of gingiva (NG), which can be seen in the upper portion of the histologic section, is covered by keratinized epithelium and the connective tissue contains no purple-stained elastic fibers. In addition, it is important to note that the junction between keratinized and non-keratinized epithelium (arrowheads) corresponds exactly to the junction between "elastic" and "non-elastic" connective tissue (small arrows). The connective tissue of the new gingiva has regenerated from the connective tissue of the supra-alveolar and periodontal ligament compartments and has separated the alveolar mucosal transplant (AM) from the tooth (see Fig. 1-53). It is likely that the epithelium which covers the new gingiva has migrated from the adjacent epithelium of the alveolar mucosa. This indicates that it is the connective tissue that determines the quality of the epithelium.

Figure 1-53 shows a schematic drawing of the development of the new, narrow zone of keratinized gingiva (NG) seen in Figs. 1-50 and 1-52.

Figure 1-53a Granulation tissue (GT) has proliferated coronally along the root surface (arrow) and has separated the alveolar mucosa transplant (AM) from its original contact with the tooth surface.

Figure 1-53b Epithelial cells have migrated from the alveolar mucosal transplant (AM) to the newly formed gingival connective tissue (NG). Thus, the newly formed gingiva has become covered with a keratinized epithelium (KE) which originated from the non-keratinized epithelium of the alveolar mucosa (AM). This implies that the newly formed gingival connective tissue possesses the ability to induce changes in the differentiation of the epithelium originating from the alveolar mucosa. This epithelium, which is normally non-keratinized, apparently differentiates to keratinized epithelium because of stimuli arising from the newly formed gingival connective tissue. (GT, gingival transplant.)

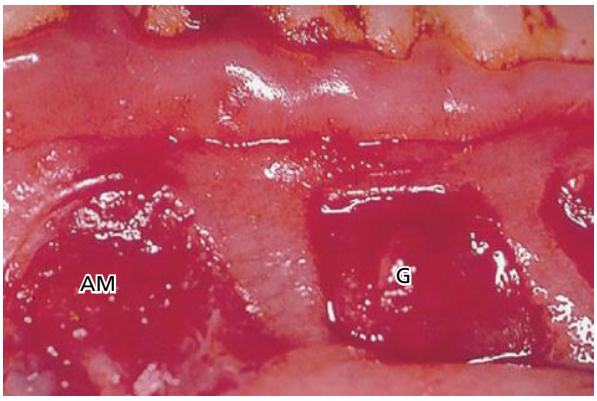

Fig. 1-54

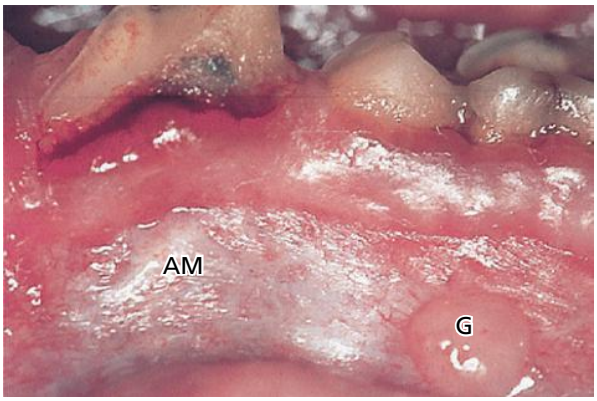

Fig. 1-55

Figure 1-54 shows a portion of gingival connective tissue (G) and alveolar mucosal connective tissue (AM) which, after transplantation, has healed into wound areas in the alveolar mucosa. Epithelialization of these transplants can only occur through migration of epithelial cells from the surrounding alveolar mucosa.

Figure 1-55 shows the transplanted gingival connective tissue (G) after re-epithelialization. This tissue portion has attained an appearance similar to that of the normal gingiva, indicating that this connective tissue is now covered by keratinized epithelium. The transplanted connective tissue from the alveolar mucosa (AM) is covered by non-keratinized epithelium, and has the same appearance as the surrounding alveolar mucosa.

Figure 1-56 shows two histologic sections through the area of the transplanted gingival connective tissue. The section shown in Fig. 1-56a is stained for elastic fibers (arrows). The tissue in the middle without elastic fibers is the transplanted gingival connective tissue (G). Figure 1-56b shows an adjacent section stained with hematoxylin and eosin. By comparing Figs. 1-56a and 1-56b, it can be seen that:

- Transplanted gingival connective tissue is covered by keratinized epithelium (between arrowheads).
- Epithelium–connective tissue interface has the same wavy course (i.e. rete pegs and connective tissue papillae) as seen in normal gingiva.

The photomicrographs shown in Figs. 1-56c and 1-56d illustrate, at a higher magnification, the border area between the alveolar mucosa (AM) and the transplanted gingival connective tissue (G). Note the distinct relationship between keratinized epithelium (arrow) and "inelastic" connective tissue (arrowheads), and between non-keratinized epithelium and "elastic" connective tissue. The establishment of such a close relationship during healing implies that the transplanted gingival connective tissue possesses the ability to alter the differentiation of epithelial cells, as previously suggested (Fig. 1-53). While starting as non-keratinizing cells, the cells of the epithelium of the alveolar mucosa have evidently become keratinizing cells. This means that the specificity of the gingival epithelium is determined by genetic factors inherent in the connective tissue.

Periodontal ligament

The periodontal ligament is the soft, richly vascular and cellular connective tissue which surrounds the roots of the teeth and joins the root cementum with the socket wall. In the coronal direction, the periodontal ligament is continuous with the lamina propria of the gingiva and is demarcated from the gingiva by the collagen fiber bundles which connect the alveolar bone crest to the root (the alveolar crest fibers).

Figure 1-57 is a radiograph of a mandibular premolar–molar region. On radiographs two types of alveolar bone can be distinguished:

1. The part of the alveolar process which covers the alveolus, denoted "lamina dura" (LD).
2. The portion of the alveolar process which, on the radiograph, has the appearance of a meshwork, denoted "trabecular bone".

The periodontal ligament is situated in the space between the roots of the teeth and the lamina dura (LD) or the alveolar bone proper. The alveolar bone surrounds the tooth from the apex to a level approximately 1 mm apical to the cementoenamel junction (CEJ). The coronal border of the bone is called the *bone crest* (BC).

The periodontal ligament space has the shape of an hourglass and is narrowest at the mid-root level. The width of the periodontal ligament is approximately 0.25 mm (range 0.2–0.4 mm). The presence of a periodontal ligament permits forces, elicited during masticatory function and other tooth contacts, to be distributed to and resorbed by the alveolar process via the alveolar bone proper. The periodontal ligament is also essential for the mobility of the teeth.

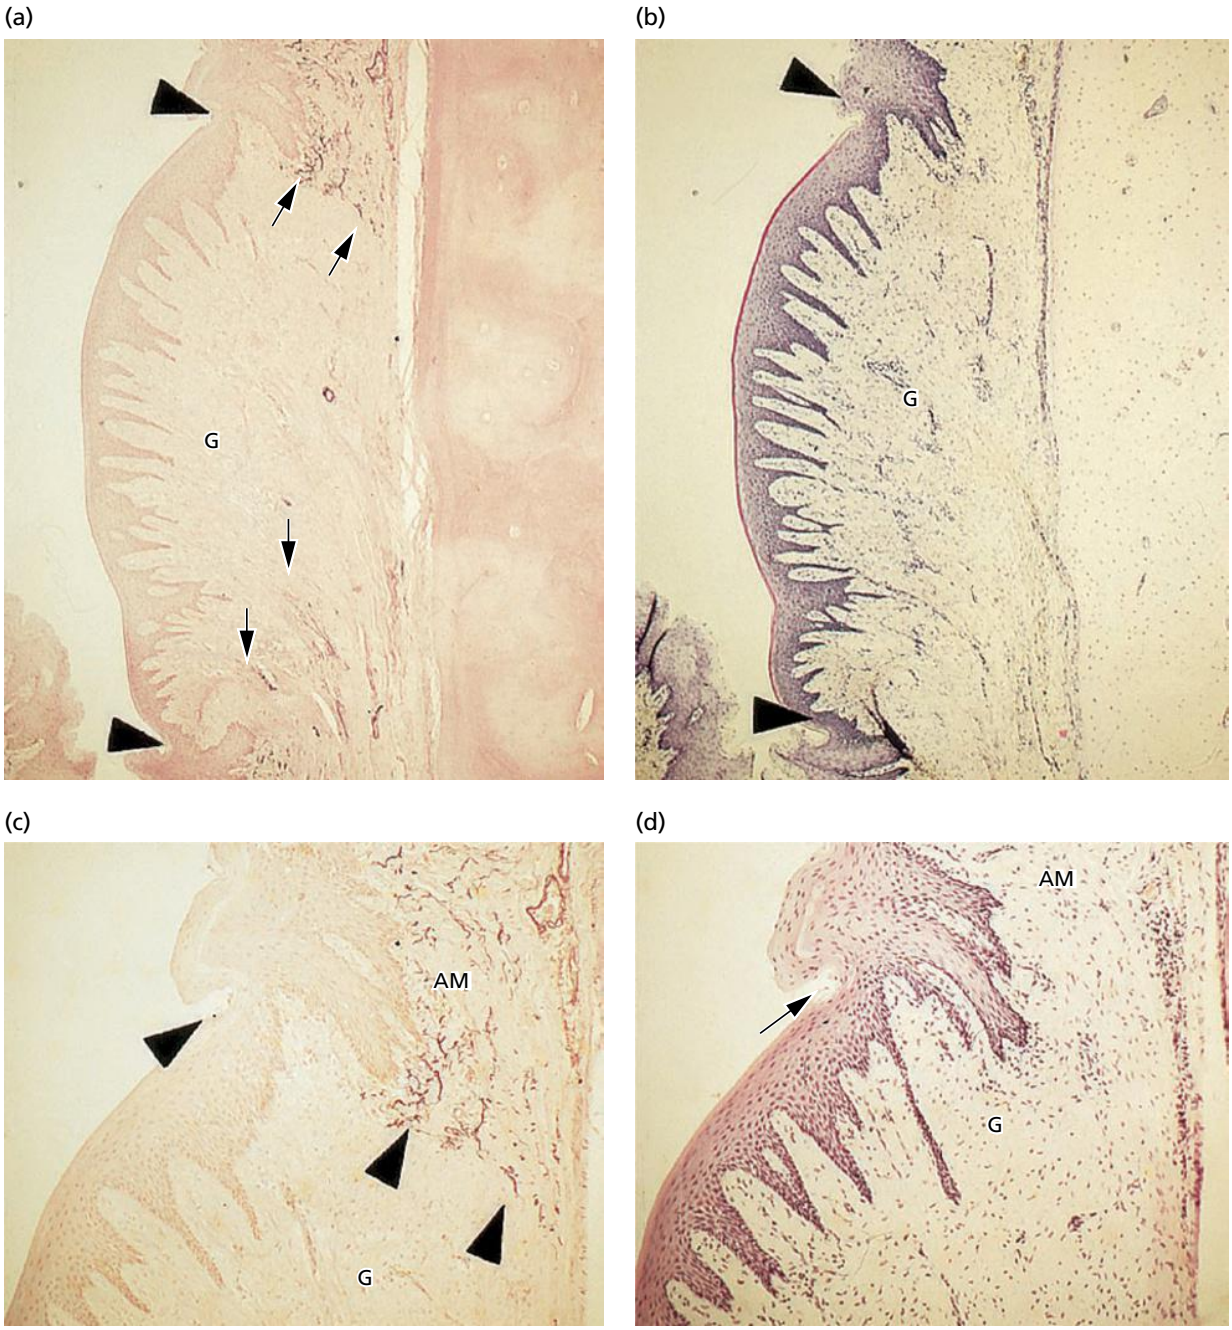

Fig. 1-56

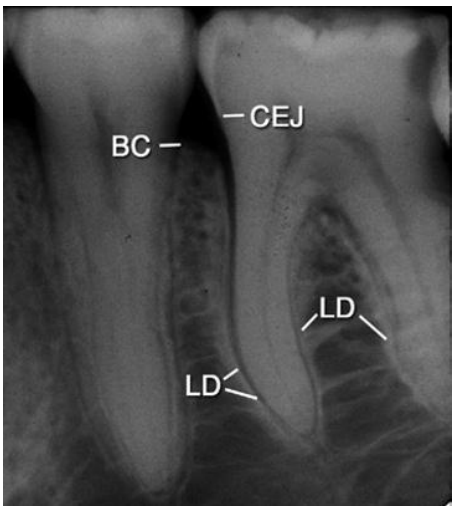

Fig. 1-57

Tooth mobility is to a large extent determined by the width, height, and quality of the periodontal ligament (see Chapters 16 and 52).

Figure 1-58 illustrates in a schematic drawing how the periodontal ligament is situated between the alveolar bone proper (ABP) and the root cementum (RC). The tooth is joined to the bone by bundles of collagen fibers which can be divided into the following main groups according to their arrangement:

1. *Alveolar crest fibers* (ACF)
2. *Horizontal fibers* (HF)
3. *Oblique fibers* (OF)
4. *Apical fibers* (APF).

Figure 1-59 The periodontal ligament and the root cementum develop from the loose connective tissue (the follicle) which surrounds the tooth bud. The schematic drawing depicts the various stages in the organization of the periodontal ligament which forms concomitantly with the development of the root and the eruption of the tooth.

Figure 1-59a The tooth bud is formed in a crypt of the bone. The collagen fibers produced by the fibroblasts in the loose connective tissue around the tooth bud are embedded, during the process of their maturation, into the newly formed cementum immediately apical to the cementoenamel junction (CEJ). These fiber bundles oriented towards the coronal portion of the bone crypt will later form the dentogingival fiber group, the dentoperiosteal fiber group, and the trans-septal fiber group, which belong to the oriented fibers of the gingiva (see Fig. 1-46).

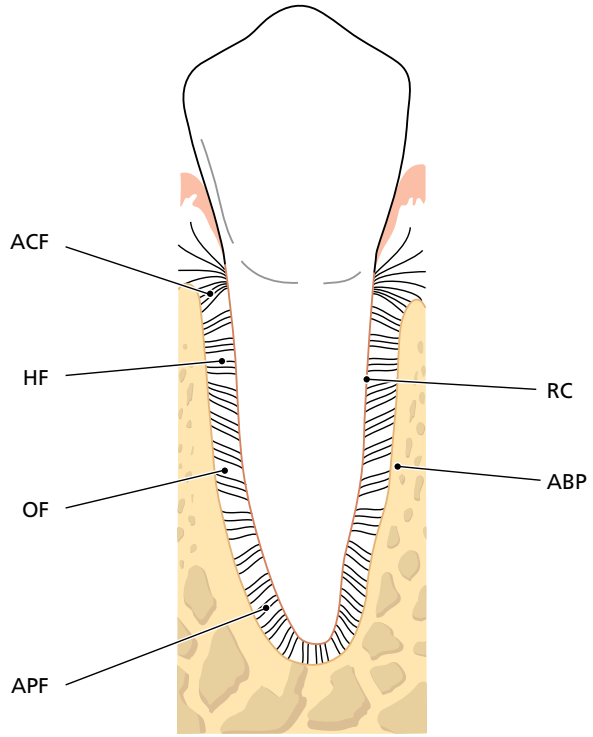

Fig. 1-58

Figure 1-59b The true periodontal ligament fibers, the *principal fibers*, develop in conjunction with the eruption of the tooth. First, fibers can be identified entering the most marginal portion of the alveolar bone.

Figure 1-59c Later, more apically positioned bundles of oriented collagen fibers are seen.

Figure 1-59d The orientation of the collagen fiber bundles alters continuously during the phase of tooth eruption. First, when the tooth has reached contact in occlusion and is functioning properly, the fibers of the periodontal ligament associate into groups of well-oriented dentoalveolar collagen fibers (see Fig. 1-58). These collagen structures undergo constant remodeling (i.e. resorption of old fibers and formation of new ones). (DGF, dentogingival fibers; DPF, dentoperiosteal fibers; HF, horizontal fibers; OF, oblique fibers; APF, apical fibers.)

Figure 1-60 This schematic drawing illustrates the development of the principal fibers of the periodontal ligament. The alveolar bone proper (ABP) is seen to the left, the periodontal ligament (PL) in the center, and the root cementum (RC) to the right.

Figure 1-60a First, small, fine, brush-like fibrils are detected arising from the root cementum and projecting into the periodontal ligament space. At this stage the surface of the bone is covered by osteoblasts. From the surface of the bone only a small number of radiating, thin collagen fibrils can be seen.

Figure 1-60b Later on, the number and thickness of fibers entering the bone increase. These fibers radiate towards the loose connective tissue in the mid-portion of the periodontal ligament space, which contains more or less randomly oriented collagen fibrils. The fibers originating from the cementum are

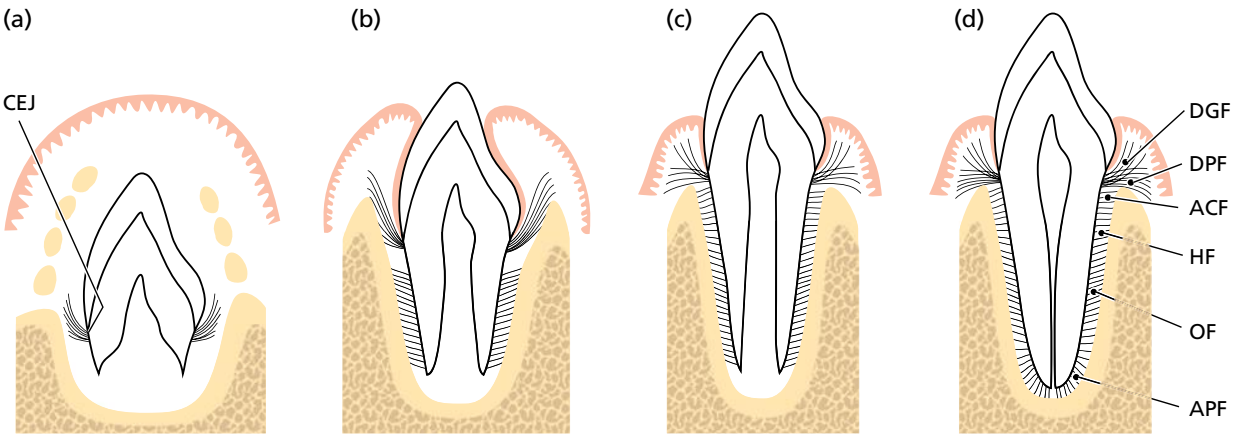

Fig. 1-59

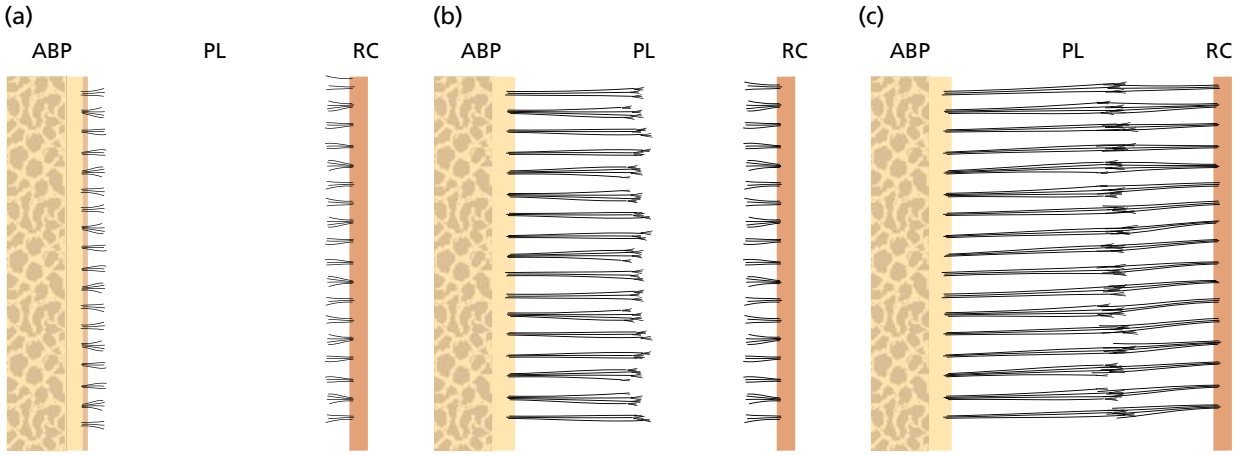

Fig. 1-60

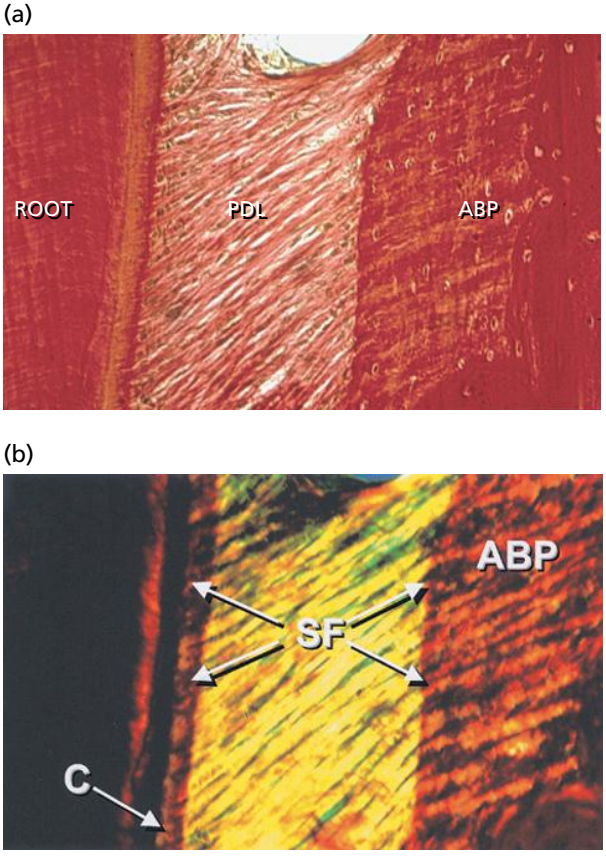

Fig. 1-61

still short, while those entering the bone gradually lengthen. The terminal portions of these fibers carry finger-like projections.

Figure 1-60c The fibers originating from the cementum subsequently increase in length and thickness and fuse in the periodontal ligament space with the fibers originating from the alveolar bone. When the tooth, following eruption, reaches contact in occlusion and starts to function, the principal fibers become organized into bundles and run continuously from the bone to the cementum.

Figure 1-61a shows how the principal fibers of the periodontal ligament (PDL) run continuously from the root cementum to the alveolar bone proper (ABP). The principal fibers embedded in the cementum (Sharpey's fibers) have a smaller diameter, but are more numerous than those embedded in the alveolar bone proper.

Figure 1-61b shows a polarized version of Fig. 1-61a. In this image the Sharpey's fibers (SF) can be seen penetrating not only the cementum (C) but also the entire width of the alveolar bone proper (ABP). The periodontal ligament also contains a few elastic fibers associated with the blood vessels. Oxytalan fibers (see Fig. 1-44) are also present in the periodontal ligament. They have a mainly apico-occlusal orientation and are located in the ligament closer to the tooth than to the alveolar bone. Very often they insert into the cementum. Their function has not been determined.

The cells of the periodontal ligament are: *fibroblasts*, *osteoblasts*, *cementoblasts*, *osteoclasts*, as well as *epithelial cells* and *nerve fibers*. The fibroblasts are aligned along the principal fibers, while cementoblasts line the surface of the cementum and the osteoblasts line the bone surface.

Figure 1-62a shows the presence of clusters of epithelial cells (ER) in the periodontal ligament (PDL). These cells, called the *epithelial cell rests of Mallassez*, represent remnants of the Hertwig's epithelial root sheath. The epithelial cell rests are situated in the periodontal ligament at a distance of 15–75 µm from the cementum (C) on the root surface. A group of such epithelial cell rests is seen in a higher magnification in Fig. 1-62b.

Figure 1-63 Under the electron microscopic it can be seen that the epithelial cell rests are surrounded by a basement membrane (BM) and that the cell membranes of the epithelial cells exhibit the presence of desmosomes (D) as well as hemidesmosomes (HD).

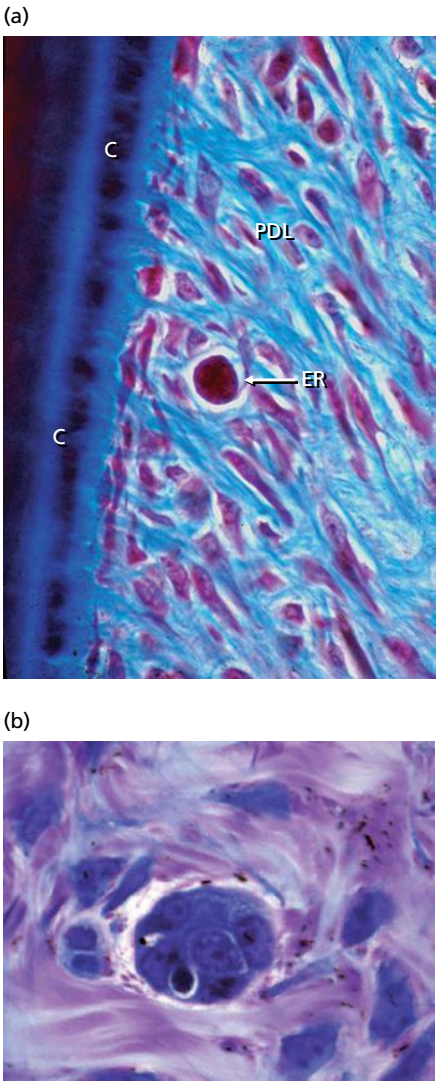

Fig. 1-62

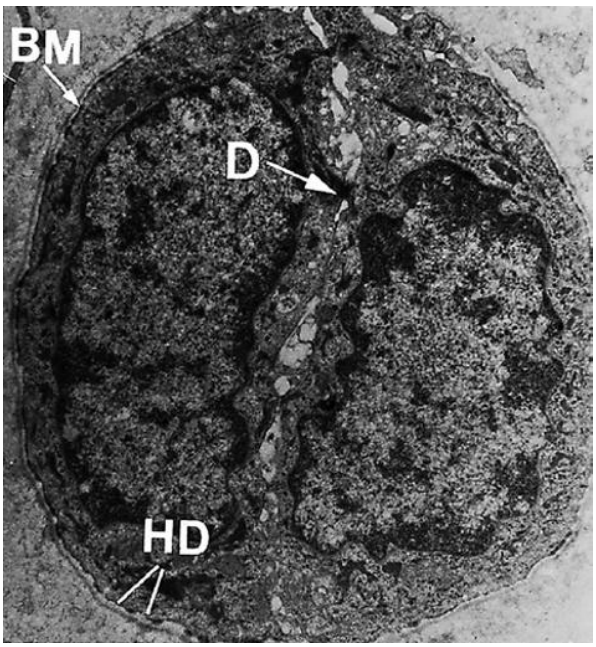

Fig. 1-63

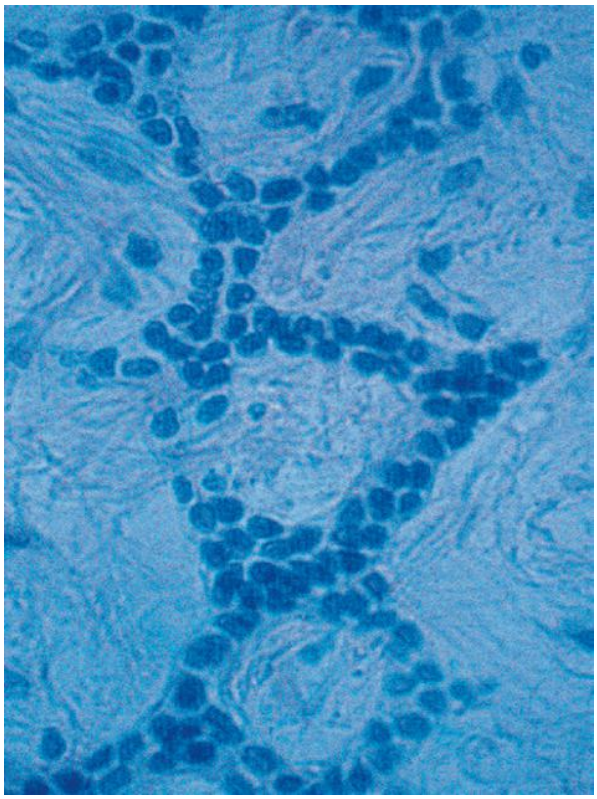

Fig. 1-64

The epithelial cells contain only a few mitochondria and have a poorly developed endoplasmic reticulum. This means that they are vital, but resting, cells with minute metabolism.

Figure 1-64 is a photomicrograph of a periodontal ligament removed from an extracted tooth. This specimen, prepared tangential to the root surface, shows that the epithelial cell rests of Mallassez, which in ordinary histologic sections appear as isolated groups of epithelial cells, in fact form a continuous network of epithelial cells surrounding the root. Their function is unknown at present.

Root cementum

The cementum is a specialized mineralized tissue covering the root surfaces and, occasionally, small portions of the crown of the teeth. It may also extend into the root canal. Unlike bone, the cementum contains no blood or lymph vessels, has no innervation, does not undergo physiologic resorption or remodeling, but is characterized by continuing deposition throughout life. Like other mineralized tissues, it contains collagen fibrils embedded in an organic matrix. Its mineral content, which is mainly hydroxyapatite, is about 65% by weight, a little more than that of bone (60%). Cementum serves different functions. It attaches the principal periodontal ligament fibers to the root and contributes to the process of repair after damage to the root surface. It

may also serve to adjust the tooth position to new requirements.

Different forms of cementum have been described:

1. *Acellular afibrillar cementum* (AAC) is found mainly at the cervical portion of the enamel.
2. *Acellular extrinsic fiber cementum* (AEFC) is found in the coronal and middle portions of the root and contains mainly bundles of Sharpey's fibers. This type of cementum is an important part of the attachment apparatus and connects the tooth with the bundle bone (alveolar bone proper).
3. *Cellular mixed stratified cementum* (CMSC) occurs in the apical third of the roots and in the furcations. It contains both extrinsic and intrinsic fibers as well as cementocytes.
4. *Cellular intrinsic fiber cementum* (CIFC) is found mainly in resorption lacunae and it contains intrinsic fibers and cementocytes.

Figure 1-65a shows a ground section viewed under polarized light. The principal collagen fibers of the periodontal ligament (PDL) span between the root covered with cementum (C) and the alveolar process covered with bundle bone (BB). The portions of the principal fibers of the periodontal ligament that are embedded in the root cementum and in the bundle bone are called *Sharpey's fibers*. (D, dentin.) (Courtesy of D.D. Bosshardt.)

Figure 1-65b The oxytalan fibers in the periodontal ligament (PDL) run in an apicocoronal direction; some (arrows) insert into acellular extrinsic fiber cementum (AEFC). Many oxytalan fibers are seen around the blood vessels (BV) in the periodontal ligament. Oxytalan fibers may have a function in mechanotransduction between the tooth root and the periodontal ligament. (BB, bundle bone; D, dentin.) (Courtesy of D.D. Bosshardt.)

Figure 1-66a shows the presence of acellular afibrillar cementum (AAC) in the region of the dentinocemental junction. The acellular afibrillar cementum covers minor areas of the cervical enamel. It neither contains cells nor collagen fibrils. It may form isolated patches on the enamel or be contiguous with the acellular extrinsic fiber cementun (AEFC). The acellular afibrillar cementum may form when the reduced enamel epithelium recedes or focally disintegrates so that the exposed enamel surface comes into contact with the surrounding soft connective tissue. (D, dentin; ES, enamel space.) (Courtesy of D.D. Bosshardt.)

Figure 1-66b shows the morphology of the acellular afibrillar cementum (AAC) under the transmission electron microscope. The acellular afibrillar cementum extends from the acellular extrinsic fiber cementum (AEFC) in the coronal direction. The layered appearance of the acellular afibrillar

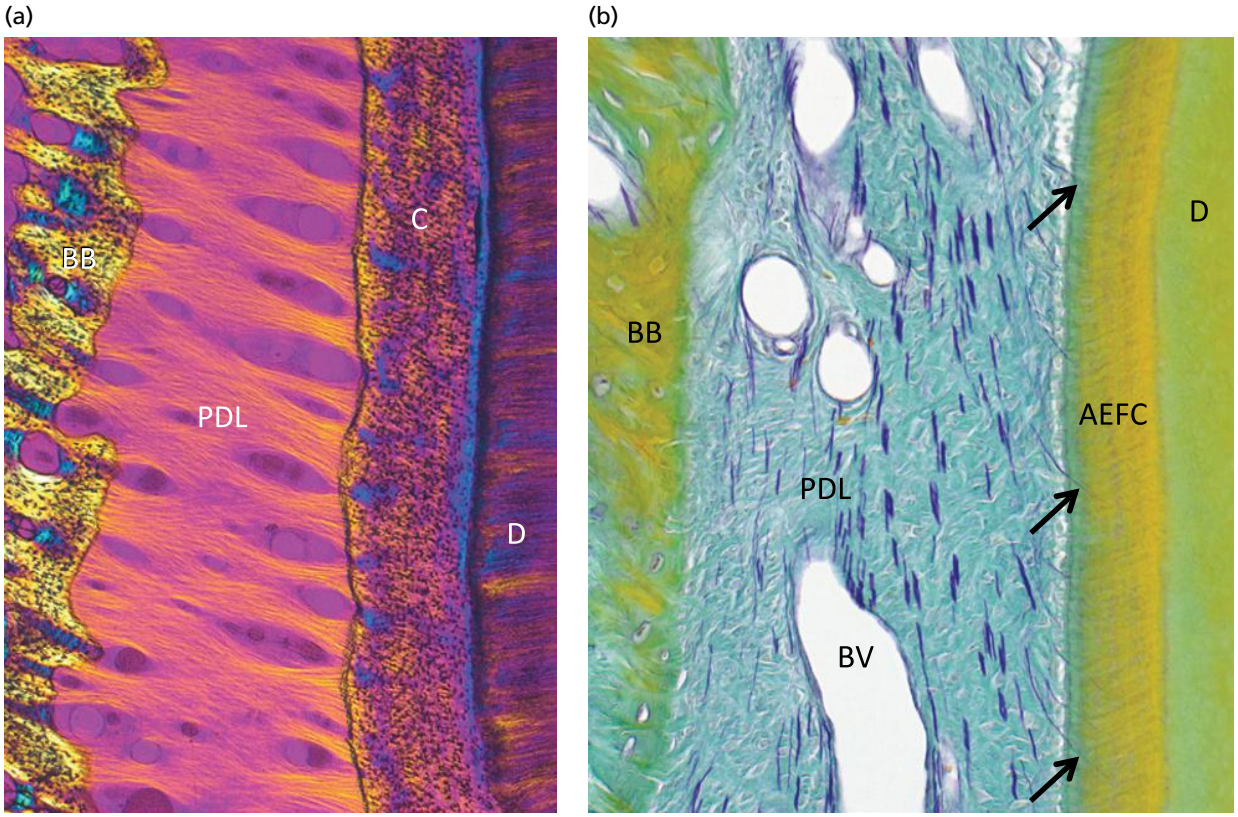

Fig. 1-65

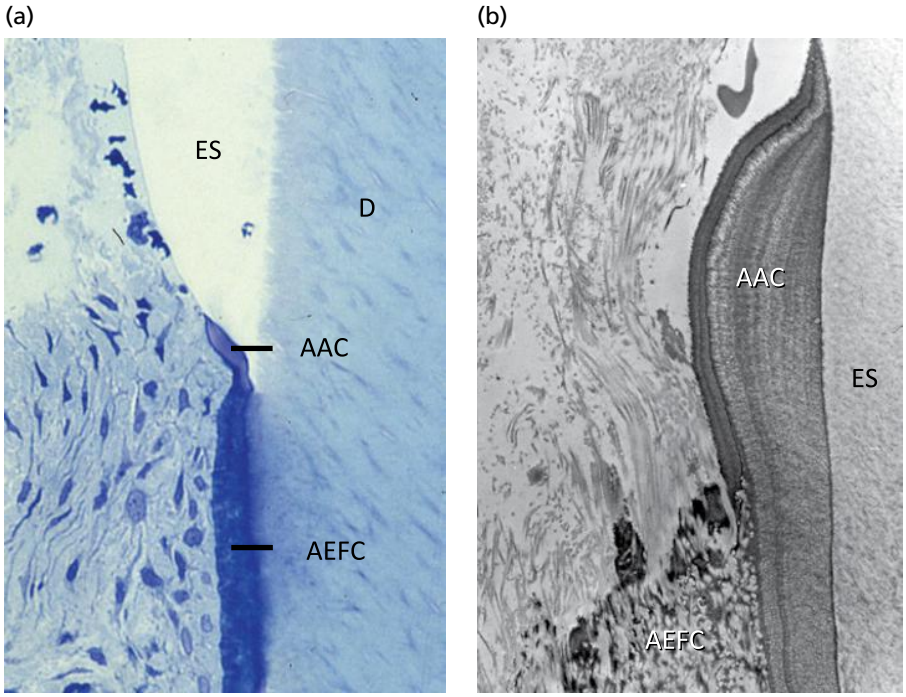

Fig. 1-66

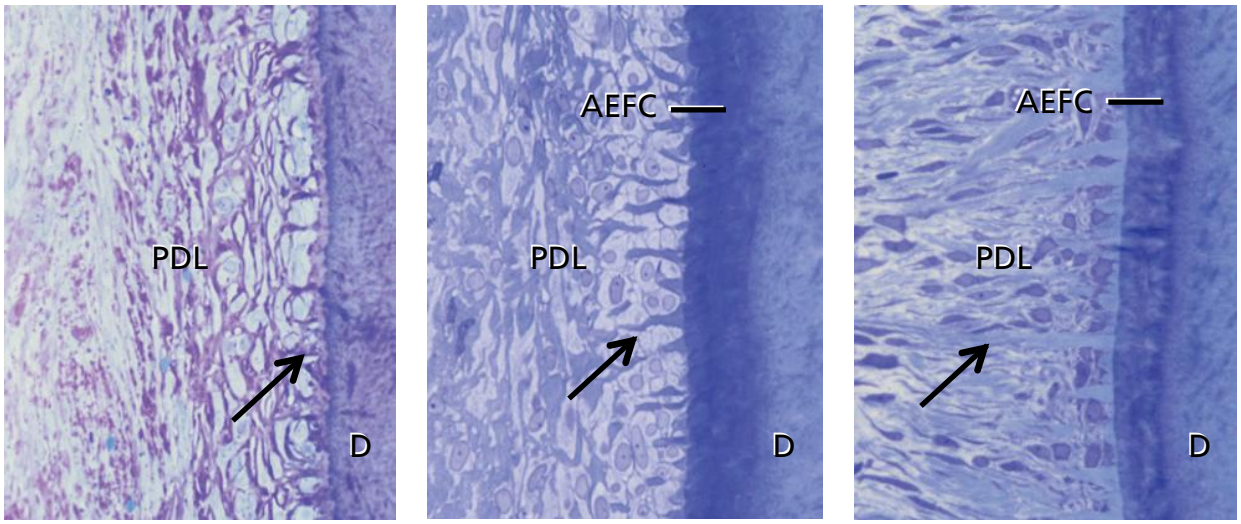

Fig. 1-67

cementum is indicative of periods of deposition and rest. The function of the acellular afibrillar cementum is unclear. The moderately electron-dense material in the enamel space (ES) adjacent to the acellular afibrillar cementum represents residual enamel matrix.

Figure 1-67 illustrates the three stages of development of the acellular extrinsic fiber cementum (AEFC). The acellular extrinsic fiber cementum is formed concomitantly with the formation of the root dentin. At the beginning of root development, the epithelial sheath of Hertwig, which lines the newly formed predentin, is fragmented. Cementoblasts then begin to synthesize collagen fibers that are implanted at a right angle to the surface. During the continuous formation of acellular extrinsic fiber cementum, portions of these short collagen fibers adjacent to the root become embedded in the mineralized tissue.

Figure 1-67a shows the short collagen fibers (arrow) protruding from the dentin (D) surface into the periodontal ligament (PDL), which constitute the future Sharpey's fibers. However, a cementum layer is not yet visible.

Figure 1-67b shows the short collagen fibers (arrow) protruding from the root surface, but their bases are now embedded as Sharpey's fibers in the mineralized cementum.

Figure 1-67c shows that most collagen fibers are now elongated and continue into the periodontal ligament space.

These micrographs demonstrate that the Sharpey's fibers in the cementum are a direct continuation of the principal fibers in the periodontal ligament and the supra-alveolar connective tissue. The AEFC increases throughout life with a very slow growth rate of 1.5–4.0 µm/year.

Figure 1-68a represents a scanning electron micrograph of a non-decalcified fracture surface of acellular extrinsic fiber cement (AEFC). Note that the extrinsic fibers attach to the dentin (D), traverse the mineralized cementum layer as Sharpey's fibers, and are continuous with the collagen fibers (CF) of the periodontal ligament (PDL). (Courtesy of D.D. Bosshardt.)

Figure 1-68b shows a transmission electron micrograph of acellular extrinsic fiber cementum (AEFC). Sharpey's fibers (i.e. the extrinsic collagen fibers of acellular extrinsic fiber cementum) pass from the dentin (D) surface through the mineralized cementum layer and continue outside the cementum as principal collagen fibers (CF) into the periodontal ligament. Cementoblasts (CB) occupy the spaces between the protruding collagen fibers.

Figure 1-69a shows a transmission electron micrograph of acellular extrinsic fiber cementum (AEFC) at the mineralization front. The Sharpey's fibers leave the cementum at the mineralization front and continue as principal periodontal ligament fibers. Cementoblasts (CB) occupy the space between the densely packed collagen fibrils. The characteristic cross-banding of the collagen fibrils is masked in the cementum because of the presence of non-collagenous proteins. Mineralization occurs by the deposition of hydroxyapatite crystals, first within the collagen fibers, later upon the fiber surface, and finally in the interfibrillar matrix.

Figure 1-69b shows high-resolution immunolabeling of acellular extrinsic fiber cementum (AEFC) at the mineralization front. The tissue section was processed for immunogold labeling with an antibody against bone sialoprotein. This non-collagenous protein has a function in the regulation of mineralization of collagen-based hard tissues. Gold particles label the interfibrillar matrix of the mineralized cementum, whereas the unmasked collagen fibrils that leave the cementum and extend into the periodontal ligament space are not labeled.

Figure 1-70a shows an unstained, undecalcified ground section viewed under polarized light. The micrograph demonstrates the structure of cellular mixed stratified cementum (CMSC) that consists of alternating layers of acellular extrinsic fiber

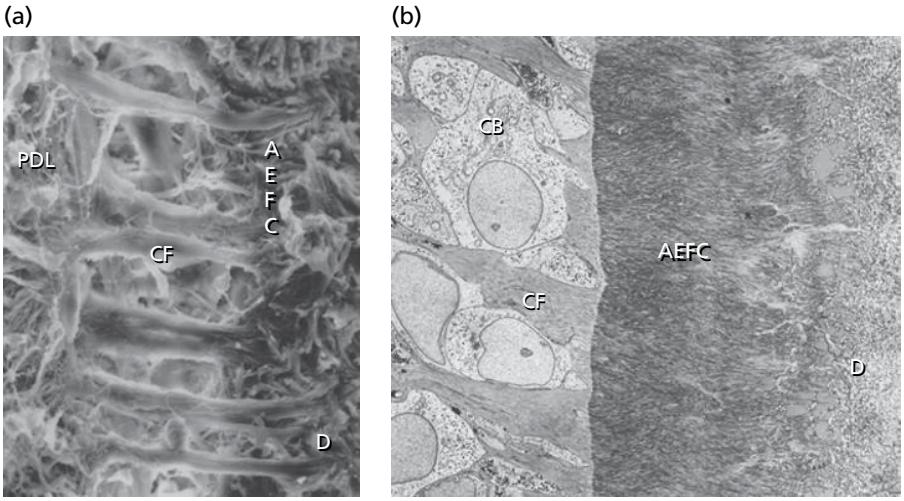

Fig. 1-68

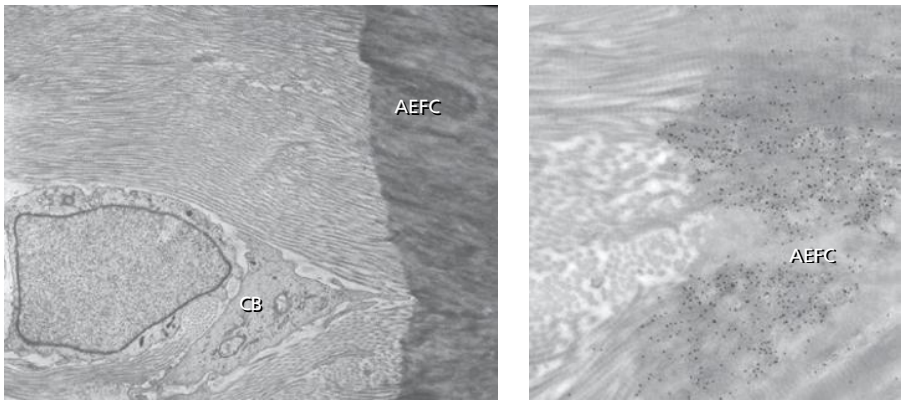

Fig. 1-69

cementum and cellular intrinsic fiber cementum. In contrast to acellular extrinsic fiber cementum, cellular intrinsic fiber cementum contains cells and intrinsic fibers. While the extrinsic Sharpey's fibers traverse the cementum layer and leave it at the mineralization front, the intrinsic fibers reside completely within the cementum. The cells that are incorporated into the cementum are called *cementocytes*. The cellular mixed stratified cementum is laid down throughout the functional period of the tooth. The stratification of cellular mixed stratified cementum is usually irregular. Cellular mixed stratified cementum is found at the mid-root and apical root surfaces and in the furcations. The cementum becomes considerably wider in the apical portion of the root than in the cervical portion. In the apical root portion, the cementum is often 150–250 µm wide or even more. The cementum often contains incremental lines, indicating alternating periods of formation and rest.

Figure 1-70b shows an unstained, undecalcified ground section viewed under polarized light. Cementocytes (black cells) reside in lacunae in the cellular intrinsic fiber cementum (CIFC), which is found in the cellular mixed stratified cementum. Cementocytes communicate with each other through a network of cytoplasmic processes (arrow) running through canaliculi in the cementum. Most cell processes point to the cementum surface (to the left). The cementocytes also communicate with the cementoblasts on the surface through cytoplasmic processes. The presence of cementocytes allows transportation of nutrients and waste products through the cementum, and contributes to the maintenance of the vitality of this mineralized tissue.

Figure 1-71a shows a transmission electron micrograph from the surface of cellular intrinsic fiber cementum (CIFC). The cementoid is lined by typical

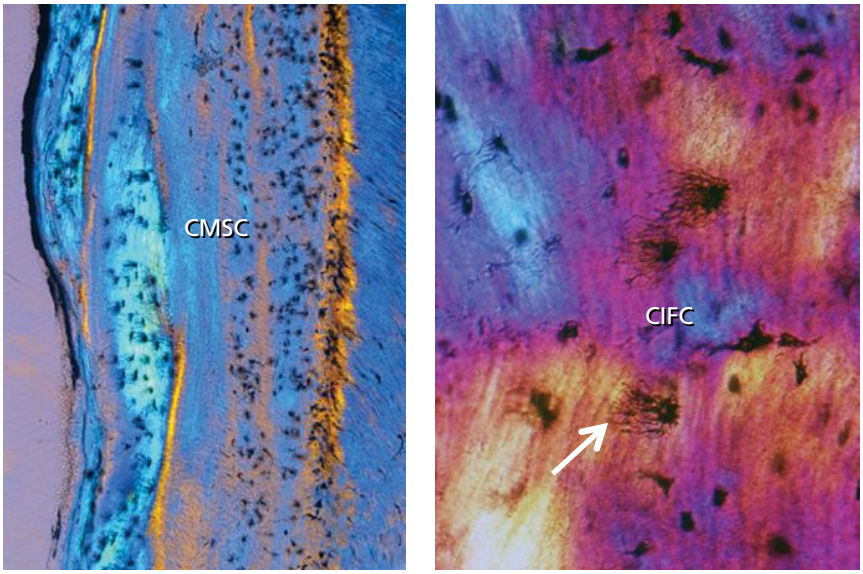

Fig. 1-70

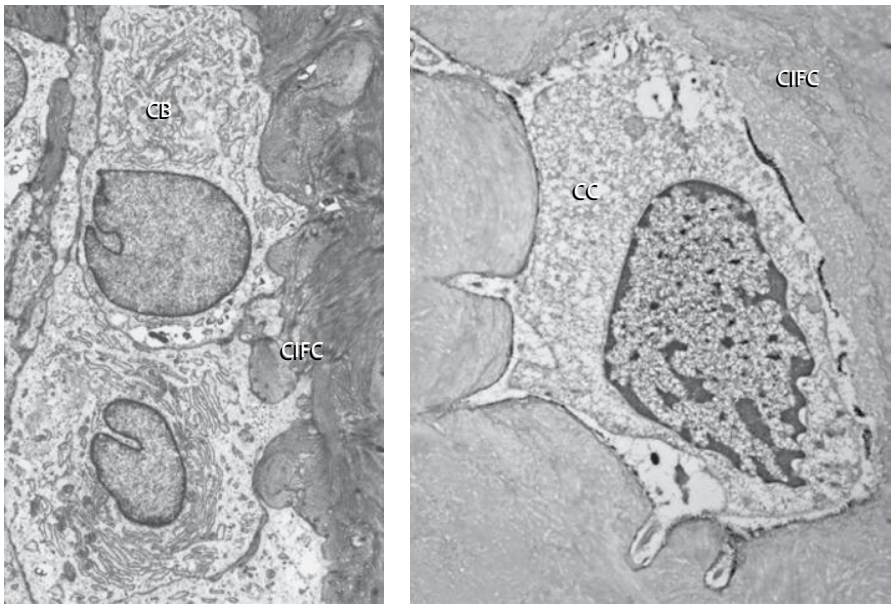

Fig. 1-71

cementoblasts (CB). They are large, cuboidal cells with a round, euchromatin-rich nucleus. The abundance of rough endoplasmic reticulum indicates that these cells are highly active and produce proteins that are secreted into the extracellular space. They elaborate a cementoid seam consisting of a collagenous matrix that later mineralizes. Generally, the acellular extrinsic fiber cementum is more mineralized than cellular mixed stratified cementum and cellular intrinsic fiber cementum. Sometimes only the periphery of the Sharpey's fibers of the cellular mixed stratified cementum is mineralized, leaving an unmineralized core within the fiber.

Figure 1-71b is a transmission electron micrograph that illustrates a cementocyte (CC) in cellular intrinsic fiber cementum (CIFC). Cementocytes are cementoblasts that become entrapped in the cementum matrix. They are present in lacunae from which several canaliculi traverse the cementum matrix and communicate with neighboring cementocytes. Cementocyte lacunae in deeper portions of the cementum often appear empty, which may be because the critical distance for exchange of metabolites is surpassed.

Bone of the alveolar process

Macroscopic anatomy

The alveolar process is defined as the parts of the maxilla and the mandible that form and support the sockets of the teeth. The alveolar process extends from the basal bone of the jaws and develops in conjunction with the development and eruption of the teeth (see Fig. 1-59). The alveolar process consists of bone that is formed both by cells from the dental follicle (to produce the alveolar bone proper) and cells which are independent of this follicle (to produce the alveolar bone). Together with the root cementum and the periodontal membrane, the alveolar bone proper constitutes the attachment apparatus of the teeth, the main function of which is to distribute forces generated by, for example, mastication and other tooth contacts.

Figure 1-72 shows a cross-section through the alveolar process (pars alveolaris) of the maxilla at the mid-root level of the teeth. Note that the bone which covers the root surfaces is considerably thicker at the palatal than at the buccal aspect of the jaw. Anatomically, the walls of the sockets (alveolar bone proper; arrows), as well as the outer walls of the alveolar process are made up of *cortical bone. The* area enclosed by the cortical bone walls is occupied by *cancellous (spongy) bone*. Thus, the cancellous bone occupies most of the interdental septa but only a relatively small portion of the buccal and palatal bone walls. The cancellous bone contains *bone trabeculae,* the architecture and size of which are partly genetically determined and partly the result of the forces to which the teeth are exposed during function. Note how the bone on the buccal and palatal aspects of the alveolar process varies in thickness from one region to another.

Figure 1-73 shows cross-sections through the mandibular alveolar process at levels corresponding to the coronal (Fig. 1-73a) and apical (Fig. 1-73b) thirds of the roots. The bone lining the wall of the sockets

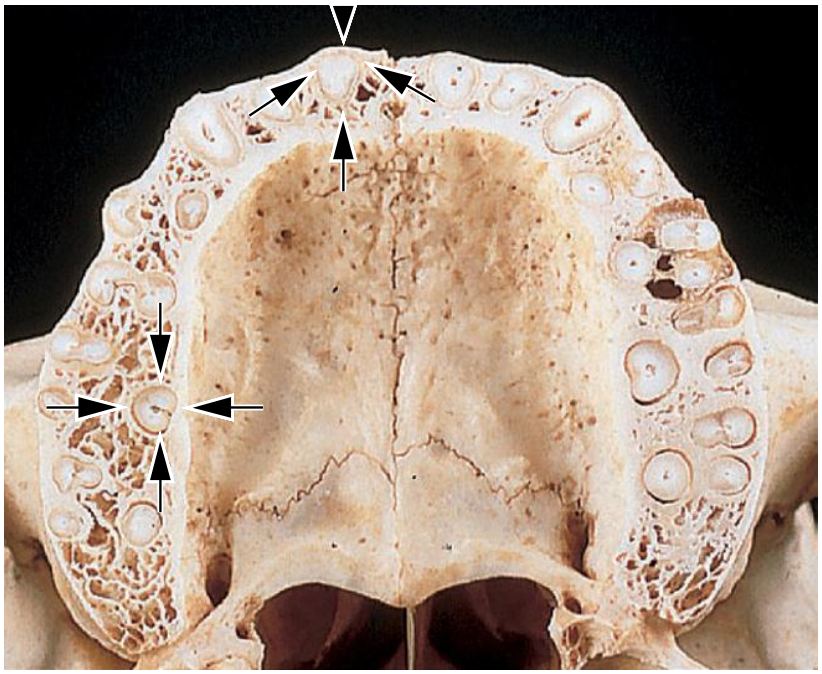

Fig. 1-72

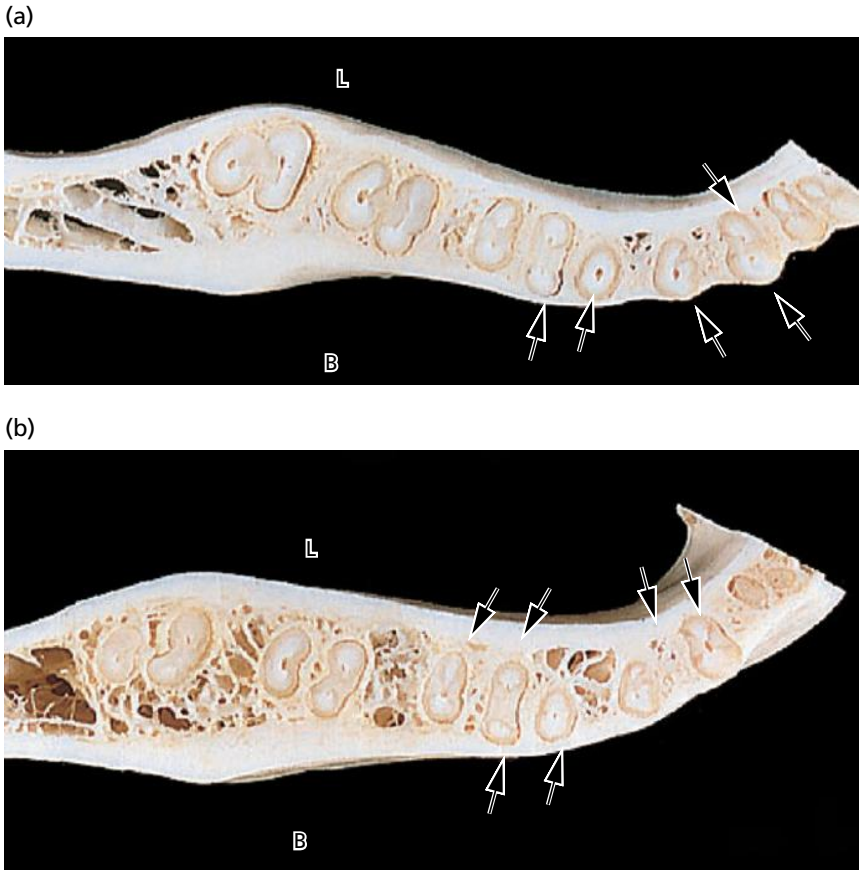

Fig. 1-73

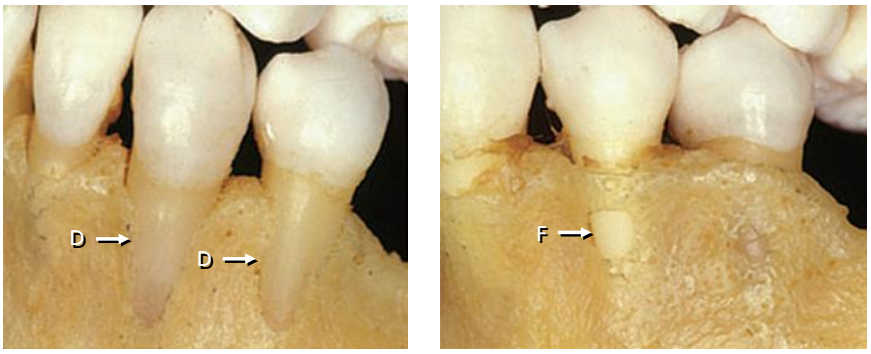

Fig. 1-74

(alveolar bone proper) is often continuous with the compact or cortical bone at the lingual (L) and buccal (B) aspects of the alveolar process (arrows). Note how the bone on the buccal and lingual aspects of the alveolar process varies in thickness from one region to another. In the incisor and premolar regions, the bone plate at the buccal aspects of the teeth is considerably thinner than at the lingual aspect. In the molar region, the bone is thicker at the buccal aspect than at the lingual aspect.

Figure 1-74 At the buccal aspect of the jaws, the bone coverage of the roots is occasionally very thin or entirely missing. An area without bone coverage in the marginal portion of the root is called *dehiscence* (D). If some bone is present in the most coronal portion of the buccal bone but the defect is located more apically, it is denoted *fenestration* (F). These defects often occur where a tooth during eruption is displaced out of the arch and are more frequent over anterior than posterior teeth. The root in such defects is covered only by a connective tissue attachment and overlying mucosa.

Figure 1-75 shows vertical sections through various regions of the mandibular dentition. The bone wall at the buccal (B) and lingual (L) aspects of the teeth varies considerably in thickness, for example from the premolar to the molar region. Note, for instance, how

Fig. 1-75

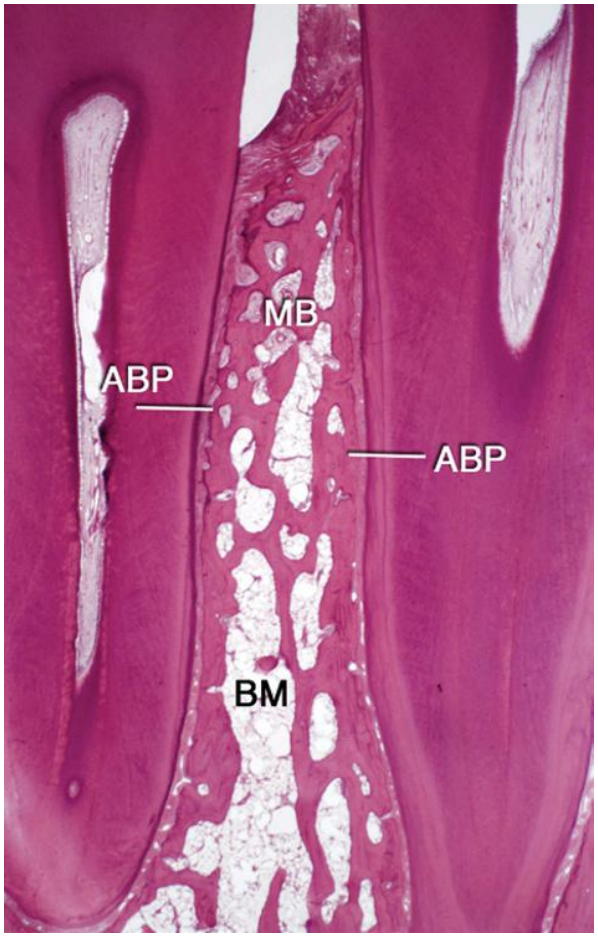

Fig. 1-76

the presence of the oblique line (*linea obliqua*) results in a shelf-like bone process (arrows) at the buccal aspect of the second and third molars.

Microscopic anatomy

Figure 1-76 illustrates a section through the interproximal septum between two premolars. Dense alveolar bone proper (ABP) is facing the periodontal ligament of the two teeth, while cancellous bone occupies the area between the alveolar bone proper. The cancellous bone is comprised of mineralized bone (MB) and bone marrow (BM).

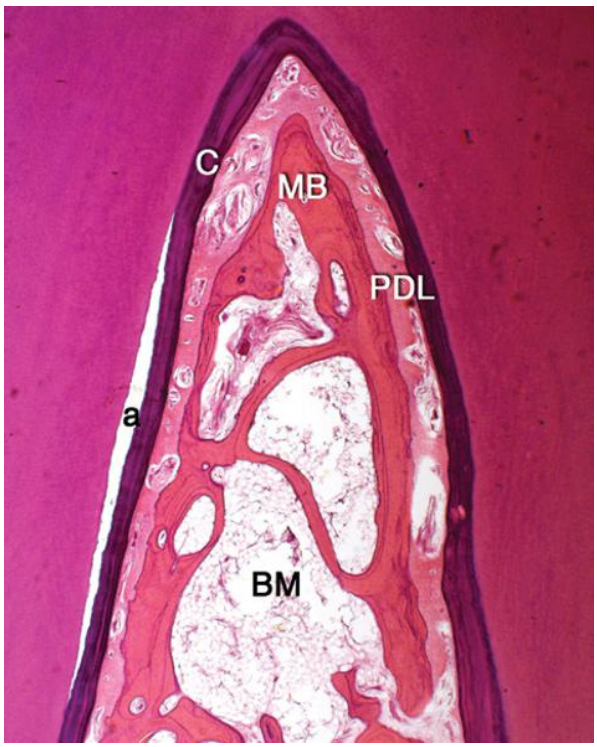

Fig. 1-77

Figure 1-77 The bone tissue within the furcation area of a mandibular molar (C, root cementum; PDL, periodontal ligament; MB, mineralized bone, BM, bone marrow; a, artifact). The mineralized bone in the furcation, as well as in the septum (Fig. 1-76), is made up of lamellar bone (including circumferential lamellae, concentric lamellae osteons, and interstitial lamellae), while the bone marrow contains adipocytes, vascular structures, and undifferentiated mesenchymal cells. Hydroxyapatite is the main mineral of the bone.

Figure 1-78 The mineralized bone facing the periodontal ligament, the alveolar bone proper (ABP) or the bundle bone, is about 250–500 µm wide. The alveolar bone proper is made up of lamellar bone including circumferential lamellae. The location of the alveolar bone proper in this image of a furcation area is indicated by the arrows. The alveolar bone (AB) is a tissue of mesenchymal origin and it is not

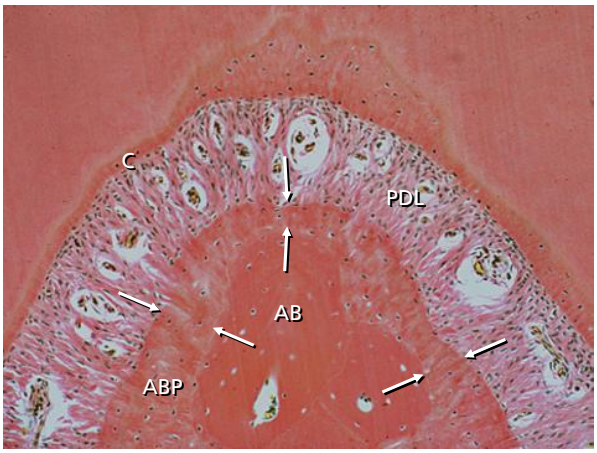

Fig. 1-78

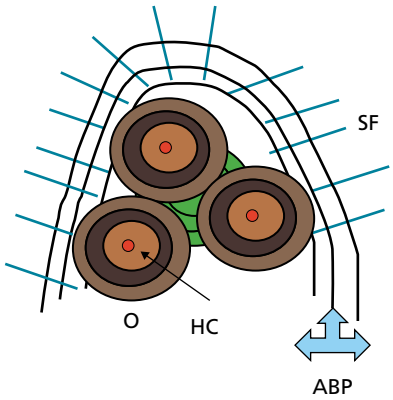

Fig. 1-79

considered as part of the genuine attachment apparatus. As stated above, alveolar bone proper, together with the periodontal ligament (PDL) and the cementum (C), is responsible for the attachment between the tooth and the skeleton. Both alveolar bone and alveolar bone proper may, as a result of altered functional demands, undergo adaptive changes.

Figure 1-79 The schematic drawing illustrates the composition of the hard tissue of the furcation area. The lamellar bone includes three brown osteons (O) with a blood vessel (red) in the centrally located Haversian canal (HC). An interstitial lamella (green) is located between the osteons (O) and represents an old and partly remodeled osteon. The alveolar bone proper (ABP) lines the lamellae and is represented by the dark lines. Sharpey's fibers (SF) insert into the alveolar bone proper.

Figure 1-80 describes a portion of lamellar bone. The hard tissue at this site contains *osteons* (white circles) each of which harbors a blood vessel in the Haversian canal (HC). The space between the different osteons is filled with so-called interstitial lamellae. The osteons are not only structural but also metabolic units. Thus, the nutrition of the bone cells (osteoblasts, osteocytes, osteoclasts) is secured by the blood vessels in the Haversian canals and the vessels in the so-called Volkmann canals.

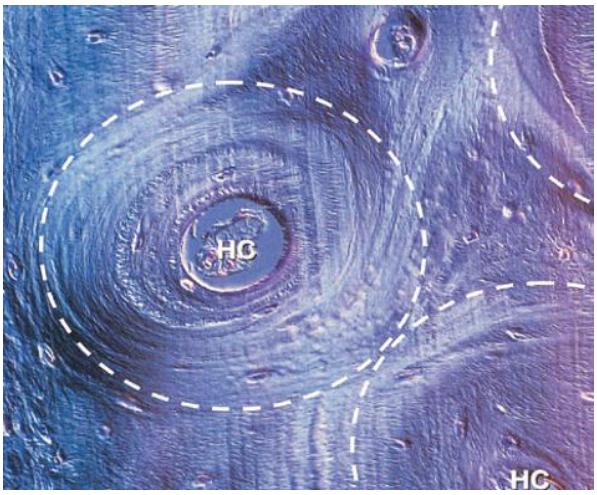

Fig. 1-80

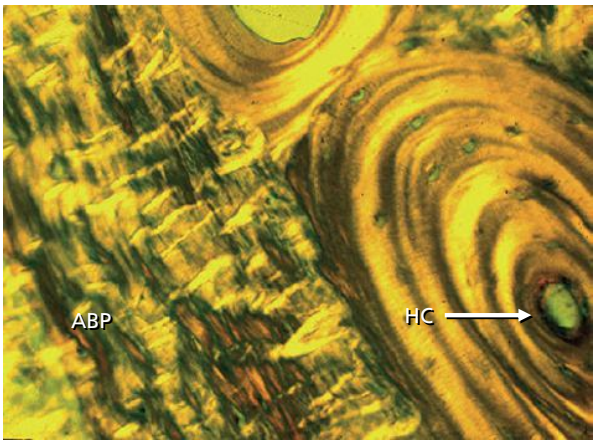

Fig. 1-81

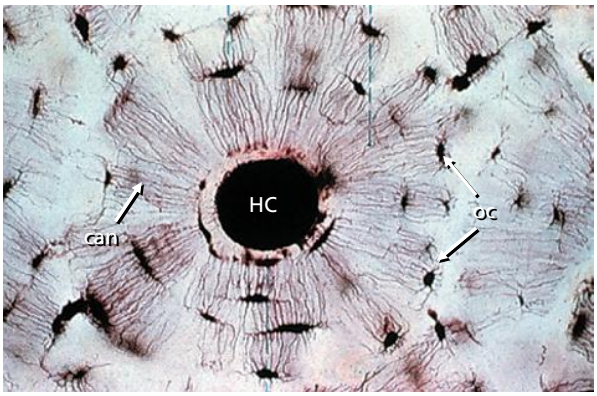

Fig. 1-82

Figure 1-81 The histologic section shows the borderline between the alveolar bone proper (ABP) and the alveolar bone that includes an osteon. The Haversian canal (HC) is in the center of the osteon. The alveolar bone proper (ABP) contains Sharpey's fibers (striations), which in lateral direction (left) extend into the periodontal ligament.

Figure 1-82 The osteon contains a large number of osteocytes (OC) that reside in lacunae within the lamellar bone. The osteocytes connect via canaliculi

(can) that contain cytoplasmic protrusions of the osteocytes. (HC, Haversian canal.)

Figure 1-83 The schematic drawing illustrates how osteocytes (OC) present in the mineralized bone also communicate with osteoblasts on the bone surface through canaliculi.

Figure 1-84 All active bone-forming sites harbor osteoblasts. The outer surface of the bone is lined by a layer of such osteoblasts which, in turn, are organized into a periosteum (P) that also contains densely packed collagen fibers. On the "inner surface" of the bone, that is in the bone marrow space, there is an endosteum (E), which has features similar to those of the periosteum.

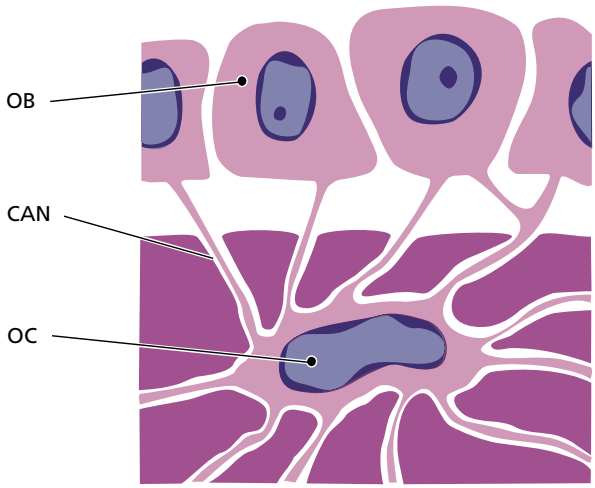

Fig. 1-83

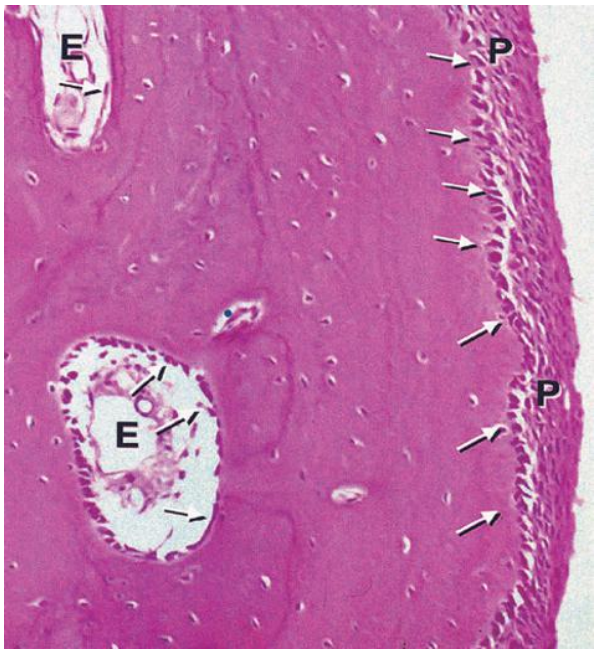

Fig. 1-84

Figure 1-85 shows an osteocyte residing in a lacuna in the bone. It can be seen that cytoplasmic processes radiate in different directions.

Figure 1-86 A schematic drawing showing how the long and delicate cytoplasmic processes of osteocytes (OC) communicate within the canaliculi (CAN) in the bone. The resulting canalicular–lacunar system is essential for cell metabolism by allowing diffusion of nutrients and waste products. The surface between the osteocytes, with their cytoplasmic processes on one side and the mineralized matrix on the other, is very large. It has been calculated that the interface

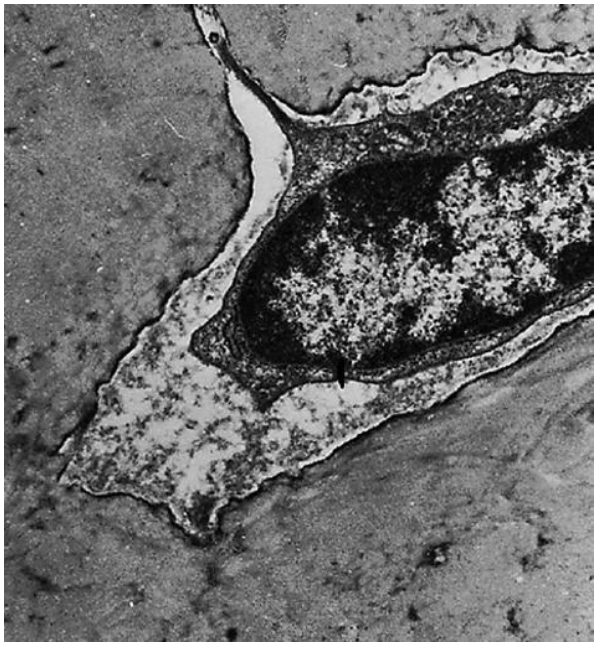

Fig. 1-85

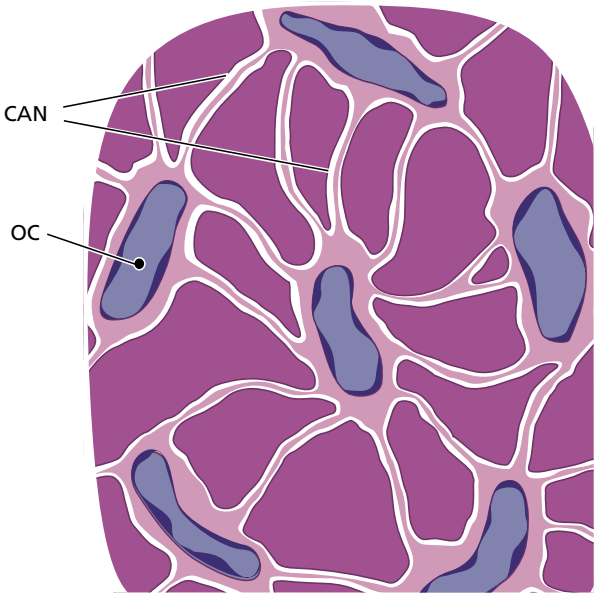

Fig. 1-86

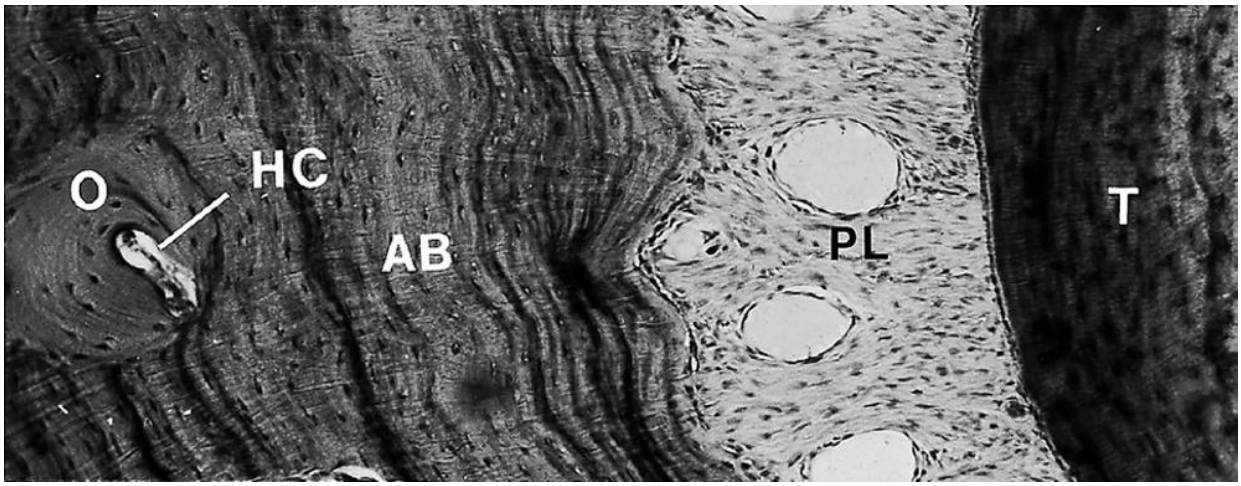

Fig. 1-87

between cells and matrix in a cube of bone, 10 × 10 × 10 cm, amounts to approximately 250 m^2. This enormous surface of exchange serves as a regulator for, for example, serum calcium and serum phosphate levels via hormonal control mechanisms.

Figure 1-87 The alveolar bone is constantly renewed in response to functional demands. The teeth erupt and migrate in a mesial direction throughout life to compensate for attrition. Such movement of the teeth implies remodeling of the alveolar bone. During the process of remodeling, the bone trabeculae are continuously resorbed and reformed, and the cortical bone mass is dissolved and replaced by new bone. During breakdown of the cortical bone, resorption canals are formed by proliferating blood vessels. Such canals, which contain a blood vessel in the center, are subsequently refilled with new bone by the formation of lamellae arranged in concentric layers around the blood vessel. A new Haversian system (O) is seen in the photomicrograph of a horizontal section through the alveolar bone (AB), periodontal ligament (PL), and tooth (T). (HC, Haversian canal.)

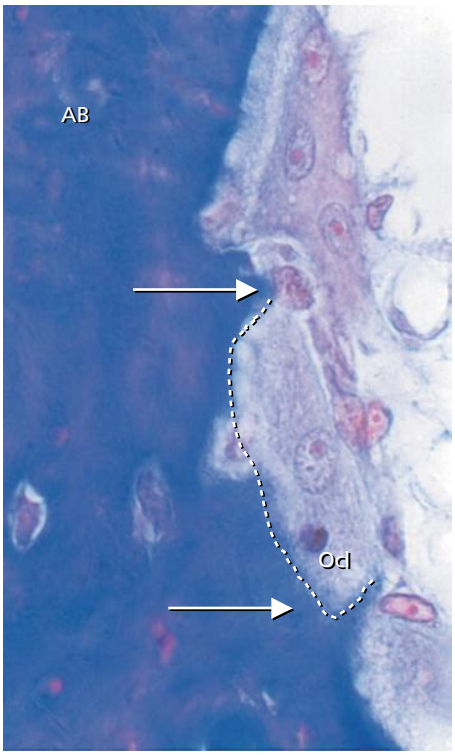

Fig. 1-88

Figure 1-88 The resorption of bone is always associated with *osteoclasts* (Ocl). These cells are large, multinucleated cells specialized in the breakdown of matrix and minerals. The osteoclasts are hematopoetic cells (derived from monocytes in the bone marrow). Hard tissue resorption occurs by the release of acid products (lactic acid, etc.), which form an acidic environment in which the mineral salts become dissolved. Remaining organic substances are eliminated by enzymes and osteoclastic phagocytosis. Actively resorbing osteoclasts adhere to the bone surface through receptors and produce lacunar pits called *Howship's lacunae* (dotted line). The osteoclasts are mobile and capable of migrating over the bone surface. The photomicrograph demonstrates osteoclastic activity (between arrows) at the surface of alveolar bone (AB).

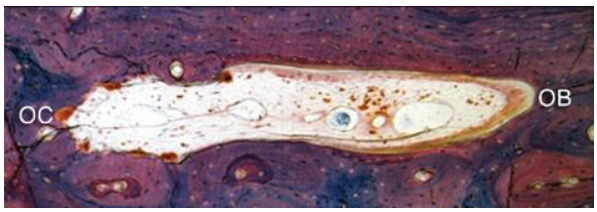

Fig. 1-89

Figure 1-89 Bone multicellular units are always present in bone tissue undergoing active remodeling. The bone multicellular unit has one resorption front (left) characterized by the presence of osteoclasts (OC) and one formation front (right) characterized by the presence of osteoblasts (OB).

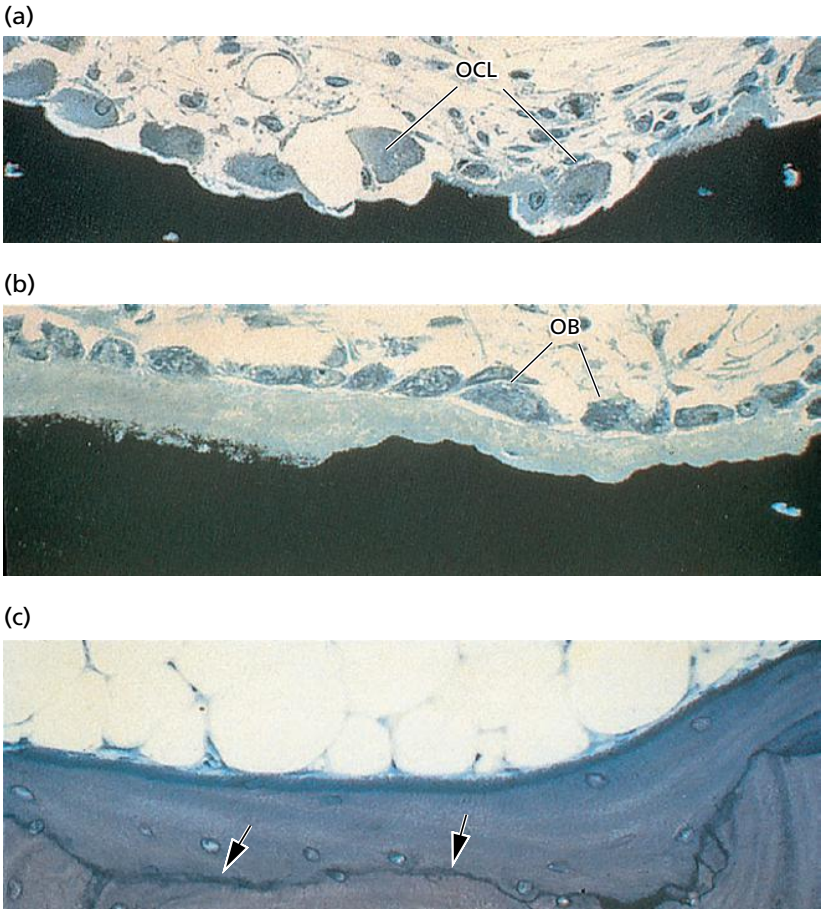

Fig. 1-90

Figure 1-90 Both the cortical and cancellous alveolar bone are constantly undergoing remodeling (i.e. resorption followed by formation) in response to tooth drifting and changes in functional forces acting on the teeth. Remodeling of the trabecular bone starts with resorption of the bone surface by osteoclasts (OCL) (Fig. 1-90a). After a short period, osteoblasts (OB) start depositing new bone (Fig. 1-90b) and finally a new bone multicellular unit is formed, clearly delineated by a reversal line (Fig. 1-90c, arrows).

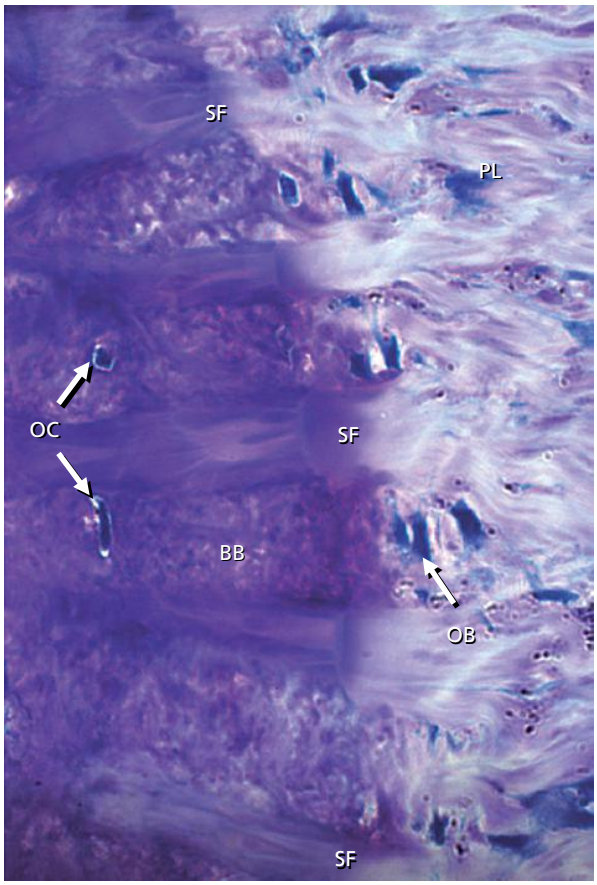

Fig. 1-91

Figure 1-91 Collagen fibers of the periodontal ligament (PL) insert in the mineralized bone which lines the wall of the tooth socket. This bone, called alveolar bone proper or bundle bone (BB), has a high turnover rate. The portions of the collagen fibers which are inserted inside the bundle bone are called Sharpey's fibers (SF). These fibers are mineralized at their periphery, but often have a non-mineralized central core. The collagen fiber bundles inserting in the bundle bone generally have a larger diameter and are less numerous than the corresponding fiber bundles in the cementum on the opposite side of the periodontal ligament. Individual bundles of fibers can be followed all the way from the alveolar bone to the cementum. However, despite being in the same bundle of fibers, the collagen adjacent to the bone is always less mature than that adjacent to the cementum. The collagen on the tooth side has a low turnover rate. Thus, while the

collagen adjacent to the bone is renewed relatively rapidly, the collagen adjacent to the root surface is renewed slowly or not at all. Note the occurrence of osteoblasts (OB) and osteocytes (OC).

Blood supply of the periodontium

Figure 1-92 The schematic drawing depicts the blood supply to the teeth and the periodontal tissues. The *dental artery* (a.d.), which is a branch of the *superior* or *inferior* alveolar artery (a.a.i.), dismisses the *intraseptal artery* (a.i.) before it enters the tooth socket. The terminal branches of the *intraseptal artery* (*rami perforantes*, rr.p.) penetrate the alveolar bone proper in canals at all levels of the socket (see Fig. 1-76). They anastomose in the periodontal ligament space, together with blood vessels originating from the apical portion of the periodontal ligament and with other terminal branches from the intraseptal artery (a.i.). Before the dental artery (a.d.) enters the root canal it puts out branches which supply the apical portion of the periodontal ligament.

Figure 1-93 The gingiva receives its blood supply mainly through *supraperiosteal* blood vessels which are terminal branches of the *sublingual artery* (a.s.), the *mental artery* (a.m.), the *buccal artery* (a.b.), the *facial artery* (a.f.), the *greater palatine artery* (a.p.), the *infra orbital artery* (a.i.), and the *posterior superior dental artery* (a.ap.).

Figure 1-94 depicts the course of the greater palatine artery (a.p.) in a monkey specimen which was perfused with plastic at sacrifice. Subsequently, the soft tissue was dissolved. The greater palatine artery, which is a terminal branch of the *ascending palatine artery* (from the *maxillary*, "internal maxillary", artery), runs through the *greater palatine canal* (arrow) to the palate. As this artery runs in a frontal direction, it puts out branches which supply the gingiva and the masticatory mucosa of the palate.

Figure 1-95 The various arteries are often considered to supply certain well-defined regions of the dentition. In reality, however, there are numerous anastomoses present between the different arteries. Thus, the *entire system of blood vessels*, rather than individual groups of vessels, should be regarded as the unit

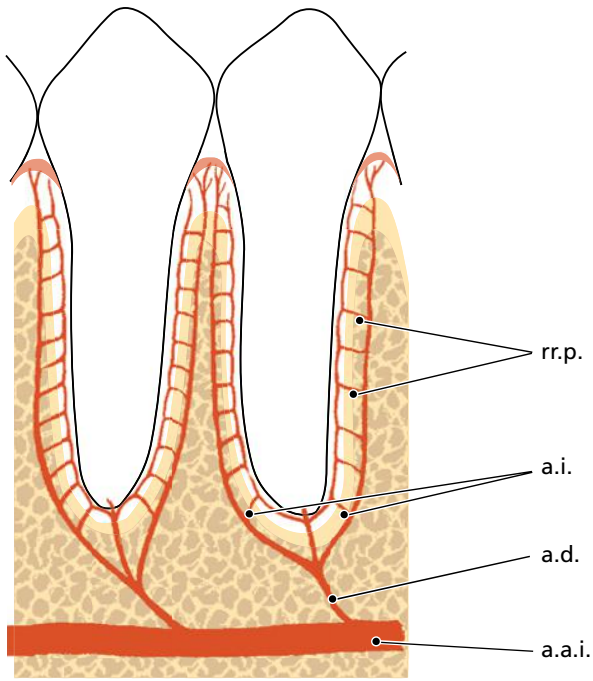

Fig. 1-92

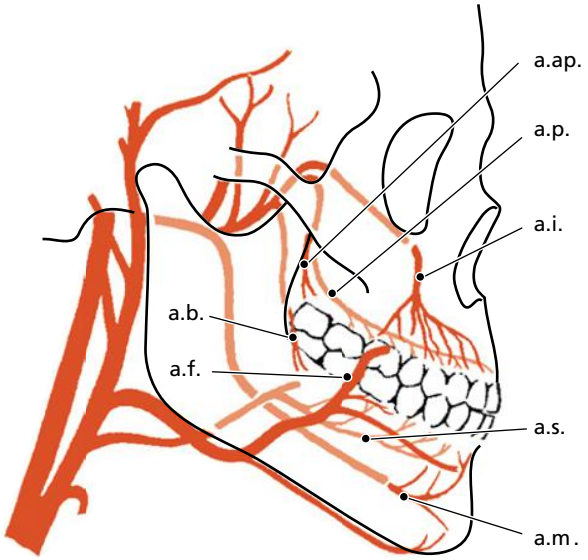

Fig. 1-93

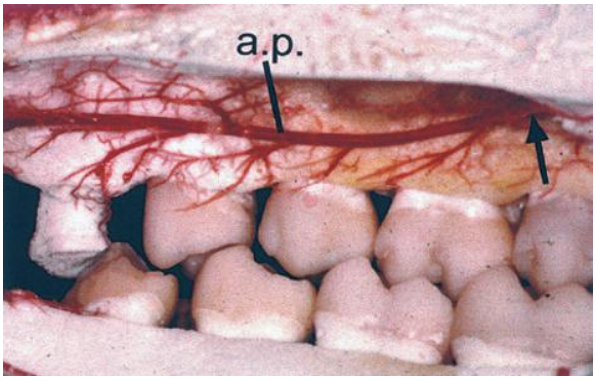

Fig. 1-94

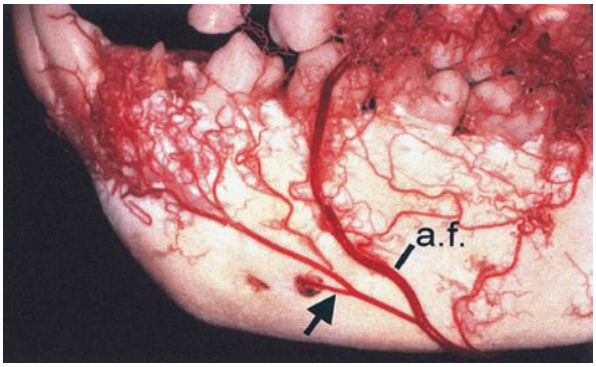

Fig. 1-95

Fig. 1-96

Fig. 1-97

supplying the soft and hard tissue of the maxilla and the mandible, for example in this image there is an anastomosis (arrow) between the *facial artery* (a.f.) and the blood vessels of the mandible.

Figure 1-96 shows a vestibular segment of the maxilla and mandible from a monkey which was perfused with plastic at sacrifice. Note that the blood supply of the vestibular gingiva is mainly through *supraperiosteal* blood vessels (arrows).

Figure 1-97 Blood vessels (arrows) originating from vessels in the periodontal ligament pass the alveolar bone crest and contribute to the blood supply of the free gingiva.

Figure 1-98 shows a specimen from a monkey perfused with ink at the time of sacrifice. Subsequently, the specimen was treated to make the tissue transparent (cleared specimen). To the right, the supraperiosteal blood vessels (sv) can be seen. During their course towards the free gingiva, they put forth numerous branches to the *subepithelial plexus* (sp), located immediately beneath the oral epithelium of the free and attached gingiva. This subepithelial

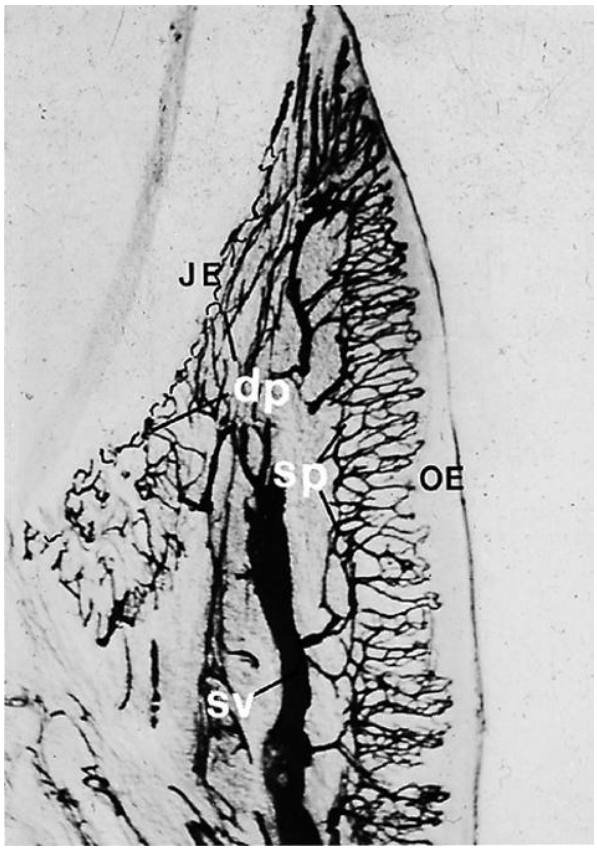

Fig. 1-98

plexus in turn yields thin *capillary loops* to each of the connective tissue papillae projecting into the oral epithelium (OE). The number of such capillary loops is constant over a very long time and is not altered by application of epinephrine or histamine to the gingival margin. This implies that the blood vessels of the lateral portions of the gingiva, even under normal circumstances, are fully utilized and that the blood flow to the free gingiva is regulated entirely by velocity alterations. In the free gingiva, the supraperiosteal blood vessels (sv) anastomose with blood vessels from the periodontal ligament and the bone. Beneath the junctional epithelium (JE), seen to the left, is a plexus of blood vessels termed the *dentogingival plexus* (dp). The blood vessels in this plexus have a thickness of approximately 40 µm, which means that they are mainly venules. In healthy gingiva, no capillary loops occur in the dento-gingival plexus.

Figure 1-99 This specimen illustrates how the subepithelial plexus (s.p.), beneath the oral epithelium of the free and attached gingiva, yields thin capillary loops to each connective tissue papilla. These capillary loops have a diameter of approximately 7 µm, which means they are the size of true capillaries.

Figure 1-100 shows the dentogingival plexus in a section parallel to the subsurface of the junctional epithelium. As can be seen, the dentogingival plexus consists of a fine-meshed network of blood vessels. In the upper portion of the image, capillary loops

Fig. 1-99

Fig. 1-100

belonging to the subepithelial plexus can be seen beneath the oral sulcular epithelium.

Figure 1-101 is a schematic drawing of the blood supply to the free gingiva. As stated earlier, the main blood supply of the free gingiva derives from the *supraperiosteal* blood vessels (SV) which, in the gingiva, anastomose

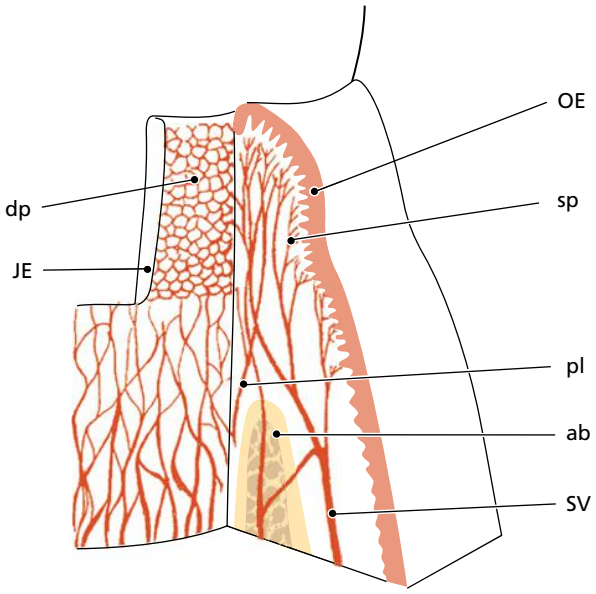

Fig. 1-101

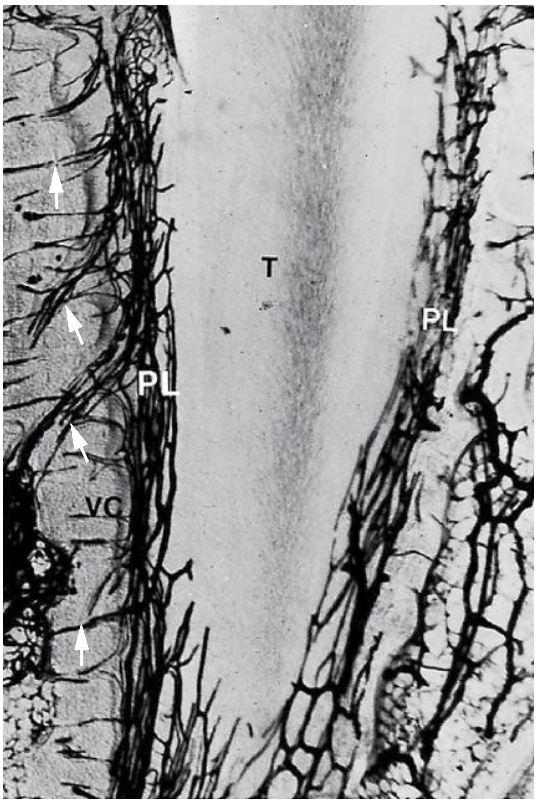

Fig. 1-102

with blood vessels from the *alveolar bone* (ab) and *periodontal ligament* (pl). To the right, the oral epithelium (OE) is depicted with its underlying subepithelial plexus of vessels (sp). To the left beneath the junctional epithelium (JE), the dentogingival plexus (dp) can be seen, which, under normal conditions, comprises a fine-meshed network without capillary loops.

Figure 1-102 shows a section prepared through a tooth (T) with its periodontium. Blood vessels (perforating rami; arrows) arising from the intraseptal

Fig. 1-103

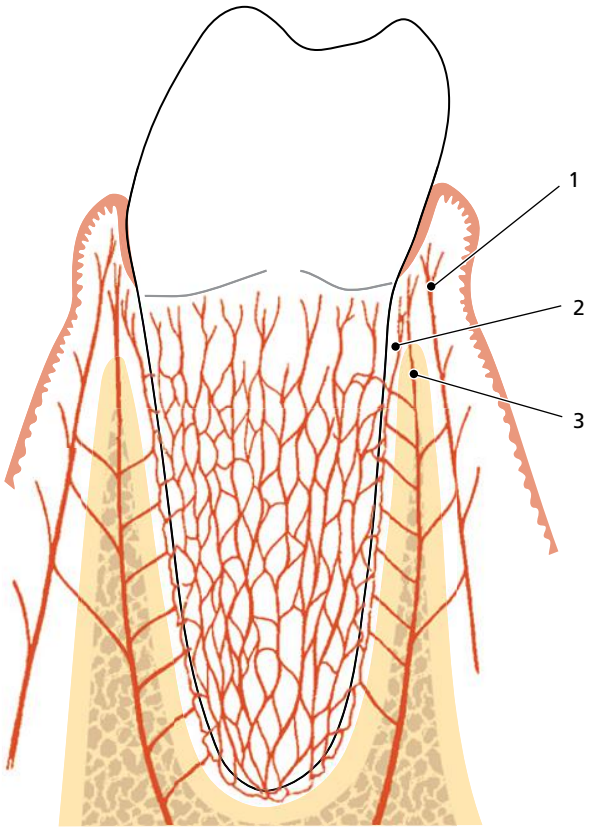

Fig. 1-104

artery in the alveolar bone run through canals (Volkmann's canals) in the socket wall (VC) into the periodontal ligament (PL), where they anastomose.

Figure 1-103 shows blood vessels in the periodontal ligament in a section parallel to the root surface. After entering the periodontal ligament, the blood vessels (perforating rami; arrows) anastomose and form a polyhedral network which surrounds the root like a stocking. The majority of the blood vessels in the periodontal ligament are found close to the alveolar bone. In the coronal portion of the periodontal ligament, blood vessels run in a coronal direction, passing the alveolar bone crest, into the free gingiva (see Fig. 1-97).

Figure 1-104 is a schematic drawing of the blood supply of the periodontium. The blood vessels in the periodontal ligament form a polyhedral network surrounding the root. Note that the free gingiva receives its blood supply from (1) supraperiosteal blood vessels, (2) the blood vessels of the periodontal ligament, and (3) the blood vessels of the alveolar bone.

Figure 1-105 illustrates schematically the so-called *extravascular* circulation through which nutrients and other substances are carried to the individual cells and metabolic waste products are removed from the

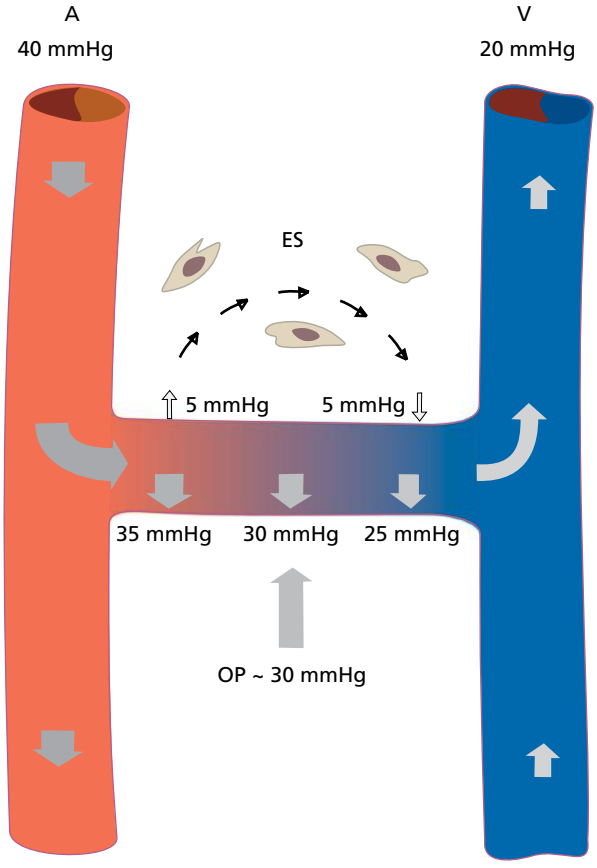

Fig. 1-105

tissue. In the arterial (A) end of the capillary, on the left, a hydraulic pressure of approximately 35 mmHg is maintained as a result of the pumping function of the heart. Since the hydraulic pressure is higher than the osmotic pressure (OP) in the tissue (approximately 30 mmHg), transportation of substances will occur from the blood vessels to the extravascular space (ES). In the venous (V) end of the capillary system, on the right, the hydraulic pressure has decreased to approximately 25 mmHg (i.e. 5 mmHg lower than the osmotic pressure in the tissue). This allows transportation of substances from the extravascular space to the blood vessels. Thus, the difference between the hydraulic pressure and the osmotic pressure results in transportation of substances from the blood vessels to the extravascular space in the arterial part of the capillary, while in the venous part, transportation of substances occurs from the extravascular space to the blood vessels. An extravascular circulation is hereby established (small arrows).

Lymphatic system of the periodontium

Figure 1-106 The smallest lymph vessels, the *lymph capillaries*, form an extensive network in the connective tissue. The wall of the lymph capillary consists of a single layer of endothelial cells. For this reason such capillaries are difficult to identify in an ordinary histologic section. The lymph is absorbed from the tissue fluid through the thin walls into the lymph capillaries. From the capillaries, the lymph passes into larger lymph vessels which are often in the vicinity of corresponding blood vessels. Before the lymph enters the blood stream, it passes through one or more *lymph nodes* in which the lymph is filtered and supplied with lymphocytes. The lymph vessels are like veins in that they have valves. The lymph from the periodontal tissues drains to the lymph nodes of the head and neck. The labial and lingual gingiva of the mandibular incisor region is drained to the *submental lymph nodes* (sme). The palatal gingiva of the maxilla is drained to the *deep cervical lymph nodes* (cp). The buccal gingiva of the maxilla and the buccal and lingual gingiva in the mandibular premolar–molar region are drained to *submandibular lymph nodes* (sma). Except for the third molars and mandibular incisors, all teeth with their adjacent periodontal tissues are drained to the submandibular lymph nodes. The third molars are drained to the *jugulodigastric lymph node* (jd) and the mandibular incisors to the *submental lymph nodes*.

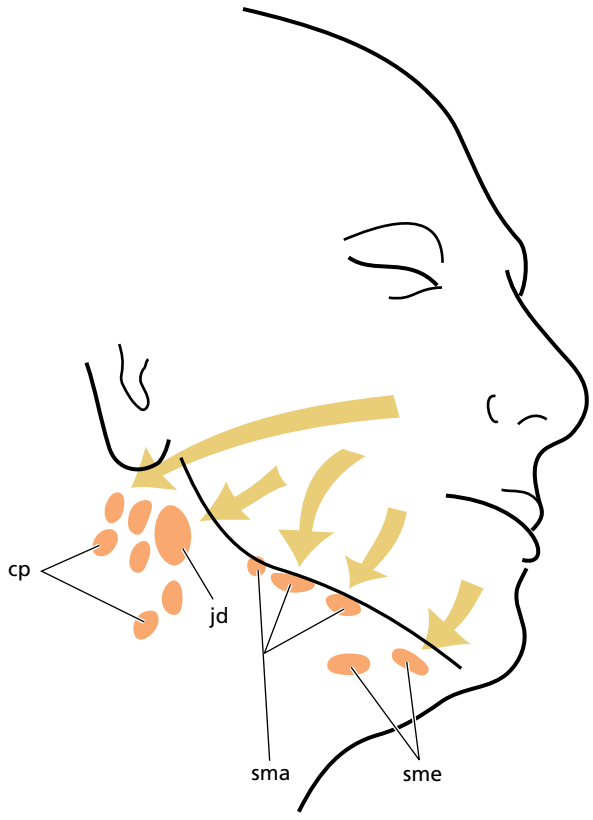

Fig. 1-106

Nerves of the periodontium

Like other tissues in the body, the periodontium contains receptors which record pain, touch, and pressure (*nociceptors* and *mechanoreceptors*). In addition to the different types of sensory receptors, nerve components are found innervating the blood vessels of the periodontium. Nerves recording pain, touch, and pressure have their trophic center in the *semilunar ganglion* and are brought to the periodontium via the *trigeminal nerve* and its end branches. Owing to the presence of receptors in the periodontal ligament, small forces applied on the teeth may be identified. For example, the presence of a very thin (10–30 µm) metal foil strip placed between the teeth during occlusion can readily be identified. It is also well known that a movement which brings the teeth of the mandible in contact with the occlusal surfaces of the maxillary teeth is arrested reflexively and altered into an opening movement if a hard object is detected in the chew. Thus, the receptors in the periodontal ligament, together with the proprioceptors in muscles and tendons, play an essential role in the regulation of chewing movements and chewing forces.

Figure 1-107 shows the various regions of the gingiva which are innervated by end branches of the trigeminal nerve. The gingiva on the labial aspect of maxillary incisors, canines, and premolars is innervated by *superior labial branches* from the *infraorbital nerve* (n. infraorbitalis) (Fig. 1-107a). The buccal gingiva in the maxillary molar region is innervated by branches from the *posterior superior dental nerve* (rr. alv. sup. post) (Fig. 1-107a). The palatal gingiva is innervated by the *greater palatal nerve* (n. palatinus major) (Fig. 1-107b), except for the area of the incisors, which is innervated by the *long sphenopalatine nerve* (n. pterygopalatini). The lingual gingiva in the

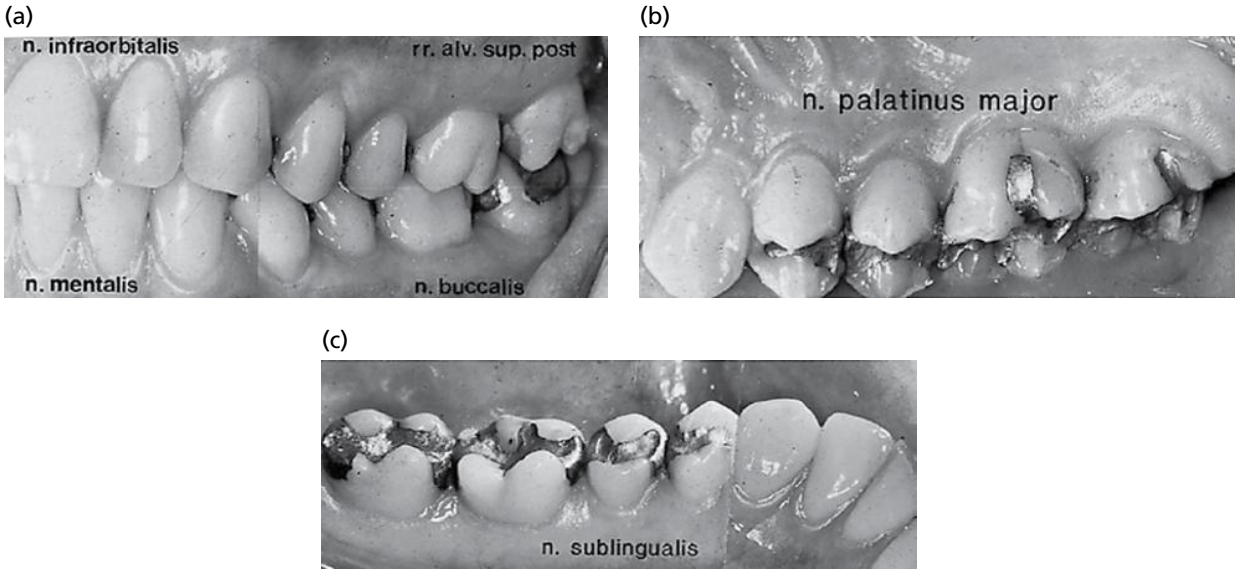

Fig. 1-107

Fig. 1-108

mandible is innervated by the *sublingual nerve* (n. sublingualis) (Fig. 1-107c), which is an end branch of the *lingual nerve*. The gingiva at the labial aspect of mandibular incisors and canines is innervated by the *mental nerve* (n. mentalis), and the gingiva at the buccal aspect of the molars by the *buccal nerve* (n. buccalis) (Fig. 1-107a). The innervation areas of these two nerves frequently overlap in the premolar region. The teeth in the mandible, including their periodontal ligament, are innervated by the *inferior alveolar nerve* (n. alveolaris inf.), while the teeth in the maxilla are innervated by the *superior alveolar plexus* (n. alveolares sup).

Figure 1-108 The small nerves of the periodontium follow almost the same course as the blood vessels. The nerves to the gingiva run in the tissue superficial to the periosteum and put out several branches to the oral epithelium on their way towards the free gingiva. The nerves enter the periodontal ligament through the perforations (Volkmann's canals) in the socket wall (see Fig. 1-102). In the periodontal ligament, the nerves join larger bundles which take a course parallel to the long axis of the tooth. The photomicrograph shows small nerves (arrows) which have emerged from larger bundles of ascending nerves in order to supply certain parts of the periodontal ligament tissue. Various types of neural terminations, such as free nerve endings and Ruffini's corpuscles, have been identified in the periodontal ligament.

Chapter 2

Bone as a Living Organ

Hector F. Rios,[1] Jill D. Bashutski,[2] and William V. Giannobile[1,2]

[1]Department of Periodontology and Oral Medicine, University of Michigan, School of Dentistry, Ann Arbor, MI, USA
[2]Department of Biomedical Engineering, College of Engineering, Ann Arbor, MI, USA

Introduction

Bone is a complex organ composed of multiple specialized tissues (osseous, periosteum/endosteum, and bone marrow) that act synergistically and serve multiple functions (Fig. 2-1). Its composition allows the bone tissue to: (1) resist load, (2) protect highly sensitive organs from external forces, and (3) participate as a reservoir of cells and minerals that contribute to systemic homeostasis of the body. Therefore, the concept of "bone as a living organ" integrates the structurally dynamic nature of bone with its capacity to orchestrate multiple mechanical and metabolic functions with important local and systemic implications. Multiple factors exert an effect in this system (e.g. biochemical, hormonal, cellular, biomechanical) and will collectively determine its quality (Ammann & Rizzoli 2003; Marotti & Palumbo 2007; Bonewald & Johnson 2008; Ma *et al.* 2008). The purpose of this chapter is to provide the foundation knowledge of bone development, structure, function, healing, and homeostasis.

Development

During embryogenesis, the skeleton forms by either a direct or indirect ossification process. In the case of the mandible, maxilla, skull, and clavicle, mesenchymal progenitor cells condensate and undergo direct differentiation into osteoblasts, a process known as *intramembranous osteogenesis.*

In contrast, in the mandibular condyle, the long bones and vertebrae form initially through a cartilage template, which serves as an anlage that is gradually replaced by bone. The cartilage-dependent bone formation and growth process is known as *endochondral osteogenesis* (Ranly 2000) (Fig. 2-2).

Intramembranous bone formation

During intramembranous osteogenesis, an ossification center develops through mesenchymal condensation. As the collagen-rich extracellular matrix develops and matures, osteoprogenitor cells undergo further osteoblastic differentiation. On the outer surfaces of the ossification center, a fibrous periosteum forms over a layer of osteoblasts. As new osteoblasts form from the underside of the periosteum, appositional growth occurs. A subpopulation of osteoblasts becomes embedded in the mineralizing matrix and gives rise to the osteocyte lacunocanalicular network. Within the craniofacial complex, most bones develop and grow through this mechanism.

Endochondral bone growth

During endochondral osteogenesis, bones develop through the formation of a cartilaginous template (hyaline cartilage model) that mineralizes and is later

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

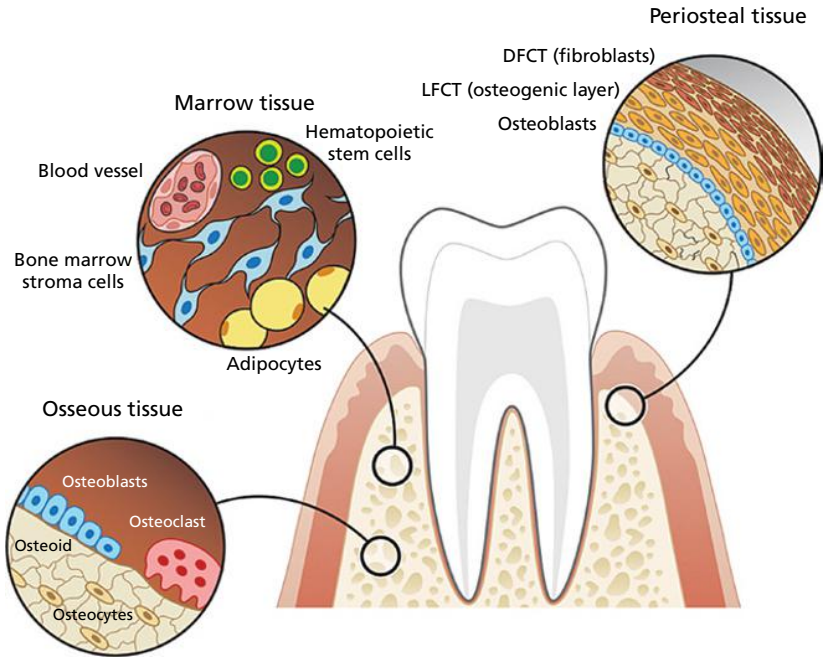

Fig. 2-1 Bone as an organ. The bone organ encompasses a number of complex tissues that synergize during health to execute a number of functions. It serves as a source of stem cells and a reservoir of minerals and other nutrients; it protects a number of delicate organs; and it acts as a mechanosensoring unit that adapts to the environment and individual demands. This figure highlights three main tissues, the cells that are involved in these roles, and the maintenance of the structure and function of bone as an organ. (DFCT, dense fibrous connective tissue; LFCT, loose fibrous connective tissue.)

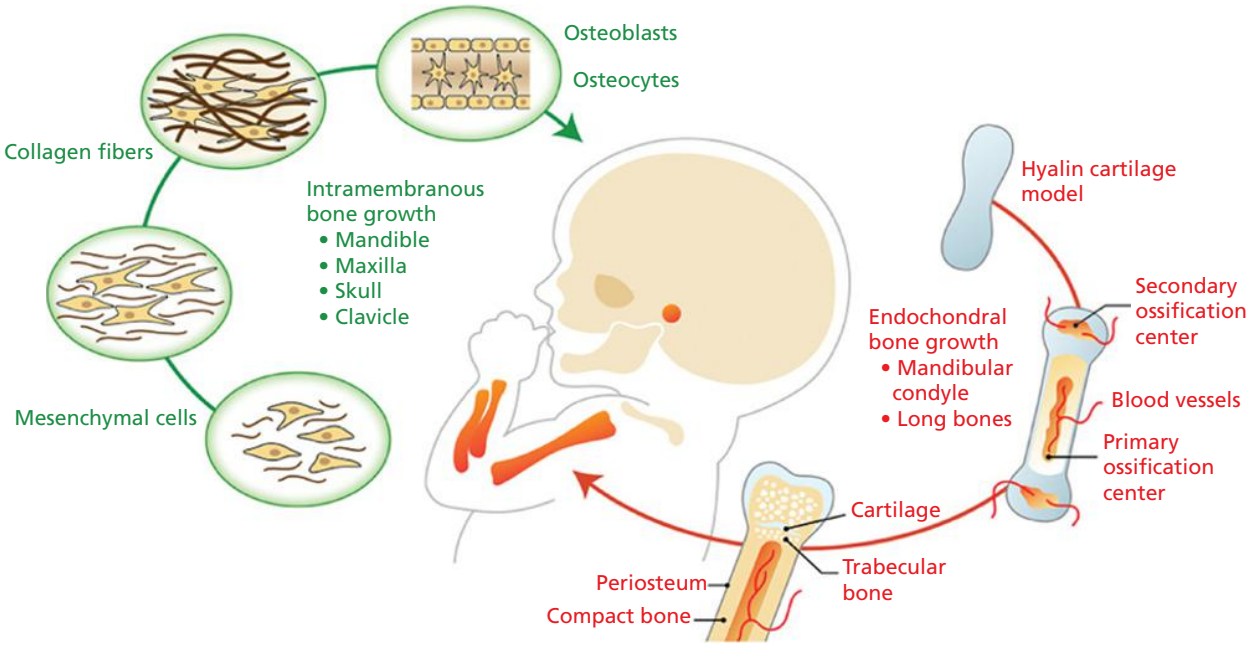

Fig. 2-2 Bone development. There are two types of processes involved in bone development: Intramembranous ossification (green arrow) and endochondral ossification (orange arrow). They primarily differ in the presence of a cartilaginous template during endochondral bone growth. During intramembranous osteogenesis, an ossification center develops through mesenchymal condensation. As the collagen-rich extracellular matrix develops and matures, osteoprogenitor cells undergo further osteoblastic differentiation. A subpopulation of osteoblasts becomes embedded in the mineralizing matrix and gives rise to the osteocyte lacunocanalicular network. Within the craniofacial complex, most bones develop and grow through this mechanism. On the other hand, long bones within the skeleton and the mandibular condyle initially develop through the formation of a cartilaginous template that mineralizes and is later resorbed by osteoclasts and replaced by bone. The endochondral bone growth process leads to the formation of primary and secondary ossification centers that are separated by a cartilaginous structure known as the growth plate. As bone develops and matures through these two processes, structurally distinct areas of compact bone and trabecular bone are formed and maintained through similar bone remodeling mechanisms.

resorbed by osteoclasts and replaced by bone that is laid down afterwards. This process begins during the third month of gestation. The endochondral bone growth process leads to the formation of primary and secondary ossification centers that are separated by a cartilaginous structure known as the growth plate. Following the formation of the primary ossification center, bone formation extends towards both ends of the bone from the center of the shaft. The cartilage cells on the leading edges of ossification die. Osteoblasts cover the cartilagenous trabeculae with woven, spongy bone. Behind the advancing front of ossification, osteoclasts absorb the spongy bone and enlarge the primary marrow cavity. The periosteal collar thickens and extends toward the epiphyses to compensate for the continued hollowing of the primary cavity.

The processes of osteogenesis and resorption occur in all directions. The spaces between the trabeculae become filled with marrow tissue. As the new bone matrix remodels, osteoclasts assist in the formation of primary medullary cavities which rapidly fill with bone marrow hematopoietic tissue. The fibrous, non-mineralized lining of the medullary cavity is the endosteum. Osteoblasts form in the endosteum and begin the formation of endosteal bone. The appositional growth of endosteal bone is closely regulated to prevent closure of the primary marrow cavities and destruction of bone marrow.

Structure

Osseous tissue

Osseous tissue is a specialized connective tissue composed of organic and inorganic elements that mineralizes and is populated by highly specialized cells that regulate its stability (Fig. 2-3a).

Matrix

The organic matrix of bone makes up approximately 30–35% of the total bone weight and is formed of 90% collagen type I and 10% non-collagenous proteins, proteoglycans, glycoproteins, carbohydrates,

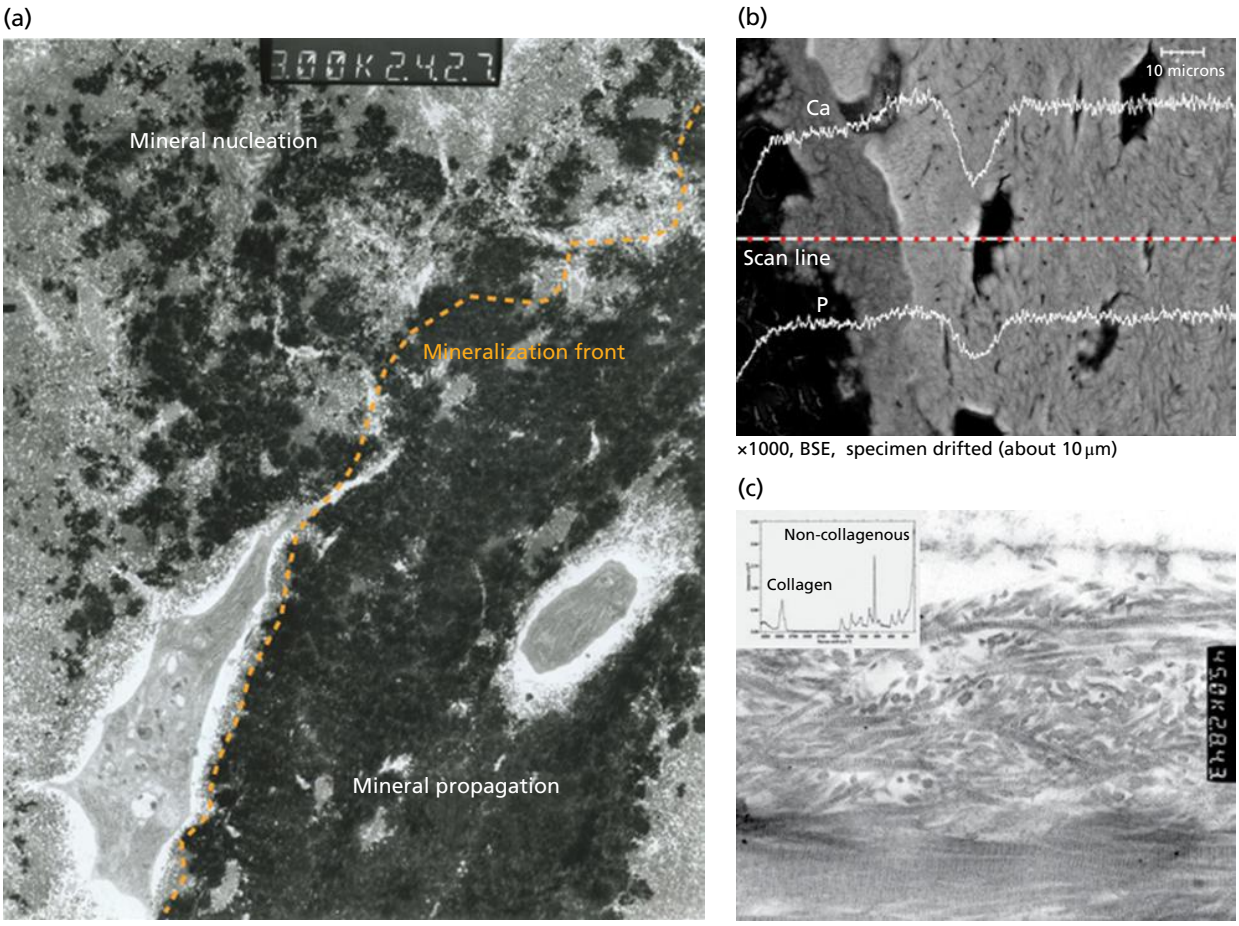

Fig. 2-3 Osseous matrix. The extracellular matrix in bone is particularly abundant as compared to its cellular counterpart. (a) Osseous matrix has the unique ability to mineralize: a process that requires the support of organic components and the assistance of highly specialized cells. (b) Calcium and phosphorus are present in the form of hydroxyapatite crystals. These crystals tend to follow the organic scaffold in the bone matrix. The orange dashed line represents a linear scan that emphasizes the high content of calcium and phosphorus in the mature bone, as shown by the energy dispersive X-ray spectroscopy analysis. (c) Collagen fibers as well as non-collangenous proteins are abundant in the matrix and are often found to be arranged in a preferential direction, as shown by the Raman spectroscopy.

and lipids. The organic matrix is synthesized by osteoblasts, and while it is still unmineralized, is known as osteoid. Within the collagen fibers, mineral nucleation occurs as calcium and phosphate ions are laid down and ultimately form hydroxyapatite crystals. Non-collagenous proteins along the surface of the collagen fibers assist in the propagation of the mineral and the complete mineralization of the matrix.

Inorganic components

Hydrated calcium and phosphate in the form of hydroxyapatite crystals [$3Ca_3(PO_4)_2(OH)_2$] are the principal inorganic constituent of the osseous matrix. Mineralization is clearly depicted in backscatter scanning electron imagines as a bright signal (Fig. 2-3b). Different degrees of mineralization are noticeable within the mature bone. Specific elements within the mineral can be further identified by energy-dispersive X-ray spectroscopy (EDS). In Fig. 2-3b, characteristic peaks of calcium and phosphorus are significantly pronounced in bone, as expected from their high content within the hydroxyapatite crystals.

Organic components

Bone is initially laid down as a purely organic matrix rich in collagen as well as in other non-collagenous molecules (Fig. 2-3c). Chemical analysis of bone by Raman spectroscopy clearly highlights this organic counterpart in the matrix. The transition from a purely organic matrix to a mineralized matrix is clearly depicted in the transmission electron micrograph in Fig. 2-3a as an osteocyte becomes embedded within the mineralized mature matrix. As the matrix matures, mineral nucleation and propagation is mediated by the organic components in the extracellular matrix. Figure 2-3a shows the aggregation of mineral crystals, forming circular structures. As the mineral propagates along the collagen fibrils, a clear mineralization front forms and clearly demarcates the transition between the osteoid area and the mature bone.

Mineralization

The initiation of the mineral nucleation within osteoid typically occurs within a few days of the laying down of calcium and phosphate ions, but maturation is completed through the propagation of the hydroxyapatite crystals over several months and as new matrix is synthesized (Fig. 2-3a). In addition to providing the bone with its strength and rigidity to resist load and protect highly sensitive organs, the mineralization of the osteoid allows the storage of minerals that contribute to systemic homeostasis.

Cells

Within bone, different cellular components can be identified. The distinct cell populations include osteogenic precursor cells, osteoblasts, osteoclasts, osteocytes, and hematopoietic elements of bone marrow. This chapter will focus on the three main functional cells that are ultimately responsible for the proper skeletal homeostasis.

Osteoblasts (Fig. 2-4)

Osteoblasts are the primary cells responsible for the formation of bone; they synthesize the organic extracellular matrix (ECM) components and control the mineralization of the matrix (Fig. 2-4a, b). Osteoblasts are located on bone surfaces exhibiting active matrix deposition and may eventually differentiate into two different types of cells: bone lining cells and osteocytes. Bone lining cells are elongated cells that cover a surface of bone tissue and exhibit no synthetic activity. The osteoblasts are fully differentiated cells and lack the capacity for migration and proliferation. Thus, for bone formation at a given site, undifferentiated mesenchymal progenitor cells, driven by the expression of a gene known as Indian hedgehog (*Ihh*) and later by *RUNX2*, and osteoprogenitor cells migrate to the site and proliferate to become osteoblasts (Fig. 2-4c). The determined osteoprogenitor cells are present in the bone marrow, in the endosteum, and in the periosteum that covers the bone surface. Such cells possess an intrinsic capacity to proliferate and differentiate into osteoblasts. The differentiation and development of osteoblasts from osteoprogenitor cells are dependent on the release of osteoinductive or osteopromotive growth factors (GFs), such as bone morphogenetic proteins (BMPs), and other growth factors, such as insulin-like growth factor (IGF), platelet-derived growth factor (PDGF), and fibroblast growth factor (FGF).

Osteocytes (Fig. 2-5)

Osteocytes are stellate-shaped cells that are embedded within the mineralized bone matrix in spaces known as lacunae (Fig. 2-5a, b). They maintain a network of cytoplasmic processes known as dendrites (Fig. 2-5c). These osteocyte cytoplasmic projections extend through cylindrical encased compartments commonly referred to as canaliculi (Bonewald 2007). They extend to different areas and contact blood vessels and other osteocytes (Fig. 2-5d, e). The osteocyte network is therefore an extracellular and intracellular communication channel that is sensitive at the membrane level to shear stress caused by the flow of fluid within the canaliculi space as the result of mechanical stimuli and bone deformation. Osteocytes translate mechanical signals into biochemical mediators that will assist with the orchestration of anabolic and catabolic events within bone. This arrangement allows osteocytes to (1) participate in the regulation of blood calcium homeostasis and (2) sense mechanical loading and transmit this information to other cells within the bone to further orchestrate osteoblast and osteoclast function (Burger *et al*. 1995; Marotti 2000). Different bone diseases and disorders affect the arrangement of the osteocyte lacunocanalicular system, causing significant alteration to this important cellular network (Fig. 2-6).

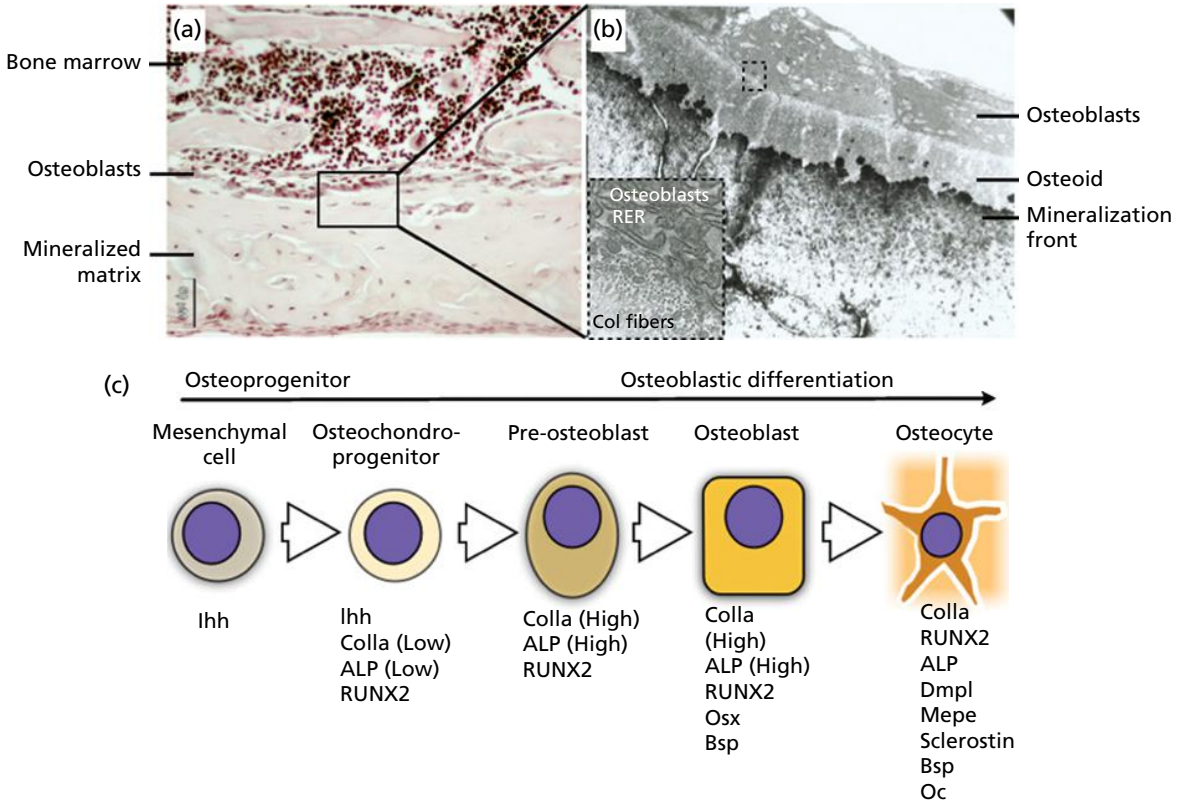

Fig. 2-4 Osteoblast. Osteoblasts are derived from bone marrow osteoprogenitor cells and are responsible for the synthesis of the immature bone matrix known as osteoid. (a) Group of osteoblasts that line the mature bone that contains cells embedded within the mineralized matrix. (b) Further detail of the osteoblasts lining the mature bone is clearly visualized with transmission electron microscopy (TEM). The abundant rough endoplasmic reticulum (RER) and Golgi apparatus within these cells reflect their high metabolic activity. (c) The key molecules involved in the differentiation of an osteoprogenitor cell through to a mature terminally differentiated osteocyte.

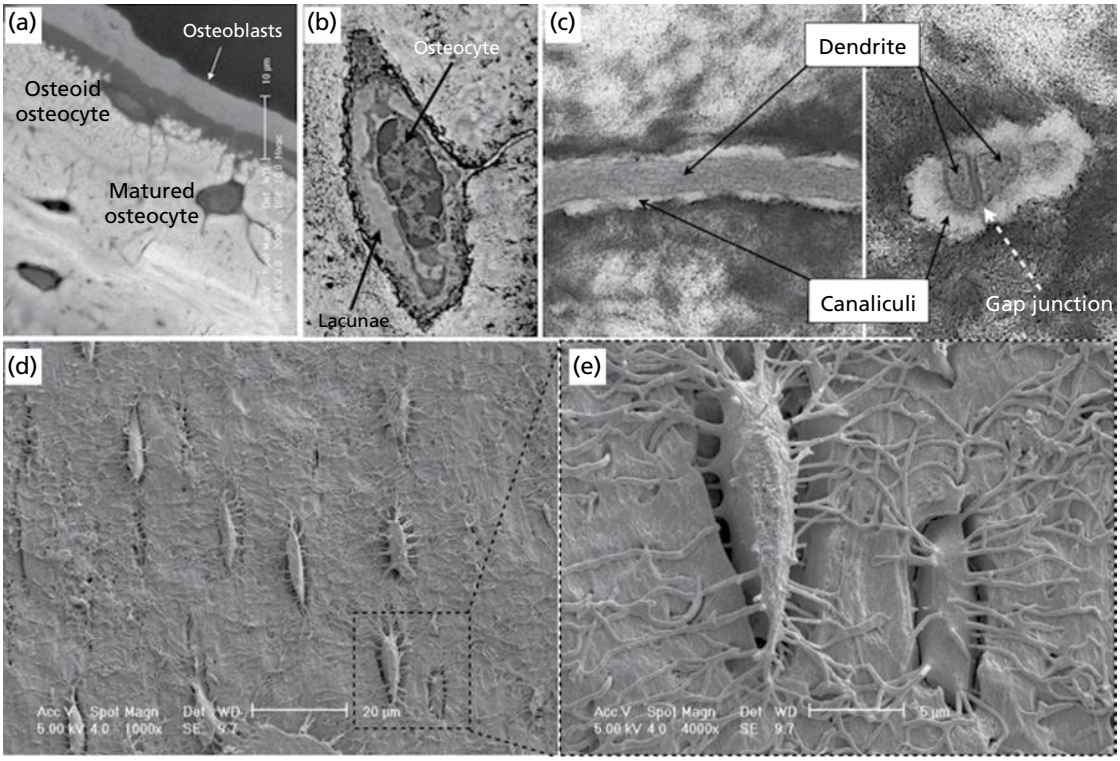

Fig. 2-5 Osteocytes. The osteocyte can be defined as the orchestrator of the remodeling process within bone. (a) As bone matrix is synthesized, a number of osteoblasts become embedded within the osteoid, which later mineralizes and resides in the mature matrix as osteocytes, as shown in this backscatter scanning electron micrograph (SEM) treated with osmium to allow the visualization of the cell. (b) Osteocytes reside within a well-defined space in bone known as the osteocyte lacuna. (c) Transmission electron micrograph of a dendrite within a canaliculi, showing the space through which fluid flows; the shear stress from this stimulates the surface of the osteocyte cell membrane. This unique biologic architectural characteristic of the osteocyte and the lacunocanalicular network represent the foundation that allows the conversion of mechanical stimuli into the biochemical signals necessary for bone homeostasis. (d and e) SEM of a casted lacunocanalicular network allows the visualization of the degree of connectivity between osteocytes and the regularly arranged canalicular structures.

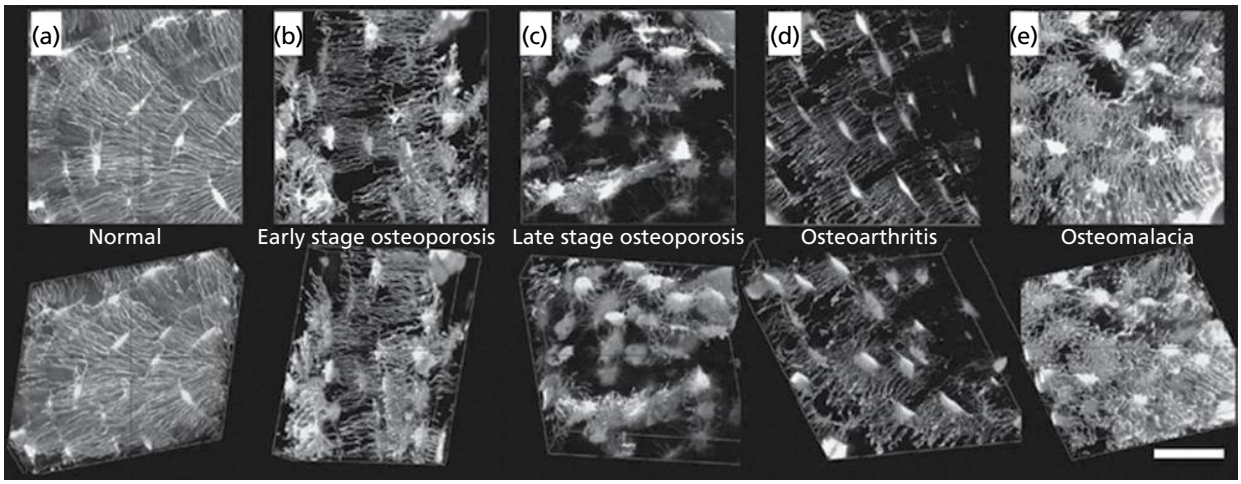

Fig. 2-6 Osteocytes: Lacunocanalicular system in disease. (a) In healthy bone, a high density osteocyte system is established throughout the mature matrix and is characterized by high cellular interconnectivity. With disease, the system is significantly disrupted, leading to important functional alterations. (b, c) In osteoporosis, osteocytic density changes and an apparent decrease in cellular interconnectivity is observed. (d) In osteoarthritis, the canalicular system is altered, but with no major lacunar changes. (e) In osteomalacia, the entire osteocyte lacunocanalicular system appears disrupted due to the altered mineralization pattern. (Source: Knothe Tate *et al*. 2004. Reproduced with permission from Elsevier.)

Osteoclasts

The bone formation activity is consistently coupled to bone resorption that is initiated and maintained by osteoclasts. These cells have the capacity to develop and adhere to bone matrix and then to secrete acid and lytic enzymes that degrade and break down the mineral and organic components of bone and calcified cartilage (Fig. 2-7a–c). The matrix degradation process results in the formation of a specialized extracellular compartment known as *Howship's lacuna* (Rodan 1992; Vaananen & Laitala-Leinonen 2008). Osteoclasts are specialized multinucleated cells that originate from the monocyte/macrophage hematopoietic lineage. The differentiation process is driven initially by the expression of the transcription factor PU-1. Macrophage colony-stimulating factor (M-CSF) engages osteoclasts in the differentiation pathway and promotes their proliferation and expression of RANKL. At this stage, RANKL-expressing stromal cells interact with preosteoclasts and further commit them to differentiation along the osteoclast lineage (Figs. 2-7d, 2-8).

Periosteal tissue

The periosteum is a fibrous sheath that lines the outer surface a long bone's shaft (diaphysis), but not the articulating surfaces. Endosteum lines the inner surface of all bones. The periosteum consists of dense irregular connective tissue. The periosteum is divided into a dense, fibrous, vascular layer (the "fibrous layer") and an inner, more loosely arranged, connective tissue inner layer (the "osteogenic layer") (see Fig. 2-1). The fibrous layer is mainly formed of fibroblasts, while the inner layer contains osteoprogenitor cells.

Osteoblasts derived from the "osteogenic layer" are responsible for increasing the width of long bones and the overall size of the other bone types. In the context of a fracture, progenitor cells from the periosteum differentiate into osteoblasts and chondroblasts, which are essential in the process of stabilizing the wound.

In contrast to the osseous tissue, the periosteum has nociceptive nerve endings, making it very sensitive to manipulation. It also allows the passage of lymphatics and blood vessels into and out of bone, providing nourishment. The periosteum anchors tendons and ligaments to bone by strong collagenous fibers in the "osteogenic layer", called Sharpey's fibers, which extend to the outer circumferential and interstitial lamellae. It also provides an attachment for muscles and tendons.

Bone marrow

The bone marrow consists of hematopoietic tissue islands, stromal cells, and adipose cells surrounded by vascular sinuses interspersed within a meshwork of trabecular bone (see Fig. 2-1). The bone marrow is the major hematopoietic organ, a primary lymphoid tissue (responsible for the production of erythrocytes, granulocytes, monocytes, lymphocytes, and platelets) and an important source of stem cells.

Types

There are two types of bone marrow: red marrow, which consists mainly of hematopoetic tissue, and yellow marrow, which is mainly made up of adipocytes. Erythrocytes, leukocytes, and platelets arise in red marrow. Both types of bone marrow contain numerous blood vessels and capillaries. At birth, all bone marrow is red. With age, more and more of it is converted to the yellow type; only around half of adult bone marrow is red. In cases of severe blood loss, the body can convert yellow marrow back to red marrow to increase blood cell production.

Cells

The stroma of the bone marrow is not directly involved in the primary function of hematopoiesis. However, it serves an indirect role by indirectly providing the

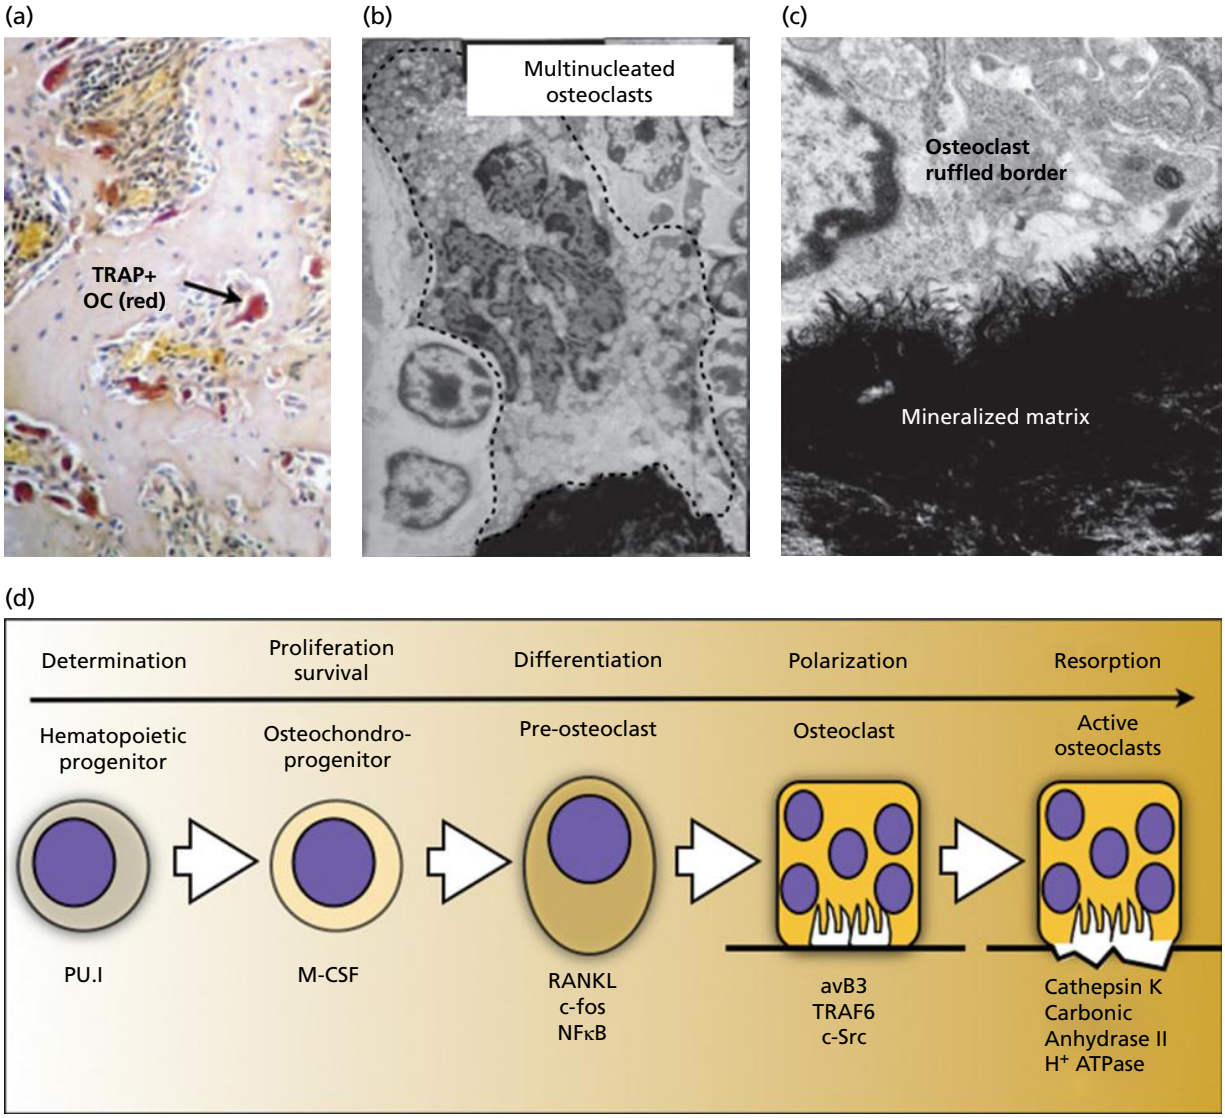

Fig. 2-7 Osteoclasts. (a) Histologically, osteoclasts can be depicted morphologically as multinucleated cells attached to bone matrix using special staining such as with the tartrate resistant acid phosphatase (TRAP) stain (arrow). (OC, osteoclast). (b) Transmission electron micrograph of a multinucleated osteoclast attached to the mineralized bone matrix is delineated by the dotted line. (c) Ruffled border at the resorbing end of the cells. (d) Osteoclasts are derived from cells of the macrophage/monocyte lineage and represent the bone resorbing units within the skeleton. The key molecules involved in the early events of differentiation of a hematopoietic progenitor through to a mature functional osteoclast are shown.

ideal hematopoietic microenvironment. For instance, it generates colony stimulating factors, which have a significant effect on hematopoiesis. Cells that constitute the bone marrow stroma are:

- Fibroblasts
- Macrophages
- Adipocytes
- Osteoblasts
- Osteoclasts
- Endothelial cells.

Stem cells

The bone marrow stroma contains mesenchymal stem cells (MSCs), also called *marrow stromal cells*. These are multipotent stem cells that can differentiate into a variety of cell types. MSCs have been shown to differentiate, *in vitro* or *in vivo*, into osteoblasts, chondrocytes, myocytes, adipocytes, and beta-pancreatic

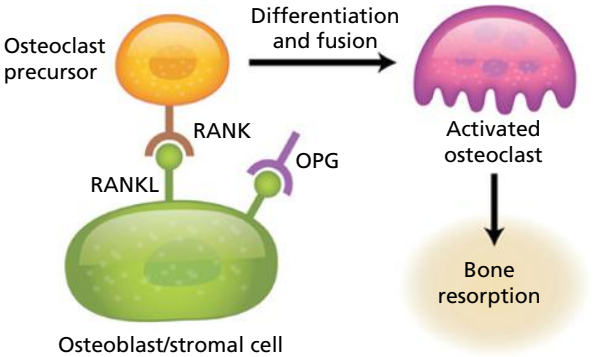

Fig. 2-8 Bone formation/resorption coupling. Bone formation and resorption processes are intimately linked. The osteoblastic/stromal cells provide an osteoclastogenic microenvironment by presenting RANKL to the osteoclast precursor, triggering their further differentiation and fusion, and leading to the formation of multinucleated and active osteoclasts. This process is modulated by inhibitors of these interactions such as osteoprotegerin (OPG). In addition, bone formation by osteoblasts depends on the preceding resorption by osteoclasts.

islet cells. MSCs can also transdifferentiate into neuronal cells. In addition, the bone marrow contains hematopoietic stem cells, which give rise to the three classes of blood cells that are found in the circulation: leukocytes, erythrocytes, and platelets.

Function

The main functions of bone are to provide locomotion, organ protection, and mineral homeostasis. Mechanical tension, local environment factors, and systemic hormones influence the balance between bone resorption and deposition. The distinct mechanical properties of bone contribute to its strength and ability to allow movement. In addition, an intricate series of interactions between cells, matrix, and signaling molecules maintains calcium and phosphorus homeostasis within the body, which also contributes to mechanical strength.

Mechanical properties

Bone is a highly dynamic tissue that has the capacity to adapt based on physiologic needs. Hence, bone adjusts its mechanical properties according to metabolic and mechanical requirements (Burr *et al*. 1985; Lerner 2006). As mentioned earlier, calcium and phosphorus comprise the main mineral components of bone in the form of calcium hydroxyapatite crystals. Hydroxyapatite regulates both the elasticity, stiffness, and tensile strength of bone. The skeletal adaptation mechanism is primarily executed by the processes of bone resorption and bone formation, referred to collectively as bone remodeling (Fig. 2-9). Bone is resorbed by osteoclasts, after which new bone is deposited by osteoblasts (Raisz 2005). From the perspective of bone remodeling, it has been proposed that osteoclasts recognize and are attracted to skeletal sites of compromised mechanical integrity, and initiate the bone remodeling process for the purpose of inducing the generation of new bone that is mechanically competent (Parfitt 1995, 2002).

In general, bone tissue responds to patterns of loading by increasing matrix synthesis, and altering composition, organization, and mechanical properties (Hadjidakis & Androulakis 2006). Evidence indicates that the same holds true for bone under repair. When bone experiences mechanical loading, osteoclast mechanoreceptors are directly stimulated, which begins the bone turnover process to regenerate and repair bone in the area. In addition, pressure increases M-CSF expression, increasing osteoclast differentiation in the bone marrow (Schepetkin 1997). Osteoclasts are also indirectly stimulated through osteoblasts and chondrocytes secreting prostaglandins in response to mechanical pressure. The extracellular matrix can also promote bone turnover through signaling. Mechanical deformation of the matrix induces electric potentials that stimulate osteoclastic resorption.

Bone strength is determined by a combination of bone quality, quantity, and turnover rate. It is well established that a loss of bone density, or quantity, decreases bone strength and results in increased fracture incidence. However, several pathologic conditions characterized by increased bone density, such as Paget's disease, are also associated with decreased bone strength and increased fracture incidence, so quality of bone is also an important factor in determining bone strength.

Metabolic properties

Calcium homeostasis is of major importance for many physiologic processes that maintain health (Bonewald 2002; Harkness & Bonny 2005). Osteoblasts deposit calcium by mechanisms including phosphate and calcium transport with alkalinization to absorb acid produced by mineral deposition; cartilage calcium mineralization occurs by passive diffusion

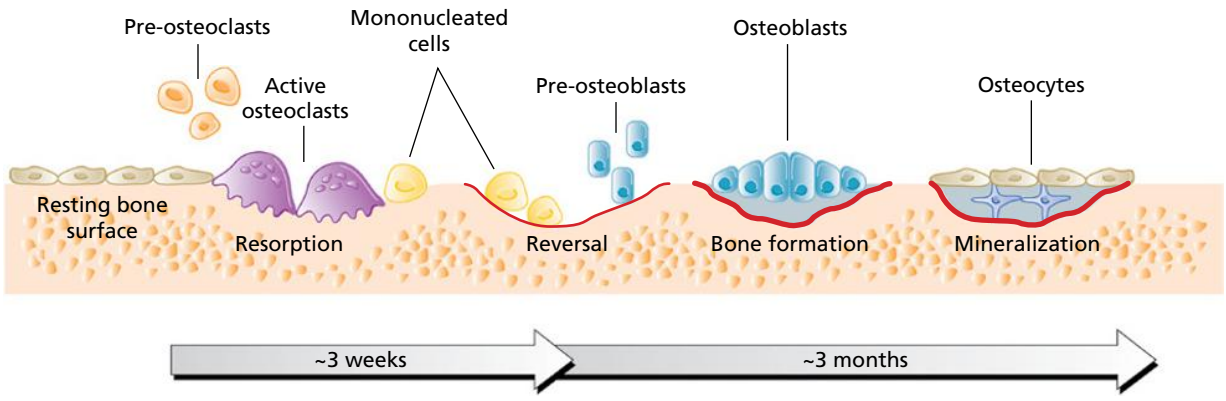

Fig. 2-9 Bone remodeling. The bone remodeling cycle involves a complex series of sequential steps that are highly regulated. The "activation" phase of remodeling is dependent on the effects of local and systemic factors on mesenchymal cells of the osteoblast lineage. These cells interact with hematopoietic precursors to form osteoclasts in the "resorption" phase. Subsequently, there is a "reversal" phase during which mononuclear cells are present on the bone surface. They may complete the resorption process and produce the signals that initiate bone formation. Finally, successive waves of mesenchymal cells differentiate into functional osteoblasts, which lay down matrix in the "formation" phase. (Source: McCauley & Nohutcu 2002. Reproduced from the American Academy of Periodontology.)

and phosphate production. Calcium mobilization by osteoclasts is mediated by acid secretion. Both bone-forming and bone-resorbing cells use calcium signals as regulators of differentiation and activity (Sims & Gooi 2008). This has been studied in more detail in osteoclasts: both osteoclast differentiation and motility are regulated by calcium.

Calcium is obtained from the diet even though bone is the major store of calcium and a key regulatory organ for calcium homeostasis. Bone, in major part, responds to calcium-dependent signals from the parathyroid glands and via vitamin D metabolites, although it responds directly to extracellular calcium if parathyroid regulation is lost. Serum calcium homeostasis is achieved through a complex regulatory process whereby a balance between bone resorption, absorption, and secretion in the intestine, and reabsorption and excretion by the kidneys is tightly regulated by osteotropic hormones (Schepetkin 1997). The balance of serum ionized calcium blood concentrations results from a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin. Other osteotropic endocrine hormones that influence bone metabolism include thyroid hormones, sex hormones, and retinoic acids. In addition, fibroblast growth factor aids in phosphate homeostasis. Figure 2-10 reflects how input from the diet and from the bones and excretion via the gastrointestinal tract and urine maintain homeostasis.

Vitamin D is involved in the absorption of calcium, while PTH stimulates calcium release from the bone, reduces its excretion from the kidney, and assists in the conversion of vitamin D into its biologically active form (1,25-dihydroxycholecalciferol) (Holick 2007). Decreased intake of calcium and vitamin D and estrogen deficiency may also contribute to calcium deficiency (Lips *et al.* 2006). Hormonal factors such as retinoids, thyroid and steroid hormones are capable of passing through biologic membranes and interacting with intracellular receptors to have a major impact on the rate of bone resorption. Lack of estrogen increases bone resorption as well as decreases the formation of new bone (Harkness & Bonny 2005). Osteocyte apoptosis has also been documented in estrogen deficiency. In addition to estrogen, calcium metabolism plays a significant role in bone turnover, and deficiency of calcium and vitamin D leads to impaired bone deposition.

Circulating PTH regulates serum calcium and is released in conditions of hypocalcemia. PTH binds to osteoblast receptors, increasing the expression of RANKL and the binding of RANKL to RANK on osteoclasts (McCauley & Nohutcu 2002). This signaling stimulates bone remodeling by activating osteoclasts with the final goal of promoting calcium

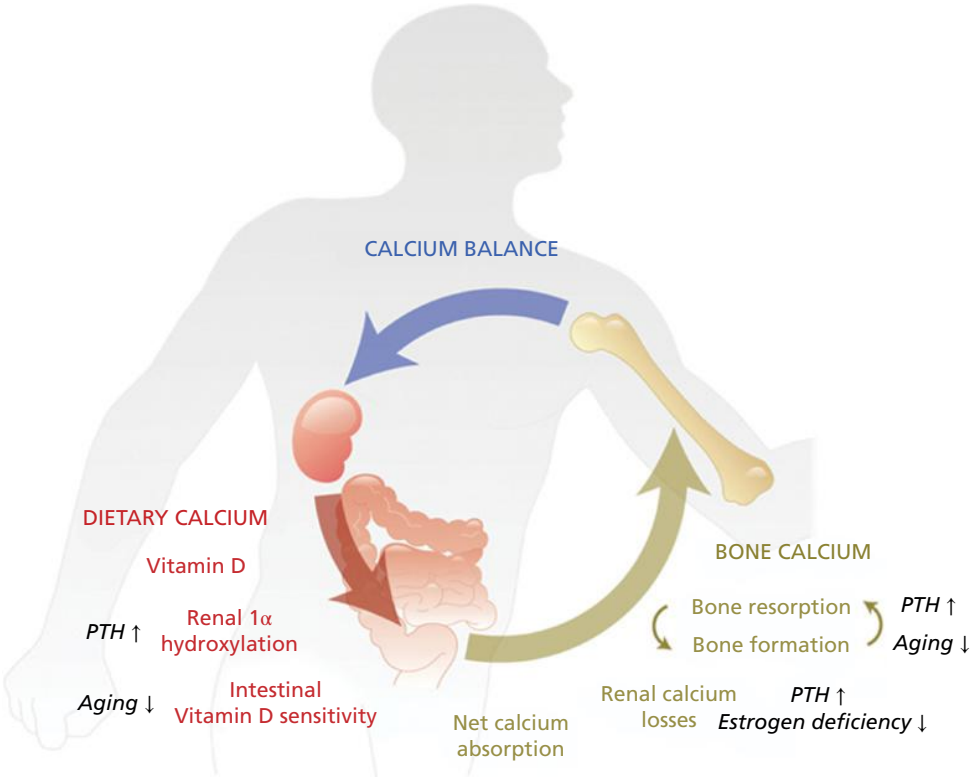

Fig. 2-10 Calcium and bone metabolism. Calcium homeostasis is of major importance for many physiologic processes that maintain health. The balance of serum ionized calcium blood concentrations results from a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin. The figure reflects how input from the diet and from the bones, and excretion via the gastrointestinal tract and urine, maintain homeostasis. Vitamin D is involved in the absorption of calcium, while PTH stimulates calcium release from the bone, reduces its excretion from the kidney, and assists in the conversion of vitamin D into its biologically active form (1,25-dihydroxycholecalciferol). Decreased intake of calcium and vitamin D, and estrogen deficiency may also contribute to calcium deficiency.

release from bone. A secondary function of PTH is to increase calcium reabsorption from the kidney. When administered therapeutically at low, intermittent doses, PTH can act as an anabolic agent to promote bone formation, although the mechanism of this action is not well understood.

T cells produce calcitonin, a 32-amino acid peptide whose main physiologic role is the suppression of bone resorption. Calcitonin receptors are present in high numbers on osteoclasts and their precursors (Schepetkin 1997). Thus, calcitonin is able to act directly on osteoclast cells at all stages of their development to reduce bone resorption through preventing fusion of mononuclear preosteoclasts, inhibiting differentiation, and preventing resorption by mature osteoclasts (McCauley & Nohutcu 2002). The concentration and phosphorylation of calcitonin receptors decreases in the presence of calcitonin. As a result, the effect of calcitonin on osteoclasts is transient and thus is not used for clinical therapeutic applications.

Skeletal homeostasis

Healing

Healing of an injured tissue usually leads to the formation of a tissue that differs in morphology or function from the original tissue. This type of healing is termed *repair*. Tissue *regeneration*, on the other hand, is a term used to describe a healing that leads to complete restoration of morphology and function. The healing of bone tissue includes both regeneration and repair phenomena, depending on the nature of the injury.

Repair

Trauma to bone tissue, whether repeated stress or a single, traumatic episode, most commonly results in fracture. When bone is damaged, a complex and multistage healing process is immediately initiated in order to facilitate repair. Tissue and cell proliferation are mediated at different stages by carious growth factors, inflammatory cytokines, and signaling molecules. Although it is a continuous process, bone repair can be roughly divided into three phases: inflammation, reparative, and remodeling (Hadjidakis & Androulakis 2006).

The inflammation phase begins immediately after tissue injury and lasts for approximately 2 weeks (Fazzalari 2011). The initial step in the repair process is the formation of a blood clot. Cytokine release from injured cells then recruits inflammatory cells into the area, where macrophages begin phagocytosis of damaged tissue and cells. Osteoclasts begin the process of resorbing damaged bone in the area to recycle mineral components. In addition, cells from myeloid and mesenchymal cell lineages are recruited to the area where they begin to differentiate into osteoblasts and chondroblasts. At this point, the RANKL-to-osteoprotegerin (OPG) ratio is reduced.

The reparative phase is characterized by the formation of a soft callous where new bone matrix and cartilage scaffolding begins to form. Osteoblasts and chondroblasts produce a protein scaffold to create this callus, which is slowly mineralized to form a hard callus. The hard callus is composed of immature woven bone. The initiation of cartilage and periosteal woven bone formation is primarily mediated through early up-regulation of interleukin 6 (IL-6), OPG, vascular endothelial growth factor (VEGF), and BMPs (Fazzalari 2011). The process of soft to hard callus formation occurs approximately 6–12 weeks from the time of bone fracture.

In the final stage of repair, known as the remodeling phase, the bone matrix and cartilage are remodeled into mature bone. Woven bone is eventually converted into mature lamellar bone through normal bone turnover mediated by osteoblast–osteoclast coupling. Adequate vitamin D and calcium are critical for proper bone repair and their levels may, in part, dictate the rate of repair. The time for the remodeling stage varies depending upon individual bone metabolism, but usually require months from the time of injury.

Regeneration

Ideal bone healing promotes tissue formation in such a way that the original structure and function is preserved. This is in contrast to tissue repair, which merely replaces lost tissue with immature tissue and does not completely restore function.

Over time, bone sustains damage from mechanical strain, overloading, and other forms of tissue injury that results in microfractures and other defects in the bony architecture. In order to prevent greater injury, the bone undergoes a natural remodeling process to regenerate or renew itself. The turnover rates of individual bones is unique, although the average turnover rate is 10% (McCauley & Nohutcu 2002).

Regeneration of bone tissue involves the coupling of bone formation and resorption in a basic multicellular unit (BMU) (Sims & Gooi 2008) (Fig. 2-11). In this process, bone resorption by osteoclasts occurs first over a period of 3–4 weeks, along with cellular signaling to promote osteoblast recruitment to the area. Osteoblasts then form bone for a period of 3–4 months, with a quiescent period between bone resorption and formation, called the reversal phase. Trabecular bone undergoes a significantly higher degree of bone turnover than cortical bone (McCauley & Nohutcu 2002). In a rodent alveolar bone healing model, this process occurs more rapidly, allowing appreciation of the cellular and molecular events that occur during the maturation of the newly regenerated bone (Figs. 2-12, 2-13) (Lin *et al*. 2011).

Bone regeneration is a normal process, but in some cases there is a need to regenerate bone at an increased rate or to overcome the effects of pathologic bone disorders. Therapeutic strategies to promote bone

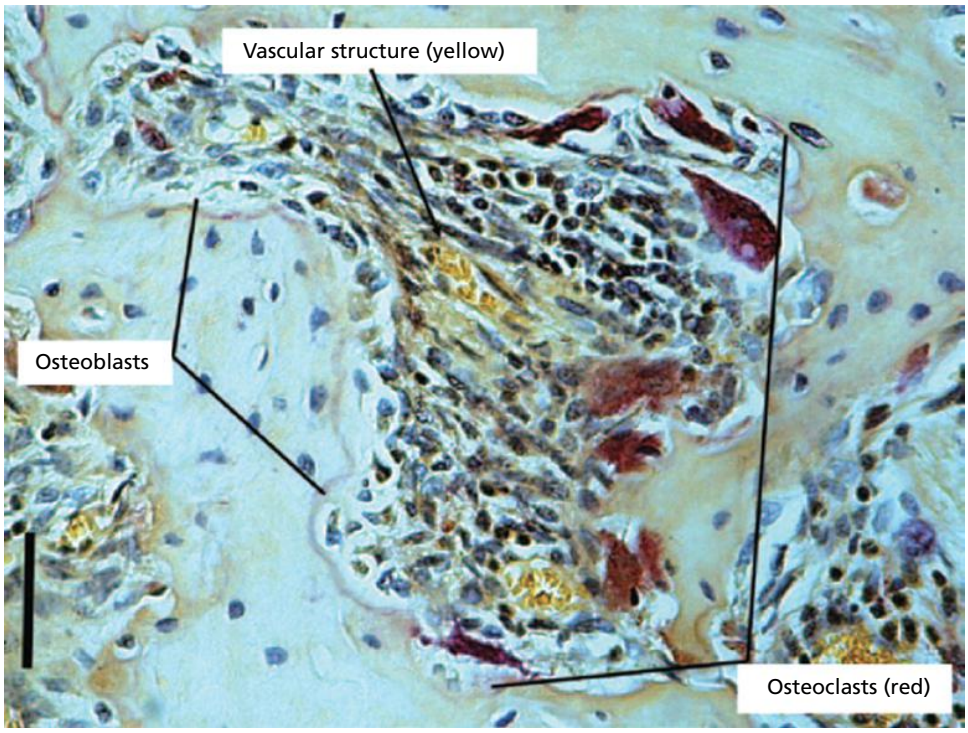

Fig. 2-11 Bone multicellular units (BMUs). Bone remodeling occurs in local groups of osteoblasts and osteoclasts called BMUs; each unit is organized into an osteoclast reabsorbing front, followed by a trail of osteoblasts reforming the bone to fill the defect left by osteoclasts. The red staining (tartrate acid phosphatase) highlights the resorption front. Note the increased number of multinucleated osteoclasts in this area.

regeneration include bone grafting from various sources, epithelial–occlusive barrier membranes, antiresorptive agents, anabolic agents, and growth factors to promote osteoblast differentiation and proliferation.

When alterations in bone turnover occur, skeletal homeostasis is disrupted, resulting in conditions of increased or decreased bone mineral density (BMD), or bone necrosis, and often accompanied by a decrease in bone strength. A wide variety of conditions can alter bone homeostasis and these include cancer, menopause, medications, genetic conditions, nutritional deficiencies, or infection. Some of these etiologies, such as vitamin D deficiency, are easily treatable, whereas others, such as genetic mutations, are typically treated through managing symptoms. Alterations in bone homeostasis cause a wide array of symptoms, including increased fracture incidence, bone pain, and other skeletal deformities that result in a high degree of morbidity and in some cases mortality. A brief review of the more common conditions is given below.

Disorders

Osteoporosis

Osteoporosis is a common condition characterized by both alterations in the macro- and micro-architecture of the bone (Fig. 2-14). There are multiple etiologies of this systemic disease, including post-menopausal, age-associated, glucocorticoid-induced, secondary to cancer, androgen ablation, and aromatase inhibitors (Kanis 2002). All forms result in reduced bone strength and increased fracture risk, accompanied by a high degree of morbidity and mortality.

Post-menopausal osteoporosis is the most common form of the disease and results from a decline in gonadal hormone secretion following menopause. Rapid loss of trabecular BMD and, to a lesser extent, cortical loss are common in this condition (Kanis 2002).

Diagnosis is made by comparing the BMD of a patient to that of a healthy 20–29-year-old adult of the same gender. Systemic BMD at least 2.5 standard deviations below the average, referred to as a T-score, is used by the World Health Organization (WHO) to define osteoporosis (WHO 1994). Osteopenia, a less severe form of the disease, is diagnosed when T-scores are between –1.0 and –2.5 (Fig. 2-15).

Osteopetrosis

Osteopetrosis is a group of related diseases in which there is a pronounced increase in BMD due to abnormal bone turnover, and in some ways this is the opposite of osteoporosis. These conditions are inherited and the mode of transmission varies from autosomal dominant to autosomal recessive. Increases in BMD in this patient population are due to a variety of defects in osteoclastic bone resorption. These include higher or lower osteoclast numbers, impaired differentiation, deficiencies in carbonic anhydrase, the ability to form a ruffled border, and alterations in signaling pathways (Stark & Savarirayan 2009). In most cases, it is the ability of the osteoclast to create an acidic environment in the lacunae to resorb bone

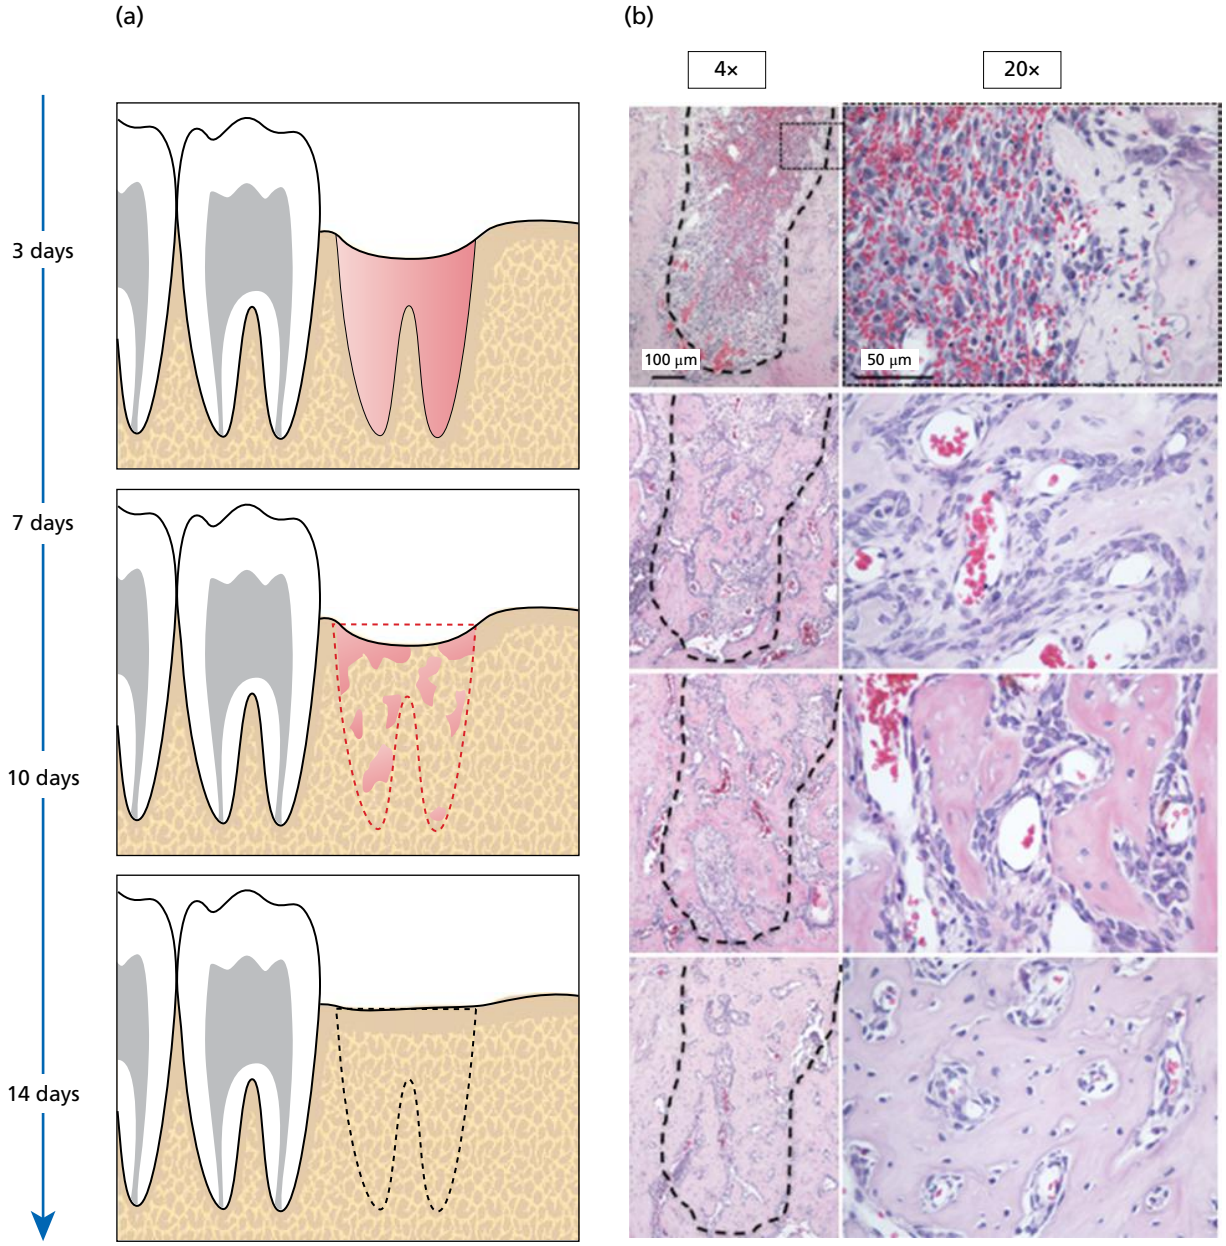

Fig. 2-12 Alveolar socket healing sites over time. (a) Rodent extraction model. Sequence of events that characterizes healing during the initial 14 days. (b) Hematoxylin and eosin (H&E) staining for tooth extraction site healing. The histologic images to the right of the healing area (black dashed lines) clearly capture the regeneration of the bone within the alveolar process. Note the clearly visible blood clot at day 3 (3d). At day 7 (7d), the cell density in the defect area is higher. At day 10 (10d), the defect site appears to be filled by a condensed mesenchymal tissue. Finally, by day 14 (14d), an integration of the newly formed bone to the original socket walls is noted.

that is in some way compromised, ultimately resulting in a net increase in bone formation (Fig. 2-16).

Osteomalacia

Vitamin D is essential for the metabolism of calcium and phosphorus in the body, which are the key minerals required for bone formation (Holick 2007). Vitamin D deficiency, or the inability to absorb the vitamin, is a common condition, especially in Northern climates since vitamin D is obtained primarily through sunlight exposure and diet. Other conditions may also predispose to vitamin D deficiency, such as oncogenic or benign tumors and liver disease.

When inadequate vitamin D is available, mineralization of the bones is impaired, resulting in a condition referred to as osteomalacia. When the disease occurs in children, it is referred to as rickets. The key features of osteomalacia are bones that contain a normal collagen matrix and osteoid structure, but lack proper mineralization, resulting in the softening of bones (Russell 2010). Osteomalacia differs from osteoporosis in that osteomalacia alters bone as it is developing, whereas osteoporosis weakens bones that have already formed (Fig. 2-17).

Severity ranges widely from an asymptomatic presentation to death in early childhood. Despite the increase in bone density, the newly formed bone is of

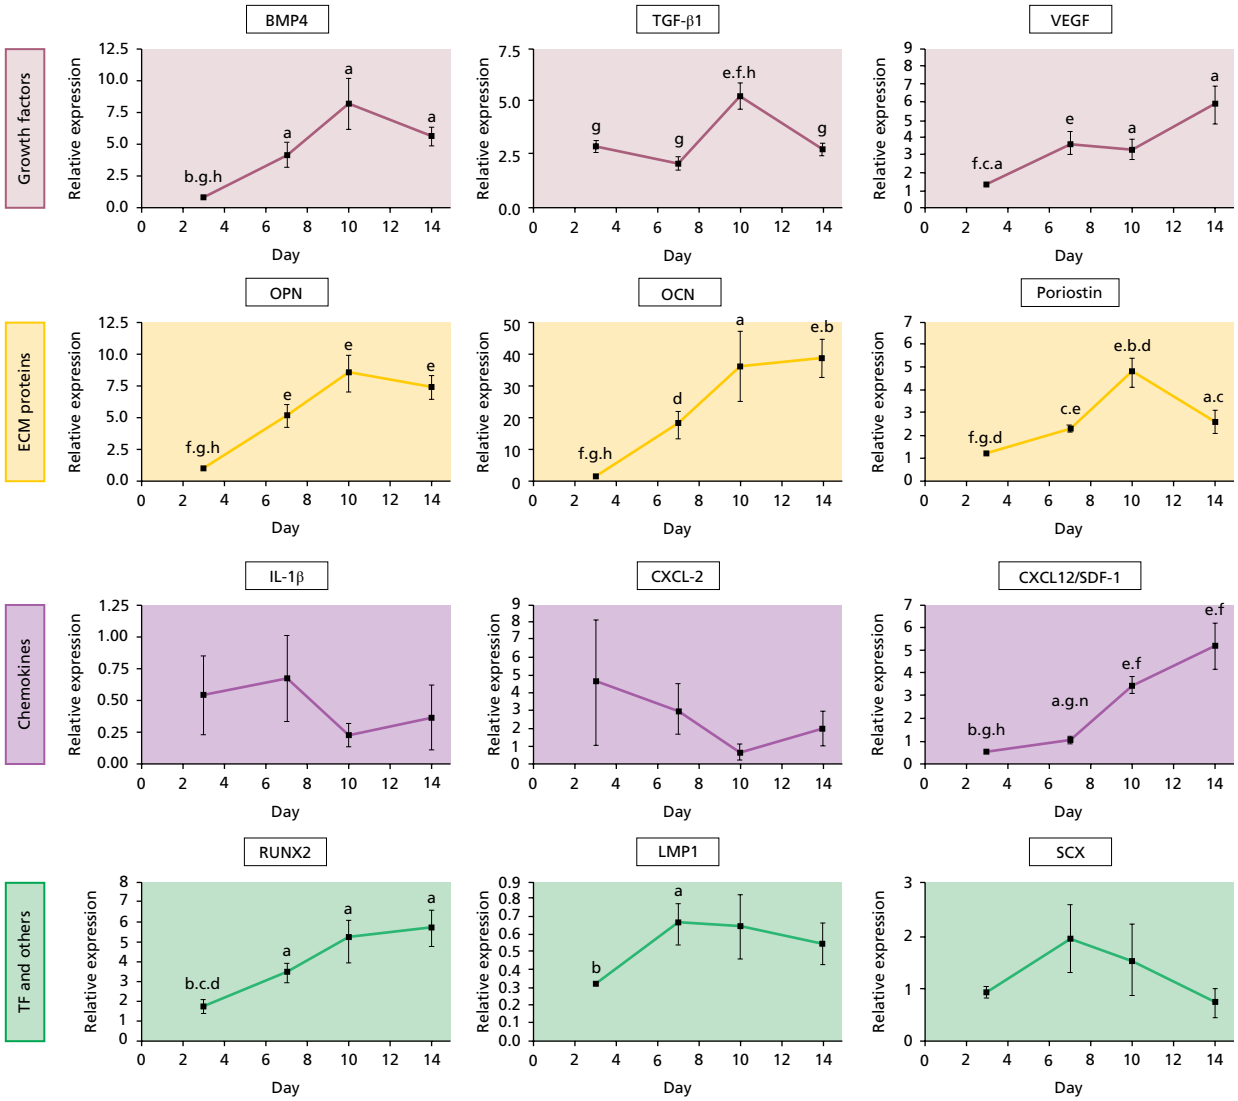

Fig. 2-13 Gene expression pattern of tooth extraction healing sites. Laser capture microdissection (LCM) analysis of genes associated with wound healing categorized them into three different groups: those for growth factors/chemokines, extracellular matrix proteins (ECM), and transcription factors (TF). The evaluation of gene expression over time captured the molecular dynamics that drive the bone healing process. Three expression patterns were evident. (1) Genes whose expression was slowly increased during the healing process: those for growth factors (*BMP4*, *BMP7*, *Wnt10b*, and *VEGF*), transcription factors (*RUNX2*), and extracellular matrix proteins related to mineralized tissue (*OPN* and *OCN*) were in this group; very interestingly, CXCL12 (SDF-1) gradually increased during extraction socket healing. Transforming growth factor beta 1 (TGF-β1) increased at the mid-stage of healing (day 10) and then decreased, and periostin (POSTN), a target gene of TGF-β1, had the same expression pattern. (2) Genes that were highly expressed at early time points and were down-regulated at later stages. Genes for chemokines IL-1β, CXCL2, and CXCL5 belonged to this category, although no statistical difference was seen due to the limited number of animals analyzed. Expression of *Wnt5a* and *Wnt4* also seemed to decrease during healing. (3) Genes that were constitutively expressed. LIM domain mineralization protein (*LMP-1*) and tendon-specific transcription factor *SCX* were in this group.

poor quality and symptoms include increased fracture incidence, neuropathy, and short stature. Treatment of osteomalacia involves reversing the vitamin D deficiency status, usually through dietary supplementation combined with removing the cause of the deficiency. Early management of this condition may involve a bone marrow transplant.

Osteonecrosis

When ischemia occurs in bone for an extended period of time, often due to an interruption in blood supply, cell death occurs. Cells from a hematopoetic lineage are most prone to the negative effects of ischemia and cannot survive for >12 hours without an adequate blood supply (Steinberg 1991). Cells directly responsible for bone mineralization and turnover – osteoblasts, osteoclasts, and osteocytes – are less prone to anoxia, although cell death occurs in these cells after 48 hours of anoxia. If the blood supply resumes quickly, healing may occur and the bone may recover. However, after this critical time period passes, the bone in question will necrose, requiring partial or total resection, followed by reconstruction.

Osteonecrosis has multiple etiologies including radiation, bisphosphonate use, steroid use, hypertension, and in some cases arthritis or lupus. Bisphosphonate-related osteonecrosis of the jaw (ONJ) is of growing concern in the dental field. ONJ is defined as an area of exposed bone that does not heal within 8 weeks after identification by

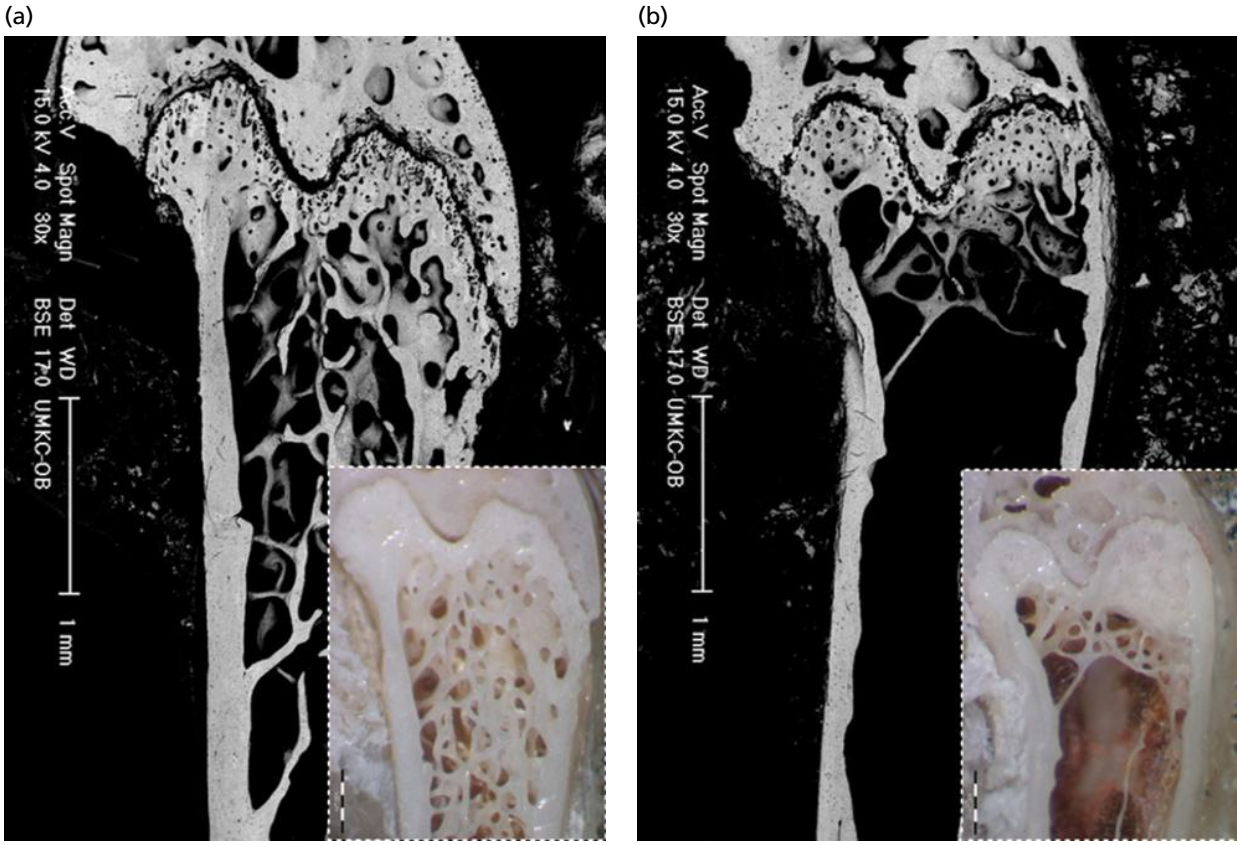

Fig. 2-14 Osteoporosis. In contrast to the image in (a), that in (b) illustrates microscopic bone morphologic changes associated with osteoporosis, such as decreased cortical thickness, in addition to a marked decrease in trabecular number and connectivity. As this process continues over time, there is further deterioration of the internal architecture with a significant impact on the ability of the bone to sustain compressive forces without failure.

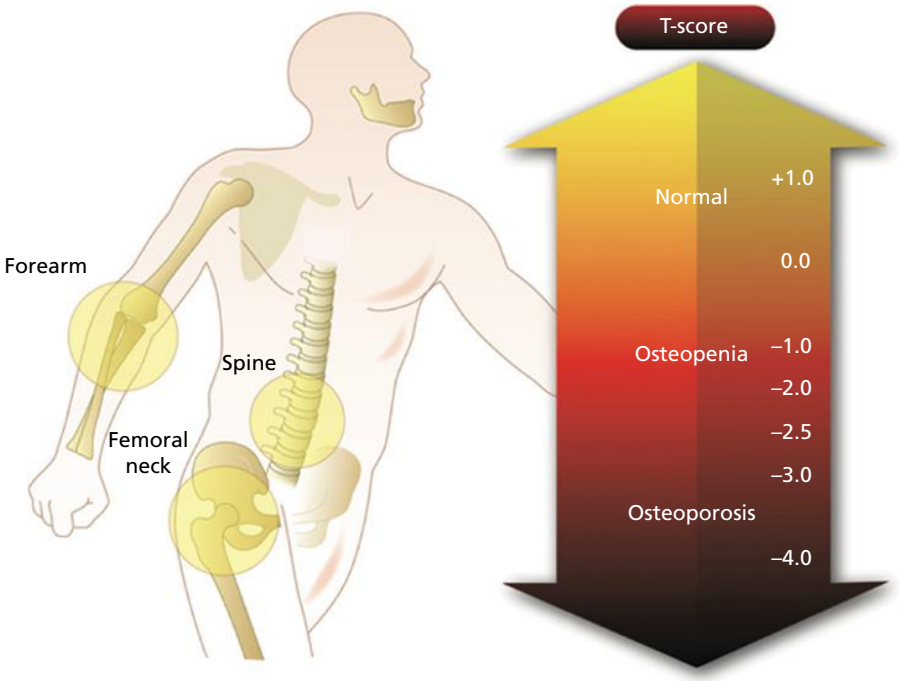

$$\text{T-Score} = \frac{\text{Measured BMD} - \text{young adult mean BMD}}{\text{Young adult standard deviation}}$$

Fig. 2-15 Bone mineral density (BMD). Dual-energy X-ray absorptiometry (DEXA) is considered the preferred technique for measurement of BMD. The sites most often used for DEXA measurement of BMD are the spine, femoral neck, and forearm. The World Health Organization defines osteoporosis based on "T-scores". T-scores refer to the number of standard deviations above or below the mean for a healthy 30-year-old adult of the same sex as the patient.

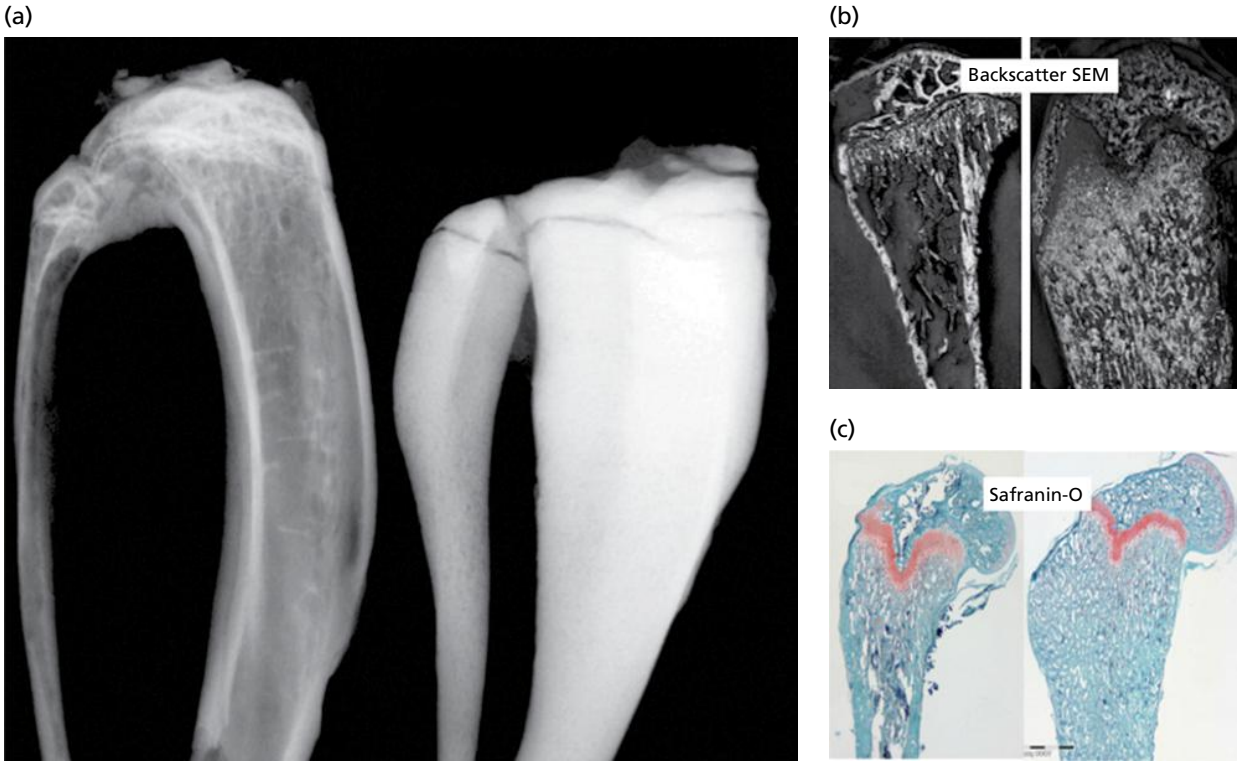

Fig. 2-16 Osteopetrosis. Increased density and deposits of mineralized bone matrix are a common finding in those with osteopetrosis. (a) Obliteration of the bone marrow cavity; (b) backscatter SEM; (c) staining with safranin-O.

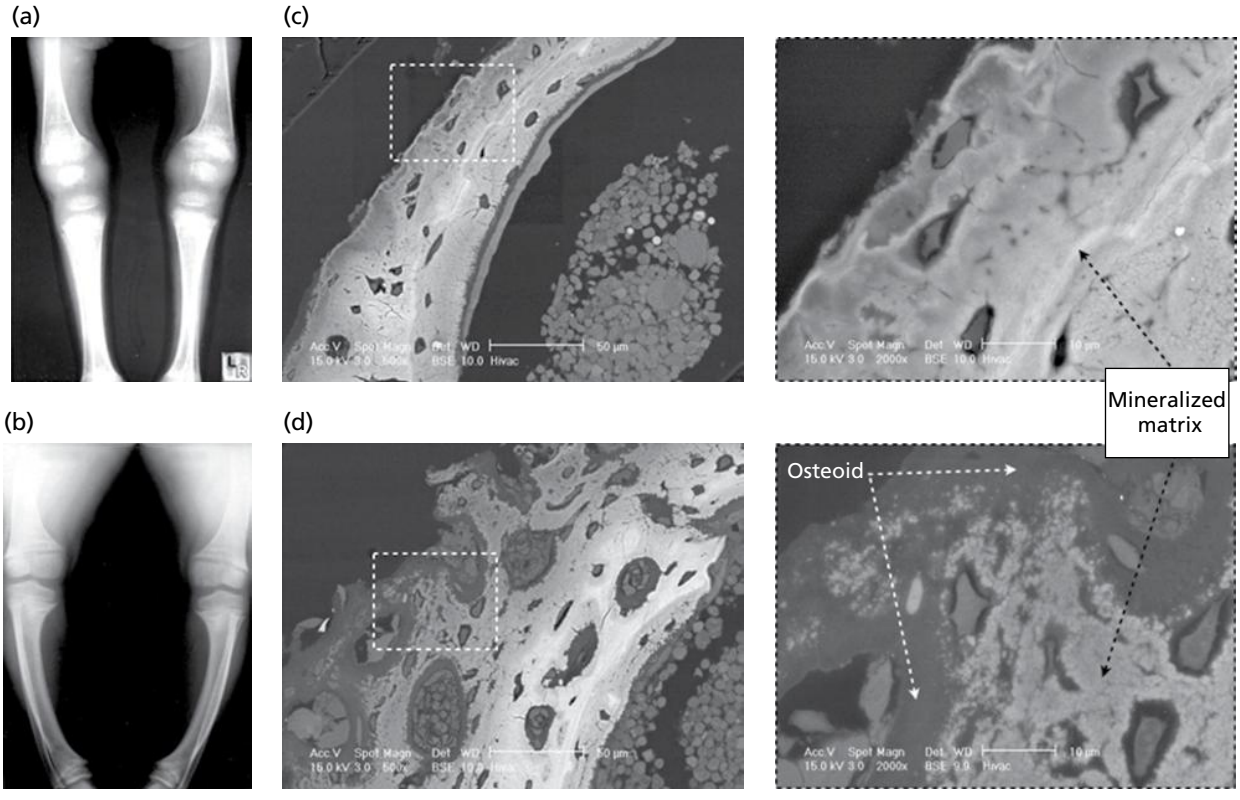

Fig. 2-17 Osteomalacia. (a, c) Normal matrix mineralization and maturation. (b, d) In osteomalacia, large hypomineralized zones accompanied by an increase in osteoid/immature matrix deposits are present.

a healthcare provider (Khosla *et al*. 2008). Patients diagnosed with bisphosphonate-related ONJ cannot have had prior radiation to the craniofacial regions. Oral bisphosphonate use is associated with lower risk and an incidence of 0.01–0.04%, compared to patients taking intravenous bisphosphonates who have a higher incidence of ONJ at 0.8–12% (Vescovi & Nammour 2011). This is likely

due to the higher dosing regimen and disease being treated. Oral bisphosphonates are typically used to treat osteoporosis, whereas intravenous bisphosphonates are given for the treatment of Paget's disease, multiple myeloma, and other conditions.

Osteomyelitis

Osteomyelitis is an infection of the bone and can be classified according to the source of infection, prognosis, bone anatomy, host factors, and clinical presentation (Calhoun & Manring 2005). Open fractures, surgery, and conditions such as diabetes mellitus and peripheral vascular disease increase the risk of developing osteomyelitis. Osteomyelitis from a hematogenous source is much more common in the pediatric population.

A definitive diagnosis of osteomyelitis is made by isolation of the bacteria in conjunction with diagnostic imaging, but can be challenging. Treatment involves antibiotic therapy in conjunction with drainage, debridement, and other appropriate surgical management, including bone stabilization and skin grafting (Conterno & da Silva Filho 2009).

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is a group of genetic disorders of impaired collagen formation leading to decreased bone quality. Fractures, bone fragility, and osteopenia are common features of the disease. OI is relatively rare, with an incidence of 1 in 10 000 births. Autosomal dominant and recessive forms exist, although the autosomal dominant form is more common (Michou & Brown 2011).

The clinical presentation of OI has features in common with other diseases of bone metabolism, including fractures, bone deformities, and joint laxity. In addition, distinct features of OI include hearing loss, vascular fragility, blue sclerae, and dentinogenesis imperfecta. Type I collagen defects, including interruptions in interactions between collagen and non-collagenous proteins, weakened matrix, defective cell–cell and cell–matrix relationships, and defective tissue mineralization contribute to the etiology of the autosomal dominant form (Forlino *et al*. 2011). In the recessive form, deficiency of any of the three components of the collagen prolyl 3-hydroxylation complex results in a reduced ability of type I procollagen to undergo post-translational modification or folding. The severity of the disease, as well as the presence of defining features, varies widely.

Multiple therapeutic options are employed to treat the symptoms of OI, including surgery, collaboration with hearing, dental, and pulmonary specialists, and medication such as bisphosphonates and recombinant human growth hormone.

Other disorders

Several other conditions can affect bone homeostasis, including primary and secondary hyperparathyroidism, Paget's disease, and fibrous dysplasia.

Hyperparathyroidism is an overproduction of PTH, which promotes resorption of calcium and phosphorus from bone to increase serum calcium to normal levels (Unnanuntana *et al*. 2011). Primary hyperparathyroidism is most commonly caused by a parathyroid gland adenoma, whereas secondary hyperparathyroidism occurs when PTH production is overstimulated in response to low serum calcium. Hyperparathyroidism often presents with no symptoms and is discovered at routine screenings. The clinical presentation is very similar to that of rickets. Treatment includes identifying and eliminating the initiating cause.

Paget's disease is a condition where bone metabolism is significantly higher than normal, with boneformation exceeding that of resorption (Noor & Shoback 2000). This results in excessive bone formation and may affect one or multiple bones. The pelvic bone is most commonly affected. The affected bones, despite having increased bone formation, are weak and deformed. This is due to irregular collagen fiber formation within the bones. Bisphosphonate therapy is effective at decreasing bone turnover in this patient population, although this carries with it an increased risk of developing ONJ. Approximately 0.01–0.04% of patients taking bisphosphonates for the treatment of Paget's disease develop ONJ (Vescovi & Nammour 2011).

Fibrous dysplasia may affect multiple bones, but in 60% of cases, only one bone is affected (Michou & Brown 2011). It most commonly presents in childhood. Fibrous dysplasia lesions form in the medullary cavity extending to the cortical bone and are comprised of hyaline cartilage, immature woven bone, and osteoblast progenitor cells. Symptoms of this condition include fractures and bone pain. Notably, this condition has other craniofacial symptoms, including craniofacial bone deformities, exophthalmos, and dental abnormalities.

Conclusion

It can be appreciated that the dynamic nature of bone and its associated structures serves as an important organ system that supports form and function of the skeleton. This chapter serves to demonstrate the complexity of the developmental process of dental and craniofacial bone formation and homeostasis during health and disease.

Chapter 3

The Edentulous Ridge

Maurício Araújo[1] and Jan Lindhe[2]

Clinical considerations

The alveolar process extends from the basal bone of the maxilla or the mandible and forms a boundary between the outer portion of the maxilla and the inner portion of the mandible (Pietrokovski *et al*. 2007). The alveolar process forms in harmony with the development and eruption of the teeth, and gradually regresses when the teeth are lost. In other words, the formation as well as the preservation of the alveolar process is dependent on the continued presence of teeth. Furthermore, the morphologic characteristics of the alveolar process are related to the size and shape of the teeth, events occurring during tooth eruption, as well as the inclination of the erupted teeth. Thus, subjects with long and narrow teeth, compared with subjects who have short and wide teeth, appear to have a more delicate alveolar process and, in particular in the front tooth regions, a thin, sometimes fenestrated, buccal bone plate (Fig. 3-1).

The tooth and its surrounding attachment tissues – the root cementum, the periodontal ligament, and the bundle bone – establish a functional unit (Fig. 3-2). Hence, forces elicited, for example during mastication, are transmitted from the crown of the tooth via the root and the attachment tissues to the load-carrying hard tissue structures in the alveolar process, where they are dispersed.

The loss of teeth and the loss or change of function within and around the socket will result in a series of adaptive alterations of the now edentulous portion of the ridge. Thus, it is well documented that following *multiple tooth* extractions and the subsequent restoration with removable dentures, the size of the ridge will become markedly reduced, not only in the horizontal but also in the vertical dimension (Figs. 3-3, 3-4). An important long-term study of dimensional ridge alterations in 42 complete denture wearers was presented by Bergman & Carlsson (1985). Cephalometric radiographic examinations were performed in a cephalostat and profiles of the edentulous mandible and maxilla were depicted 2 days after tooth extraction, and subsequently after 5 years and 21 years (Fig. 3-5). The authors concluded that during the observation interval most of the hard tissue component of the ridge was lost. However, there was wide variation in the degree of bone resorption and amount of remaining bone among the patients (Tallgren 1957, 1966; Atwood 1962, 1963; Johnson 1963, 1969; Carlsson *et al*. 1967).

Also, following the removal of *single* teeth, the ridge at the site will be markedly diminished (Fig. 3-6). The magnitude of this change was studied and reported by Pietrokovski and Massler (1967). The authors had access to 149 dental cast models (72 maxillary and 77 mandibular) in which one tooth was missing on one side of the jaw. The outer contours of the buccal and lingual (palatal) portions of the ridge at a tooth site and at the contralateral edentulous site were determined by the use of a profile stylus and an imaging technique. Their findings are reported in Table 3-1.

It was concluded that the amount of tissue resorption (hard and soft tissues combined) following the loss

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

(a)

(b)

Fig. 3-1 Buccal aspect of adult skull preparations illustrating a dentate maxilla of one subject with a relatively thick (a) and another subject with a relatively thin (b) biotype.

of a single tooth was substantial and that the reduction of the ridge was twice as large at the buccal aspect as along the lingual and palatal aspect in all teeth groups examined. The absolute amounts of tissue loss varied from one group of teeth to the next. As a result of this tissue modeling, the center of the edentulous site shifted toward the lingual or palatal aspect of the ridge. The observations made by Pietrokovski and Massler (1967) were supported by findings presented by Schropp *et al*. (2003). They studied bone and soft tissue volume changes that took place during a 12-month period following the extraction of single premolars and molars. Clinical as well as cast model measurements were made immediately after tooth extraction and subsequently after 3, 6, and 12 months of healing. It was observed that the bucco-lingual/-palatal dimension during the first 3 months was reduced by about 30%, and after 12 months the edentulous site had lost at least 50% of its original width. Furthermore, the height of the buccal bone plate was reduced and after 12 months of healing the buccal prominence was located 1.2 mm apical of its lingual/palatal counterpart.

The information provided by Pietrokovski and Massler (1967) and Schropp *et al*. (2003) suggests that if an alveolar process includes a tooth that has a horizontal width of, for example, 12 mm, the edentulous site will be only 6 mm wide 12 months after healing following tooth extraction. During this 12-month interval, 4 mm of tissue will be lost from the buccal and 2 mm from the lingual aspect of the site.

(a) (b)

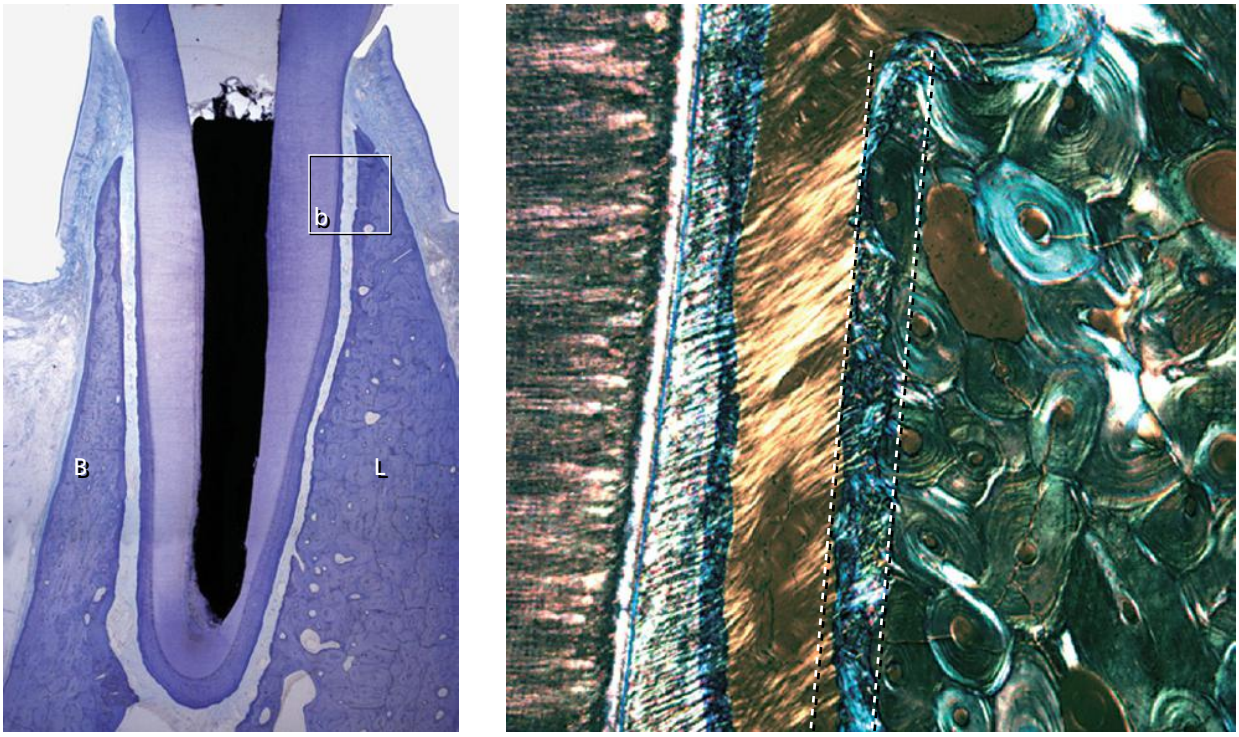

Fig. 3-2 Buccolingual histologic section of the alveolar process. (a) Tooth is surrounded by its attachment tissues (cementum, periodontal ligament, alveolar bone proper). (B, buccal aspect; L, lateral aspect.) (b) Higher magnification of the attachment tissues. Note that the dentin is connected to the alveolar bone via the root cementum, and the periodontal ligament. The alveolar bone is characterized by its content of circumferential lamellae. The portion of the bone that is facing the periodontal ligament (between the dotted lines) is called the alveolar bone proper or the bundle bone.

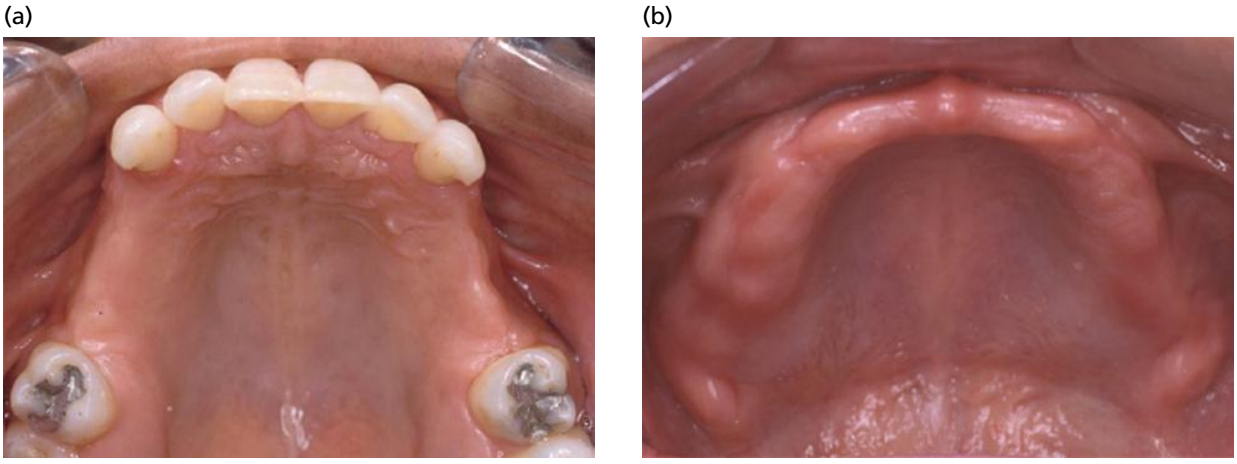

Fig. 3-3 (a) Clinical view of a partially edentulous maxilla. Note that the crest of the edentulous portions of the ridge is narrow in the buccopalatal direction. (b) Clinical view of a fully edentulous and markedly resorbed maxilla. Note that *papilla incisiva* is located in the center of the ridge. This indicates that the entire buccal and also a substantial portion of the palatal ridge are missing.

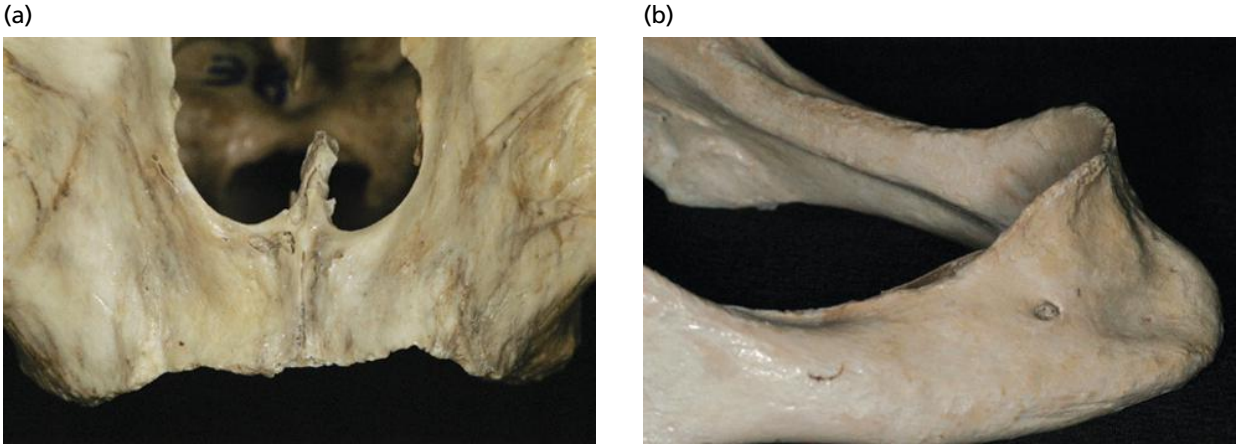

Fig. 3-4 Buccal aspect of a skull preparation illustrating a fully edentulous maxilla (a) and mandible (b). The small segments of the alveolar ridge that still remain are extremely thin in the bucco-palatal/-lingual direction.

In a clinical study (Sanz *et al*. 2010; Tomasi *et al*. 2010) it was observed that the degree of early (4 months) resorption of the buccal bone plate following tooth extraction was dependent on its original dimension. Thus, bone plates that were <1 mm wide lost substantially more dimension (width and height) than plates that were >1 mm wide.

In this context it is important to acknowledge that the buccal bone plate in the frontal tooth region in humans is frequently (>80% of sites) <1 mm wide (Januário *et al*. 2011; Braut *et al*. 2011; Nowzari *et al*. 2012). Hence, it can be anticipated that tooth loss in this part of the dentition may result in marked dimension alterations (horizontal as well as vertical) of the ridge and that this in turn may cause esthetic concerns.

Conclusion: The extraction of single as well as multiple teeth induces a series of adaptive changes in the soft and hard tissues that result in an overall regression of the edentulous site(s). Resorption appears to be more pronounced at the buccal than at the lingual/palatal aspects of the ridge.

It should be realized that the alveolar process might also undergo change as the result of tooth-related disease processes, such as aggressive, chronic,

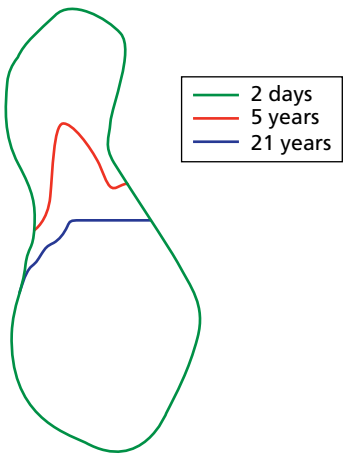

Fig. 3-5 Profile of the mandibular bone following tooth extraction at 2 days, 5 years, and 21 years after tooth removal. (Source: Bergman & Carlsson 1985. Reproduced with permission from Elsevier.)

and necrotizing forms of marginal periodontitis, as well as periapical periodontitis. Furthermore, traumatic injuries (including from improper tooth removal techniques) may cause marked damage to the alveolar process of the maxilla and mandible.

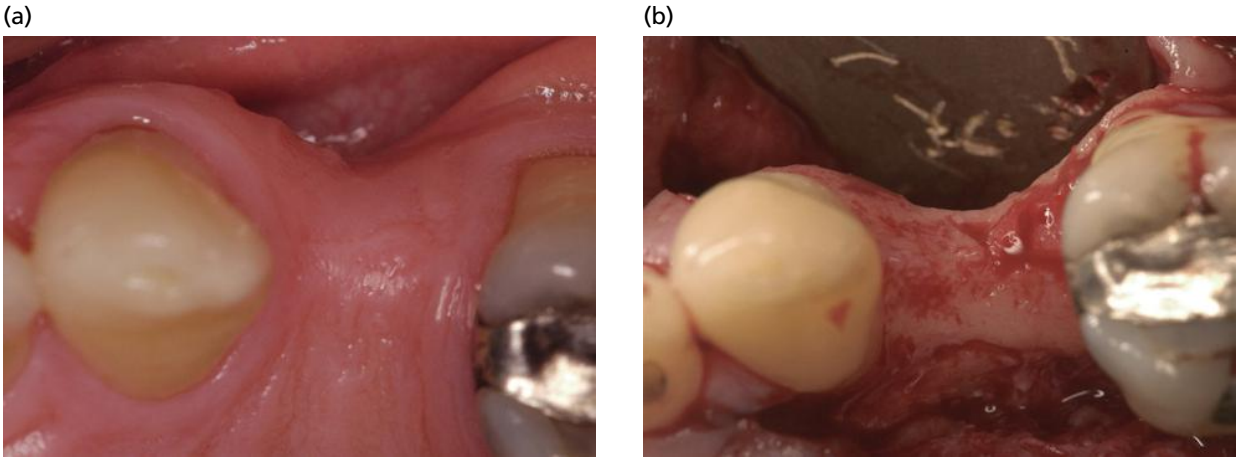

Fig. 3-6 Clinical view of an edentulous ridge in the maxillary premolar region. The premolar was extracted several years before the clinical documentation was made. (a) Note the presence of a buccal invagination of the ridge. (b) Following flap elevation, the crest region of the severely resorbed buccal portion of the alveolar process is disclosed.

Table. 3-1 Average amount of resorption of tooth extraction in different tooth areas.[a]

Tooth	Average amount of resorption (mm)		Difference
	Buccal surface	Lingual/ palatal surface	
Mandibular teeth			
Central incisor	2.08	0.91	1.17
Lateral incisor	3.54	1.41	2.13
Canine	3.25	1.59	1.66
First premolar	3.45	1.40	2.05
Second premolar	3.28	0.75	2.53
First molar	4.69	2.79	1.90
Second molar	4.30	3.00	1.30
Maxillary teeth			
Central incisor	3.03	1.46	1.57
Lateral incisor	3.47	0.86	2.61
Canine	3.33	1.91	1.42
First premolar	3.33	2.04	1.29
Second premolar	2.58	1.62	0.96
First molar	5.25	3.12	2.13

[a] "The amount of resorption was greater along the buccal surface than along the lingual or palatal surface in every specimen examined, although the absolute amounts and differences varied very widely. This caused a shift in the center of the edentulous ridge toward the lingual or palatal side of the ridge with a concomitant *decrease* in arch length in the mandible as well as the maxillae" (Pietrokovski & Massler 1967).

Remaining bone in the edentulous ridge

In the publication by Schropp *et al*. (2003), bone tissue formation in single extraction sockets was studied by means of subtraction radiography. Thus, radiographs of the study sites were obtained using a standardized technique immediately after tooth extraction and then after 3, 6, and 12 months of healing (Fig. 3-7). It was observed that in the first few months, some bone loss (height) took place in the alveolar crest region. Most of the bone gain in the socket occurred in the first 3 months. There was additional gain of bone in the socket between 3 and 6 months. In the interval between 6 and 12 months, the newly formed bone obviously remodeled and the amount of mineralized tissue was reduced. In other words, in the later phases of socket healing, small amounts of mineralized tissue may have remained in the center of the edentulous site.

The bony part of the edentulous ridge in humans was examined in biopsies sampled from the posterior portions of the jaw by Lindhe *et al*. (2012). The peripheral borders of the ridge were consistently lined with dense cortical bone. More central parts harbored cancellous bone and included trabeculae made up mainly of lamellar bone (Fig. 3-8a). The trabeculae that were embedded in bone marrow varied in shape, and frequently had a haphazard orientation. The bone marrow was dominated by adipocytes, vascular structures, and scattered inflammatory cells. The hard tissue component of the ridge was comprised of a mixture of mineralized bone (about 60%), bone marrow (about 20%), and fibrous tissue (about 15%) (Fig. 3-8b).

Classification of remaining bone

Based on the volume of remaining mineralized bone, the edentulous sites may, according to Lekholm and Zarb (1985), be classified into five different groups (Fig. 3-9). In groups A and B, substantial amounts of the ridge still remain, whereas in groups C, D, and E, only minute amounts of hard tissue remain. Lekholm and Zarb (1985) also classified the "quality" of the bone in the edentulous site. Class 1 and class 2 characterized a location in which the walls – the cortical plates – of the site are thick and the volume of bone

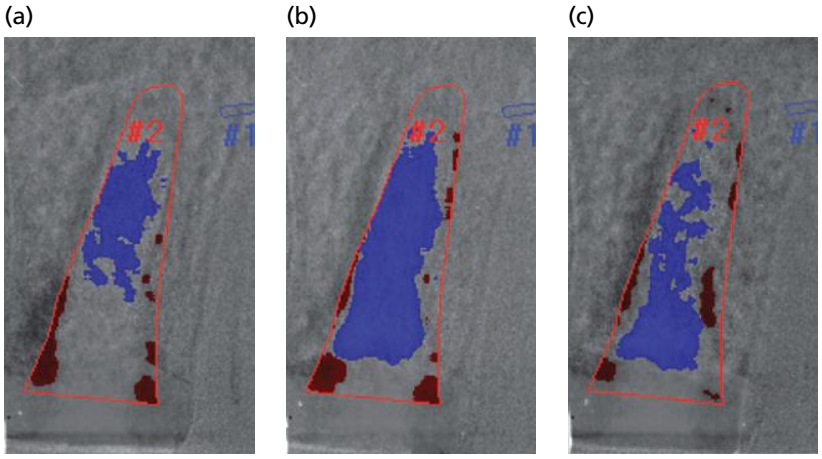

Fig. 3-7 Radiographic (subtraction radiography) images of an extraction site obtained after (a) 3 months, (b) 6 months, and (c) 12 months of healing. The blue color represents areas of new bone formation. During the first 6 months, the deposition of new bone was intense. Between 6 and 12 months, some of the newly formed bone was remodeled. (Courtesy of L. Schropp.)

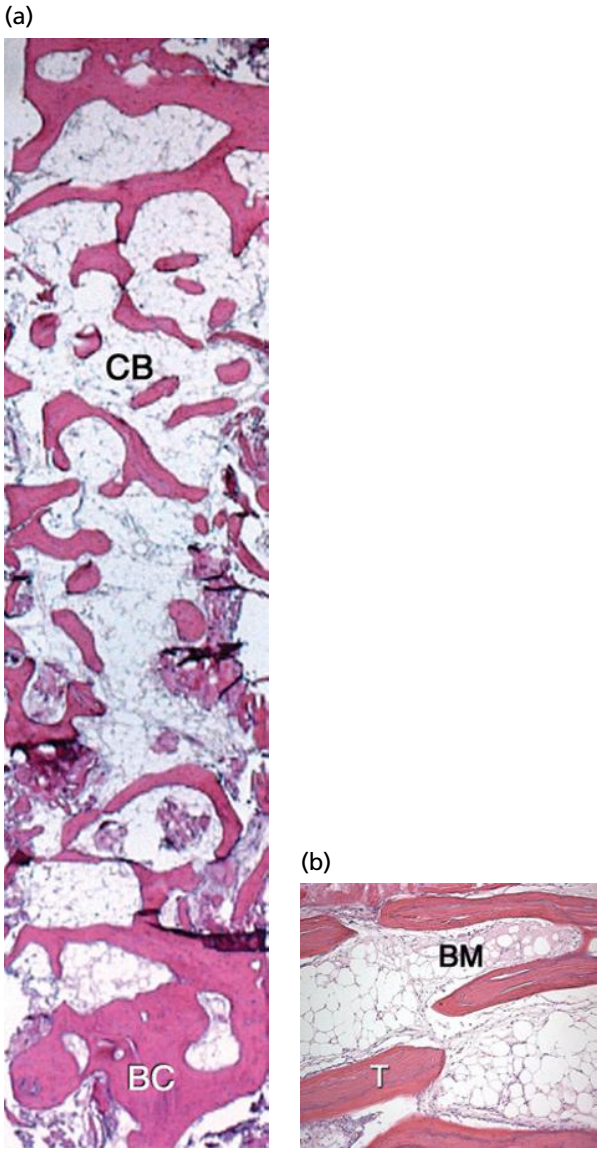

Fig. 3-8 Histologic sections of an edentulous site obtained from the maxillary premolar region in man. (a) The marginal portion of the ridge (BC) is protected by a cortical cap made up of lamellar bone, while more central regions house the cancellous bone (CB). (b) The cancellous bone is characterized by the trabeculae of mineralized bone (T) within the bone marrow (BM) compartment.

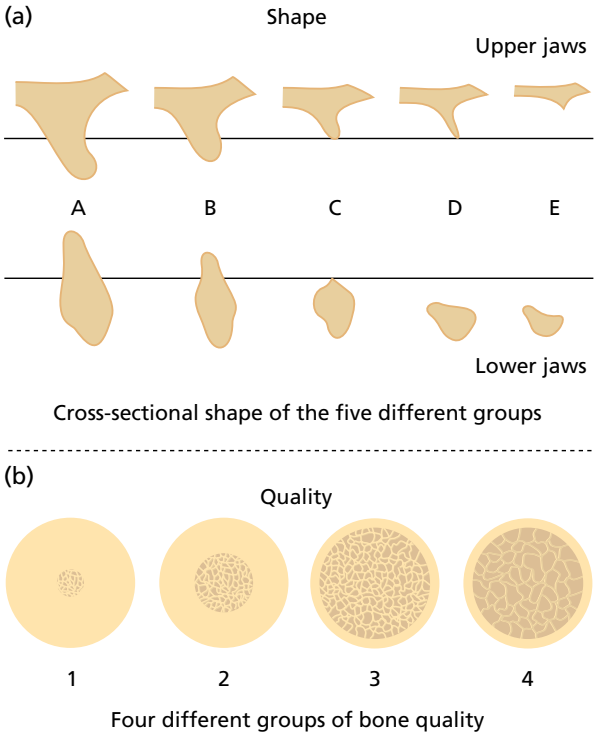

Fig. 3-9 Schematic drawings showing (a) a classification of residual jaw shape and (b) jaw bone quality. (Source: Lekholm & Zarb 1985. Reproduced from Quintessence.)

marrow is small. Relatively thin walls of cortical bone, however, will border sites that belong to class 3 and class 4, while the amount of cancellous bone (spongiosa), including trabeculae of lamellar bone and marrow, is large.

Topography of the alveolar process

The alveolar process that houses the roots of the teeth extends from the basal bone (Fig. 3-10a) of the maxilla and the mandible. The shape and dimensions (height and width) of the basal bone vary considerably from subject to subject (Figs. 3-10a, b) and from site to site in the same individual. There

is no distinct boundary between the alveolar process and the basal bone of the jaws.

At sites of the jaws where the teeth erupt in "normal" orientation in the developing alveolar process, hard tissue will be present on the facial (buccal) as well as on the lingual (palatal) aspect of the roots (Fig. 3-10c). However, at sites where the teeth erupt with a facial orientation, the facial (buccal) bone of the alveolar process will become thin and at times even disappear (dehiscence, fenestration) (Fig. 3-10d).

The outer walls of the alveolar process – facial (buccal), marginal, and lingual (palatal) aspects – are continuous with the outer walls of the basal bone. The walls are comprised of dense cortical bone, while more central portions harbor trabecular bone (radiographic term; spongy bone, anatomic term; cancellous bone, histologic term) that contains bone trabeculae within the bone marrow.

The cortical walls (plates) of the alveolar process are continuous with the bone that lines the sockets, that is the alveolar bone proper or the bundle bone (see Fig. 3-2b). The cortical plates (the outer walls) of the alveolar process meet the alveolar bone proper at the crest of the interdental septum. In subjects (sites) with healthy periodontium, the crest of the septum is located 1–2 mm apical of the cementoenamel junction.

In some portions of the dentition (such as in the symphysis region of the mandible), the trabecular bone component of the alveolar process may be absent.

From an alveolar process to an edentulous ridge

The alterations that occur in the alveolar process following the extraction of a single tooth can, for didactic reasons, be divided in two interrelated series of events, namely *intra-alveolar processes* and *extra-alveolar processes.*

Intra-alveolar processes

The healing of extraction sockets in human volunteers was studied by, for example, Amler (1969) and Evian *et al.* (1982). Although the biopsy technique

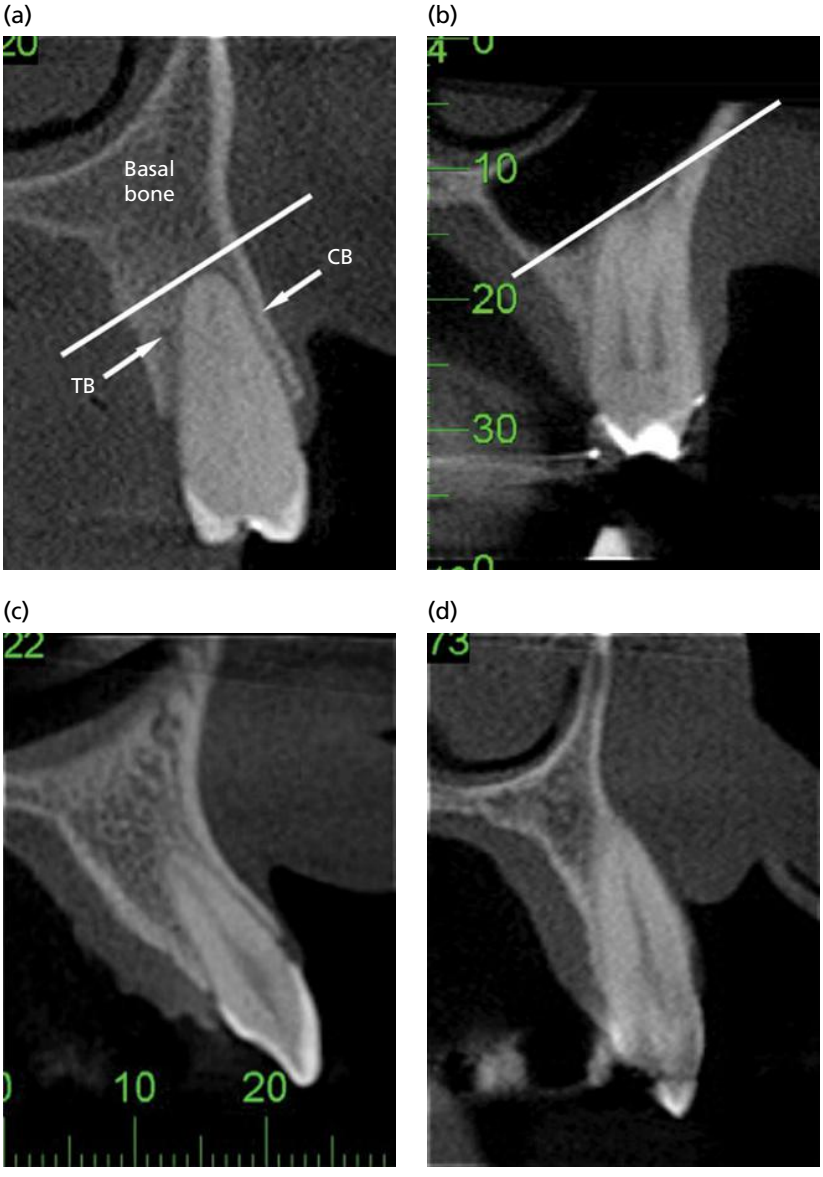

Fig. 3-10 (a) Cone-beam tomogram of the premolar region of the maxilla. The alveolar process is continuous with the voluminous basal bone of the maxilla. (CB, cortical bone plate; TB, trabecular bone.) (b) Cone-beam tomogram of the premolar region of the maxilla. Note that at this site the dimension of the basal bone is very small. (c) Tomogram of an anterior maxillary tooth with a "normal" direction of eruption. The incisor resides within the bony compartment of the alveolar process. (d) Tomogram of a canine tooth that erupted in a facial orientation. The facial (buccal) bone of the alveolar process is thin or even absent.

used by Amler only allowed the study of healing in the marginal portions of the empty socket, his findings are often referred to.

Amler stated that following tooth extraction, the first 24 hours are characterized by the formation of a *blood clot* in the socket. Within 2–3 days the blood clot is gradually replaced with *granulation tissue.* After 4–5 days, the *epithelium* from the margins of the soft tissue starts to proliferate to cover the granulation tissue in the socket. One week after extraction, the socket contains granulation tissue and *young connective tissue*, and *osteoid* formation is ongoing in the apical portion of the socket. After 3 weeks, the socket contains connective tissue and there are signs of mineralization of the osteoid. The *epithelium* covers the wound. After 6 weeks of healing, bone formation in the socket is pronounced and trabeculae of newly formed bone can be seen.

Amler's study was of short duration, so it could only evaluate events that took place in the marginal portion of the healing socket. His experimental data did not include the important later phase of socket healing that involves the processes of modeling and remodeling of the newly formed tissue in various parts of the alveolus. Thus, the tissue composition of the fully healed extraction site was not documented in the study.

In a later and longer-term study, Trombelli *et al*. (2008) examined socket healing in biopsies sampled during a 6-month period from human volunteers. They confirmed most of Amler's findings and reported that in the early healing phase (tissue modeling), the socket was filled with granulation tissue that was subsequently replaced with a provisional connective tissue and woven bone. In biopsies sampled in later phases of healing, it was observed that the process by which woven bone was replaced by lamellar bone and marrow, that is remodeling, was slow and exhibited great individual variation. In only a limited number of specimens representing 6 months of healing had woven bone been replaced with bone marrow and trabeculae of lamellar bone. It can be assumed therefore that tissue modeling following tooth extraction in humans is a rather rapid process, while the subsequent remodeling is slow and may take years to be completed.

The results from experiments using the dog model (Cardaropoli *et al*. 2003, Araújo & Lindhe 2005) will be used in this chapter to describe details of the various phases of socket healing, including processes of both modeling and remodeling. It should be remembered that healing of the post-extraction sites in these animal studies, including phases of modeling and remodeling, was a rapid process compared to socket healing in humans. Thus, the extraction socket was in most instances completely healed (filled with cancellous bone) after 2–3 months.

The model

Buccal and lingual full-thickness flaps are elevated and the distal roots of mandibular premolars extracted (Fig. 3-11a). The mucosal flaps are subsequently replaced to provide soft tissue coverage of the fresh extraction wound (Fig. 3-11b). Healing of the experimental sites is monitored in biopsy specimens obtained at time intervals varying from 1 day to 6 months (Fig. 3-11c).

Overall pattern of socket healing

Figure 3-12 shows a mesiodistal section of a fresh extraction socket bordered by adjacent roots. The socket walls are continuous with the alveolar bone proper of the neighboring teeth. The tissue inside the interdental (inter-radicular) septa is made up of cancellous bone and includes trabeculae of lamellar bone within bone marrow.

The empty socket is first filled with blood and a *coagulum* (clot) forms (Fig. 3-13a). Inflammatory cells (polymorphonuclear leukocytes and monocytes/macrophages) migrate into the coagulum and start to phagocytose elements of necrotic tissue. The process of wound cleansing is initiated (Fig. 3-13b). Sprouts of newly formed vessels and mesenchymal cells (from the severed periodontal ligament) enter the coagulum and *granulation tissue* is formed. The granulation tissue is gradually replaced with *provisional connective tissue* (Fig. 3-13c) and subsequently immature bone (*woven bone*) is laid down (Fig. 3-13d). The hard tissue walls of the socket – the alveolar bone proper or the bundle bone – are gradually resorbed and the socket becomes filled with immature woven bone (Fig. 3-13e). The initial phase of the healing process (tissue modeling) is now complete. In subsequent phases, the woven bone in the socket will be gradually remodeled into lamellar bone and marrow (Fig. 3-13f–h).

Important events in socket healing

Blood clotting

Immediately after tooth extraction, blood from the severed vessels will fill the socket. Proteins derived from vessels and damaged cells initiate a series of events that lead to the formation of a fibrin network (Fig. 3-14). *Platelets* form aggregates and interact with the fibrin network to produce a *coagulum* (a blood clot) that effectively plugs the severed blood vessels and stops the bleeding. The blood clot acts as a physical matrix that directs cellular movements and it contains substances that are of importance for the forthcoming healing process. Thus, the clot contains substances (i.e. *growth factors*) that (1) influence mesenchymal cells and (2) enhance the activity of inflammatory cells. Such substances will thus induce and amplify the migration of various types of cells into the socket wound, as well as their proliferation, differentiation, and synthetic activity within the coagulum.

Although the blood clot is crucial in the initial phase of wound healing, its removal is mandatory to allow the formation of new tissue. Thus, within a few days after the tooth extraction, the blood clot will

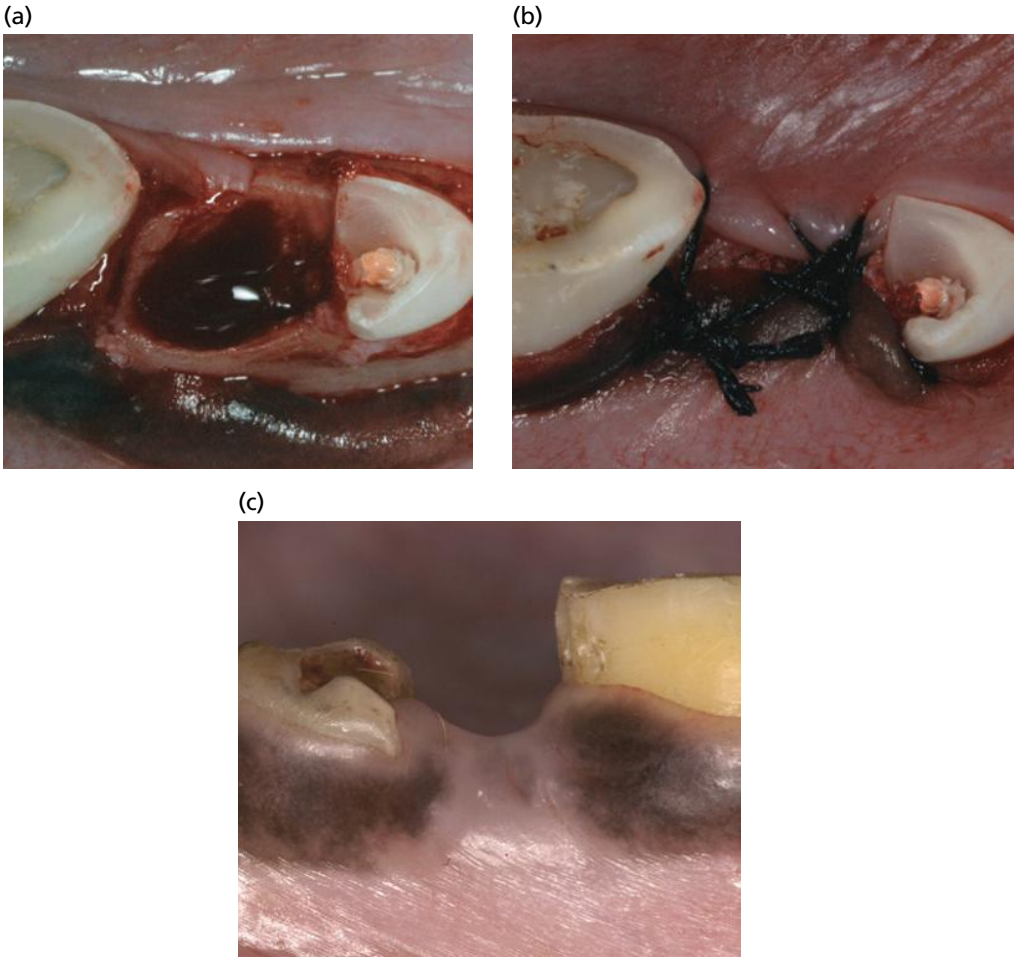

Fig. 3-11 (a) Photograph illustrating a mandibular premolar site (from a dog model) from which the distal root of the fourth premolar had been removed. (b) Mucosal, full-thickness flaps were replaced and sutured to close the entrance of the socket. (c) Site after 6 months of healing. Note the saddle-shaped outline (loss of tissue) of the alveolar crest region.

Fig. 3-12 Histologic section showing the mesiodistal aspect of a fresh extraction socket bordered by two neighboring roots. Note that the alveolar bone from the tooth sites is continuous with the walls of the empty socket. The interdental septum contains cancellous bone including trabeculae of lamellar bone and marrow.

start to break down, that is the process of "fibrinolysis" is initiated (Fig. 3-15).

Wound cleansing

Neutrophils and macrophages migrate into the wound, engulf bacteria and damaged tissue, and clean the site before the formation of new tissue can start. The neutrophils enter the wound early, while macrophages appear somewhat later. The macrophages are not only involved in the cleaning of the wound but they also release growth factors and cytokines that further promote the migration, proliferation, and differentiation of mesenchymal cells. Once the debris has been removed and the wound has been "sterilized", the neutrophils undergo a programmed cell death (*apoptosis*) and are removed from the site through the action of macrophages. The macrophages subsequently withdraw from the wound.

Tissue formation

Sprouts of vascular structures (from the severed periodontal ligament) as well as mesenchymal, fibroblast-like cells (from the periodontal ligament and from adjacent bone marrow regions) enter the socket. The mesenchymal cells start to proliferate and deposit

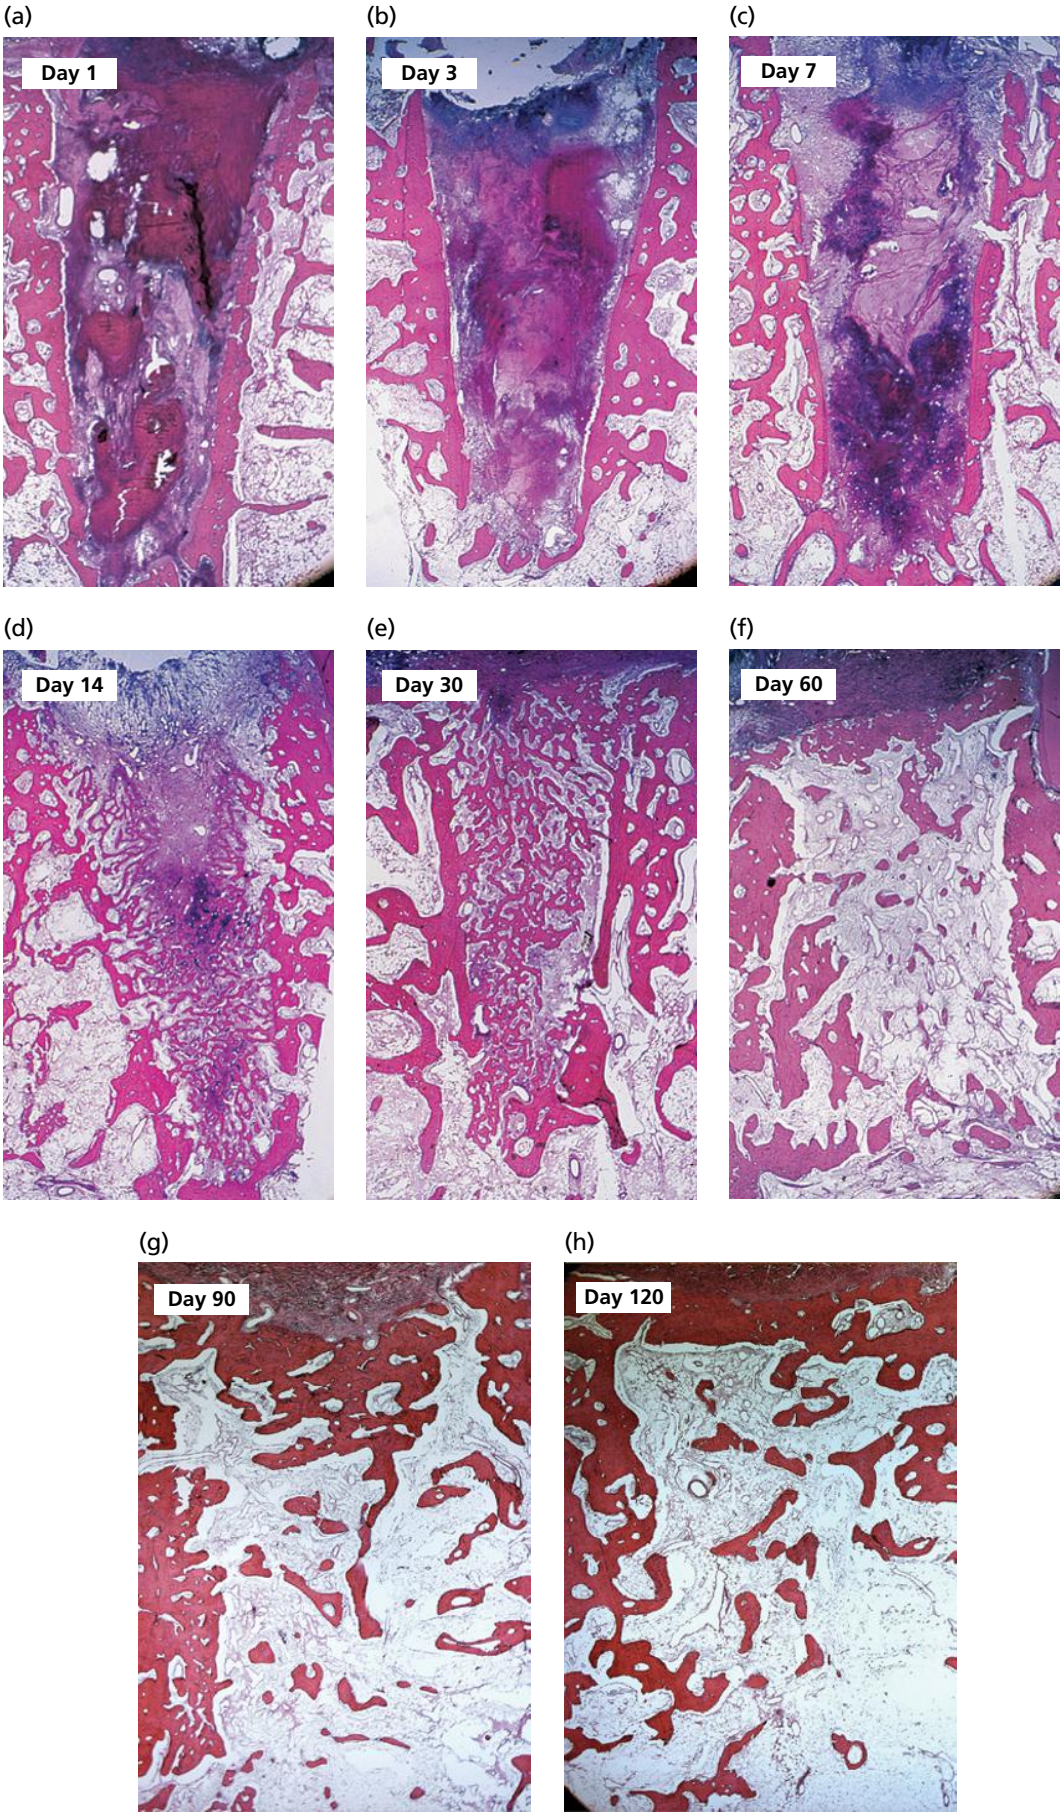

Fig. 3-13 (a–h) Overall pattern of bone formation in an extraction socket. For details see text.

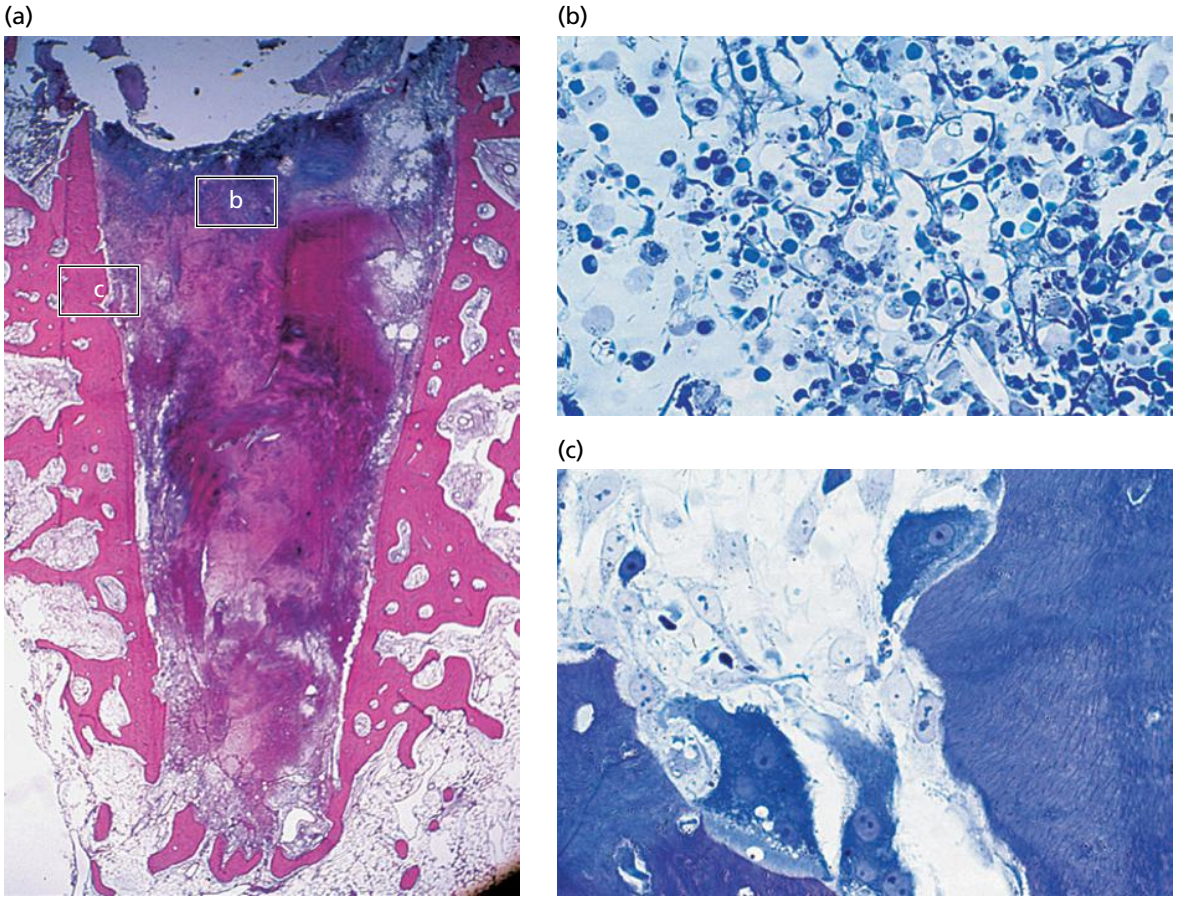

Fig. 3-15 (a) Histologic section (mesiodistal aspect) representing 3 days of healing. (b) Note the presence of neutrophils and macrophages that are engaged in wound cleansing and the breakdown of the blood clot. (c) Osteoclastic activity occurs on the surface of the old bone in the socket walls.

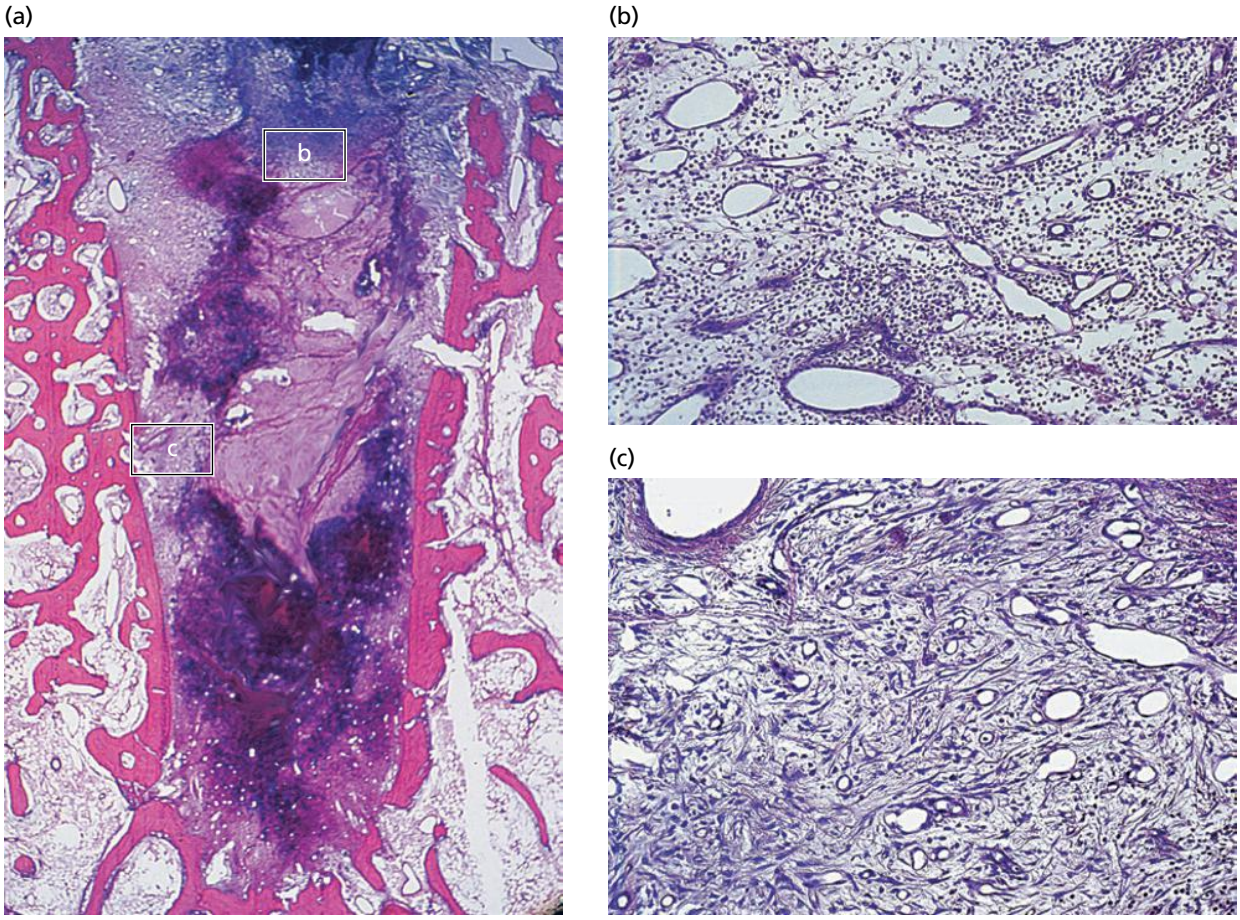

Fig. 3-16 (a) Histologic section (mesiodistal aspect) representing 7 days of healing. (b) Note the presence of a richly vascularized early granulation tissue with large numbers of inflammatory cells in the upper portion of the socket. (c) In more apical areas, a tissue including large numbers of fibroblast-like cells is present (late granulation tissue).

matrix components in an extracellular location (Fig. 3-16); *granulation tissue* will gradually replace the blood clot. This granulation tissue eventually contains macrophages and a large number of fibroblast-like cells, as well as numerous newly formed blood vessels. The fibroblast-like cells continue to (1) release growth factors, (2) proliferate, and (3) deposit a new extracellular matrix that guides the ingrowth of additional cells and allows the further differentiation of the tissue. The newly formed vessels provide the oxygen and nutrients that are needed for the increasing number of cells that occur in the new tissue. The intense synthesis of matrix components exhibited by the mesenchymal cells is called *fibroplasia*, while the formation of new vessels is called *angiogenesis*. A *provisional connective tissue* is established through the combination of fibroplasia and angiogenesis (Fig. 3-17).

The transition of the provisional connective tissue into bone tissue occurs along the vascular structures. Thus, osteoprogenitor cells (e.g. pericytes) migrate and gather in the vicinity of the vessels. They differentiate into osteoblasts that produce a matrix of collagen fibers, which takes on a woven pattern. The *osteoid* is formed. The process of mineralization is initiated within the osteoid. The osteoblasts continue to lay down osteoid and occasionally such cells are trapped in the matrix and become osteocytes. This newly formed bone is called *woven bone* (Figs. 3-17, 3-18).

The woven bone is the first type of The transition of the provisional connective tissue into bone tissue occurs along the vascular structures. Thus, osteoprogenitor cells (e.g. pericytes) migrate and gather in the vicinity of the vessels. They differentiate into osteoblasts that produce a matrix of collagen fibers, which takes on a woven pattern. The *osteoid* is formed. The process of mineralization is initiated within the osteoid. The osteoblasts continue to lay down osteoid and occasionally such cells are trapped in the matrix and become osteocytes. This newly formed bone is called *woven bone* (Figs. 3-17, 3-18).bone to be formed and is characterized by (1) its rapid deposition as finger-like projections along the route of vessels, (2) the poorly organized collagen matrix, (3) the large number of osteoblasts that are trapped in its mineralized matrix, and (4) its low load-bearing capacity. Trabeculae of woven bone are shaped around and encircle the vessel. The trabeculae become thicker through the deposition of additional woven bone. Cells (osteocytes) become entrapped in the bone tissue and the first set of osteons, the *primary osteons*, are organized. The woven bone is occasionally reinforced by the deposition of so-called *parallel-fibered bone* (collagen fibers organized not in a woven but in a concentric pattern).

It is important to realize that during this early phase of healing most of the bone tissue in the walls of the socket (the bundle bone) is removed.

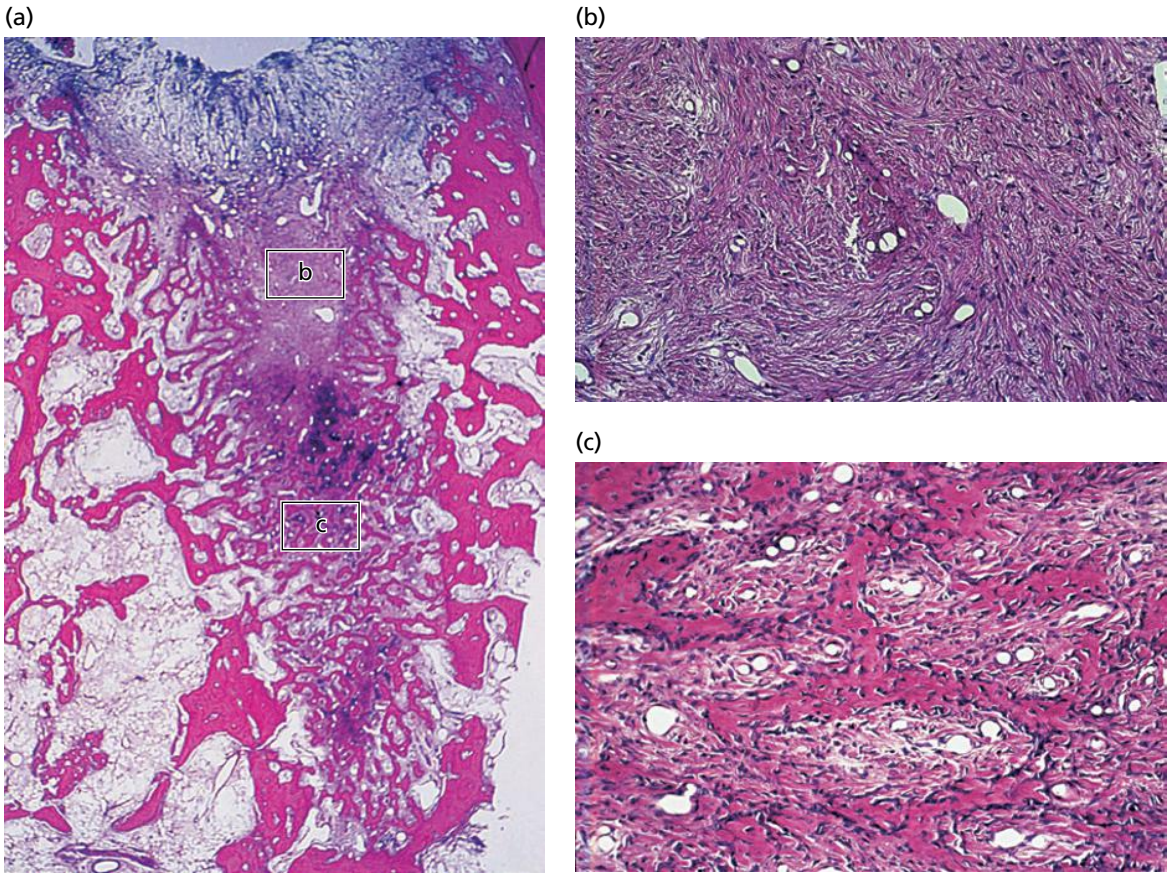

Fig. 3-17 (a) Histologic section (mesiodistal aspect) representing 14 days of healing. (b) In the marginal portion of the wound, a provisional connective tissue rich in fibroblast-like cells is present. (c) The formation of woven bone has at this time interval already begun in the apical and lateral regions of the socket.

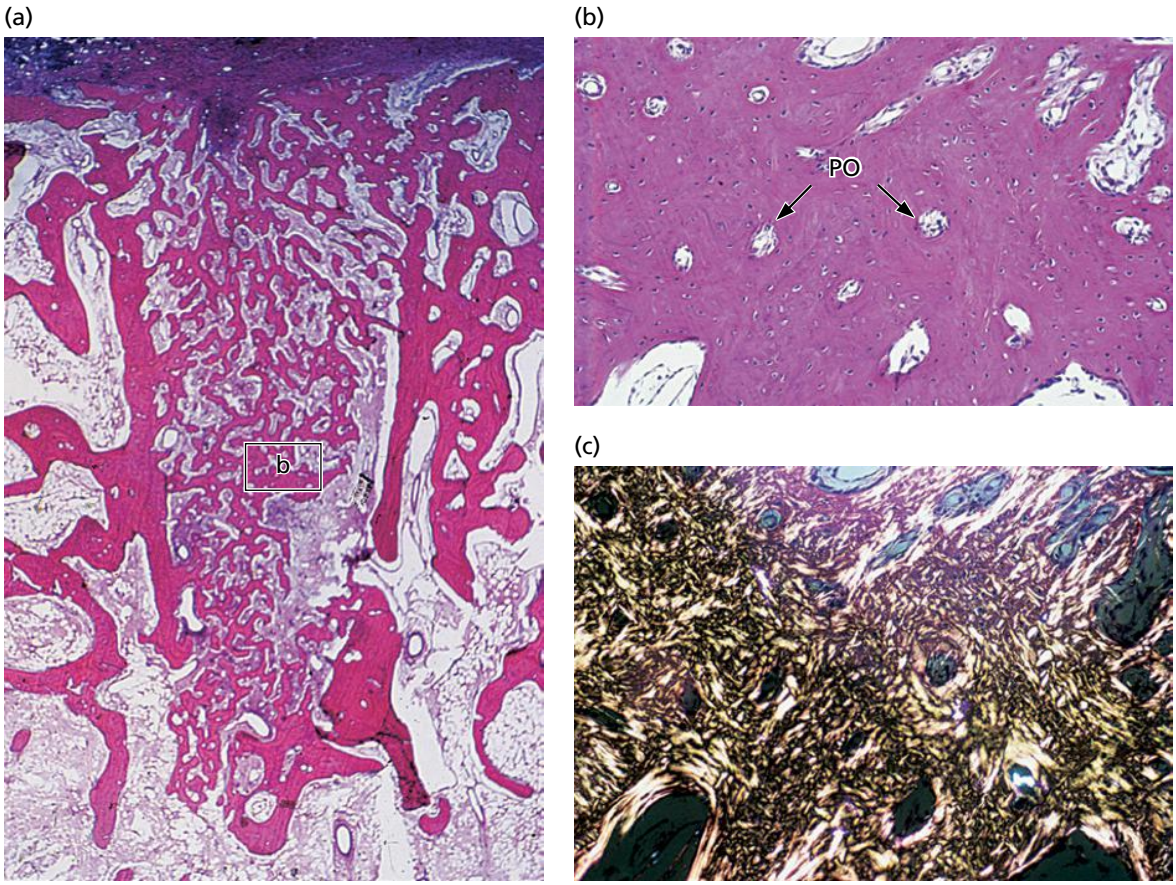

Fig. 3-18 (a) Histologic section (mesiodistal aspect) representing 30 days of healing. The socket is filled with woven bone. (b) Woven bone contains a large number of cells and primary osteons (PO). (c) The woven pattern of the collagen fibers of this type of bone is illustrated (polarized light).

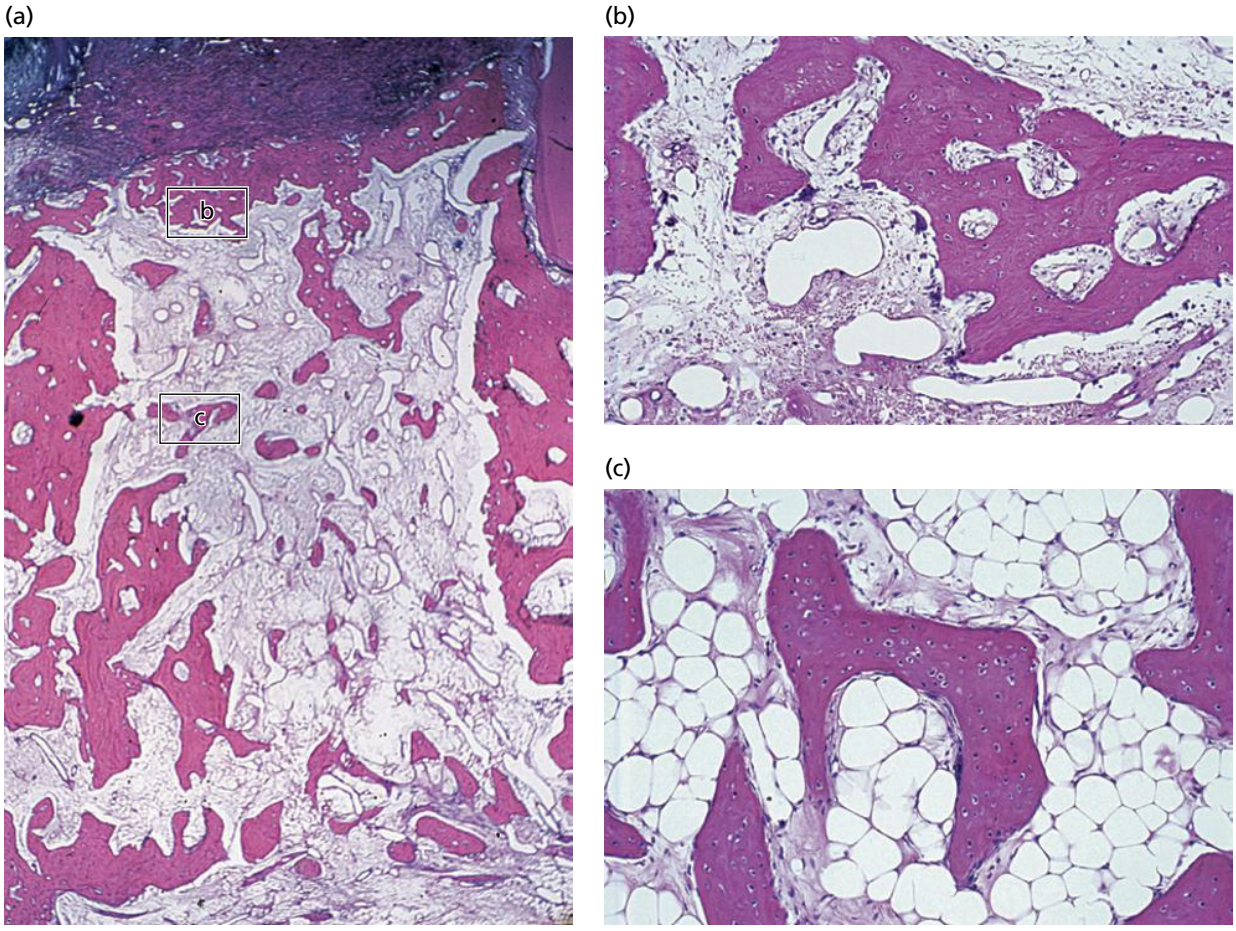

Fig. 3-19 (a) Histologic section (mesiodistal aspect) representing 60 days of healing. (b) A large portion of the woven bone has been replaced with bone marrow. (c) Note the presence of a large number of adipocytes residing in a tissue that still contains woven bone.

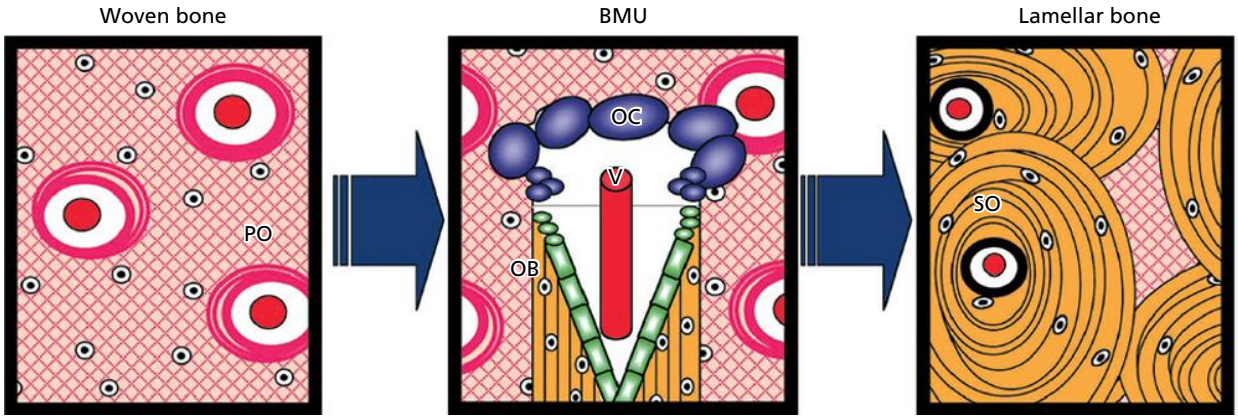

Fig. 3-20 Schematic drawing showing how woven bone is replaced by lamellar bone. Woven bone with primary osteons (PO) is substituted by lamellar bone in a process that involves the presence of bone multicellular units (BMU). The BMU contains osteoclasts (OC), as well as vascular structures (V) and osteoblasts (OB). Thus, the osteoblasts in the BMU produce bone tissue in a concentric fashion around the vessel, and lamellar bone with secondary osteons (SO) is formed.

Tissue modeling and remodeling

The initial bone formation in this dog model is a fast process. Within a few weeks, the entire extraction socket is filled with woven bone or, as this tissue is also called, *primary bone spongiosa*. The woven bone offers (1) a stable scaffold, (2) a solid surface, (3) a source of osteoprogenitor cells, and (4) an ample blood supply for cell function and matrix mineralization.

The woven bone with its primary osteons is gradually replaced with lamellar bone and bone marrow (Fig. 3-19). In this process, the primary osteons are replaced with *secondary osteons*. The woven bone is first resorbed to a certain level. The level of the resorption front will establish a so-called *reversal line*, which is also the level from which new bone with secondary osteons will form (Fig. 3-20). Although this remodeling may start early during socket healing, it will take several months until all woven bone in the extraction socket has been replaced with lamellar bone and marrow.

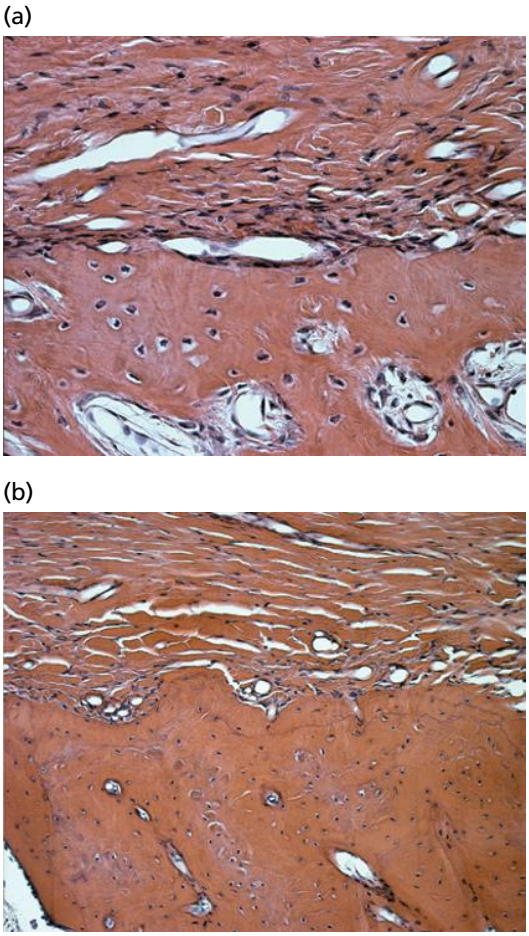

Fig. 3-21 Histologic sections (mesiodistal aspect) describing the hard tissue that has formed at the entrance of a healing extraction socket and the process of corticalization. (a) Woven bone with primary osteons occupies the socket entrance after 60 days of healing. (b) After 180 days, the woven bone has mainly been replaced with lamellar bone.

An important part of socket healing involves the formation of a *hard tissue cap* that will close the marginal entrance to the socket. This cap is initially comprised of woven bone (Fig. 3-21a), but is subsequently remodeled and replaced with lamellar bone that becomes continuous with the cortical plate at the periphery of the edentulous site (Fig. 3-21b). This process is called corticalization.

The wound is now healed, but the tissues in the site will continue to adapt to functional demands. Since there is no stress from forces elicited during mastication and other occlusal contacts, there is no demand on the mineralized bone in the areas previously occupied by the tooth. Thus, in this model the socket apical of the hard tissue cap will remodel mainly into marrow.

Extra-alveolar processes

In an experiment using the dog model (Araújo & Lindhe, 2005), alterations in the profile of the edentulous ridge that occurred following tooth extraction were carefully examined. In this study the third and fourth mandibular premolars were hemi-sected. Buccal and lingual full-thickness flaps were raised; the distal roots were carefully removed. The flaps were replaced and sutured to cover the fresh extraction socket. Biopsy specimens, including an individual extraction socket and adjacent roots, were obtained after 1, 2, 4, and 8 weeks of healing. The blocks were sectioned in the *buccolingual* plane.

- *1 week after tooth extraction* (Fig. 3-22). At this interval the socket is occupied by a coagulum. Furthermore, a large number of osteoclasts can be seen on the outside as well as on the inside of the buccal and

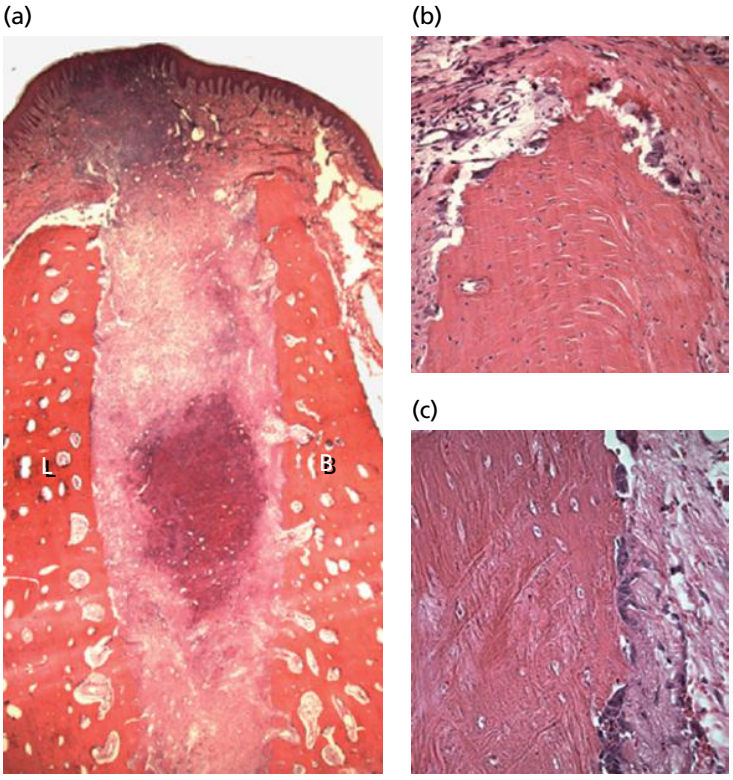

Fig. 3-22 (a) Histologic section (buccolingual aspect) of the socket after 1 week of healing. Note the presence of a large number of osteoclasts on the crestal portion (b) and inner portion (c) of the buccal wall. (B, buccal bone; L, lingual bone.)

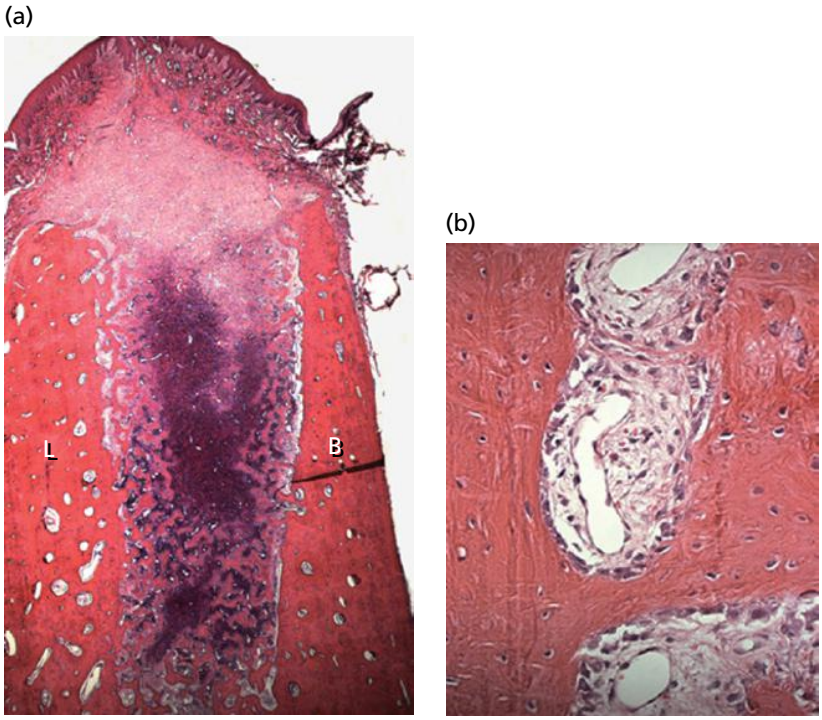

Fig. 3-23 (a) Histologic section (buccolingual aspect) of the socket after 2 weeks of healing. (b) Note that the bundle bone in the lingual aspect of the socket is being replaced with woven bone. (B, buccal bone; L, lingual bone.)

lingual bone walls. The presence of osteoclasts on the inner surface of the socket walls indicates that the bundle bone is being resorbed.

- *2 weeks after tooth extraction* (Fig. 3-23). Newly formed immature bone (woven bone) resides in the apical and lateral parts of the socket, while more central and marginal portions are occupied by a provisional connective tissue. In the marginal and outer portions of the socket walls, numerous osteoclasts can be seen. In several parts of the socket walls the bundle bone has been replaced with woven bone.
- *4 weeks after tooth extraction* (Fig. 3-24). The entire socket is occupied with woven bone at this stage of healing. Large numbers of osteoclasts are present in the outer and marginal portions of the hard tissue walls. Osteoclasts also line the trabeculae of woven bone present in the central and lateral aspects of the socket. In other words, the newly formed woven bone is being replaced with a more mature type of bone.
- *8 weeks after tooth extraction* (Fig. 3-25). A layer of cortical bone covers the entrance to the extraction site. Corticalization has occurred. The woven bone that was present in the socket at the 4-week interval is replaced with bone marrow and some trabeculae of lamellar bone in the 8-week specimens. On the outside and on the top of the buccal and lingual bone wall there are signs of ongoing hard tissue resorption. The crest of the buccal bone wall is located apical of its lingual counterpart.

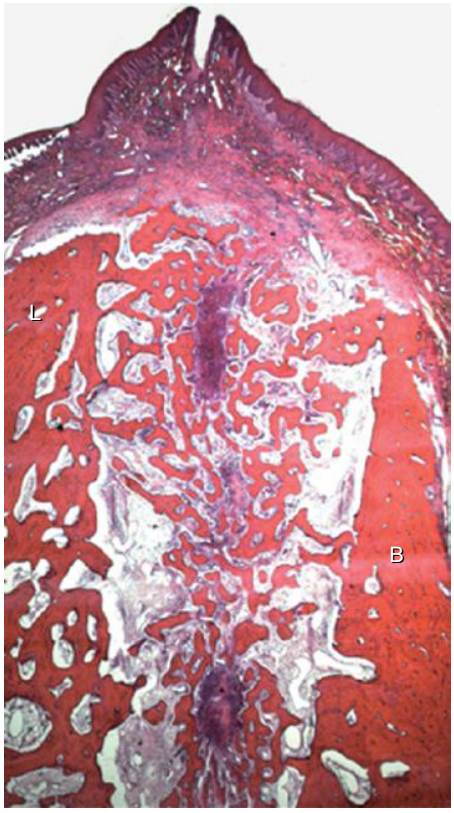

Fig. 3-24 Histologic section (buccolingual aspect) of the socket after 4 weeks of healing. The extraction socket is filled with woven bone. On the top of the buccal wall, the old bone in the crest region is being resorbed and replaced with either connective tissue or woven bone. (B, buccal bone; L, lingual bone.)

The relative change in the location of the crest of the buccal and lingual bone walls that took place during the 8 weeks of healing is illustrated in Fig. 3-26. While the level of the margin of the lingual wall remained reasonably unchanged, the margin of the buccal wall shifted several millimeters in an apical direction. The reason why more bone loss occurred in the buccal than in the lingual wall during socket healing in this animal model is not completely understood.

Prior to tooth extraction, the marginal 1–2 mm of the crest of the thin buccal bone wall was occupied by bundle bone. Only a minor fraction of the crest of the wider lingual wall contained bundle bone. Bundle bone, as stated above, is a tooth-dependent tissue and will gradually disappear after tooth extraction. Thus, since there is relatively more bundle bone in the crest region of the buccal than of the lingual wall, hard tissue loss may become most pronounced in the buccal wall.

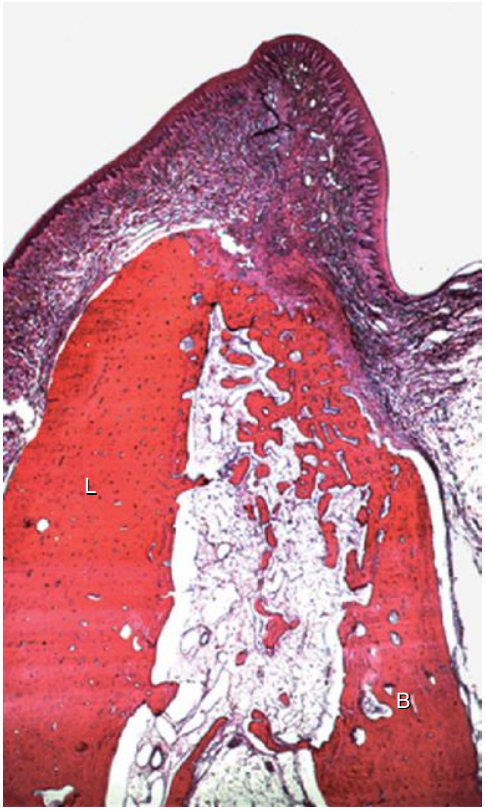

Fig. 3-25 Histologic section (buccolingual aspect) of the socket after 8 weeks of healing. The entrance of the socket is sealed with a cap of newly formed mineralized bone. Note that the crest of the buccal wall is located apical of the crest of the lingual wall. (B, buccal bone; L, lingual bone.)

Topography of the edentulous ridge: Summary

As described previously in this chapter, the processes of modeling and remodeling that occur following tooth extraction (loss) result in resorption of the various components of the previous alveolar process. The amount of tissue loss that occurs in these processes varies considerably from subject to subject and from site to site in the same individual (Figs. 3-27, 3-28).

As a rule, the resorption of the buccal bone wall is more pronounced than the resorption of the lingual/palatal wall and hence the center of the ridge will move in a lingual/palatal direction. In the extreme case, the entire alveolar process may be lost following tooth removal and then only the basal bone of the mandible and the maxilla may remain to constitute the ridge.

The outer (cortical) walls of the remaining portion of the alveolar ridge (basal bone and residues of the alveolar process) are comprised of lamellar bone. The cortical plates of the ridge often enclose the cancellous bone that harbors trabeculae of lamellar bone and marrow (Fig. 3-29). The bone marrow contains numerous vascular structures as well as adipocytes and pluripotent mesenchymal cells.

Depending on factors such as the type of jaw (maxilla or mandible), location (anterior, posterior) in the jaw, depth of the buccal and lingual vestibule, and amount of hard tissue resorption, the edentulous ridge may be lined with either masticatory, keratinized mucosa, or lining, non-keratinized mucosa.

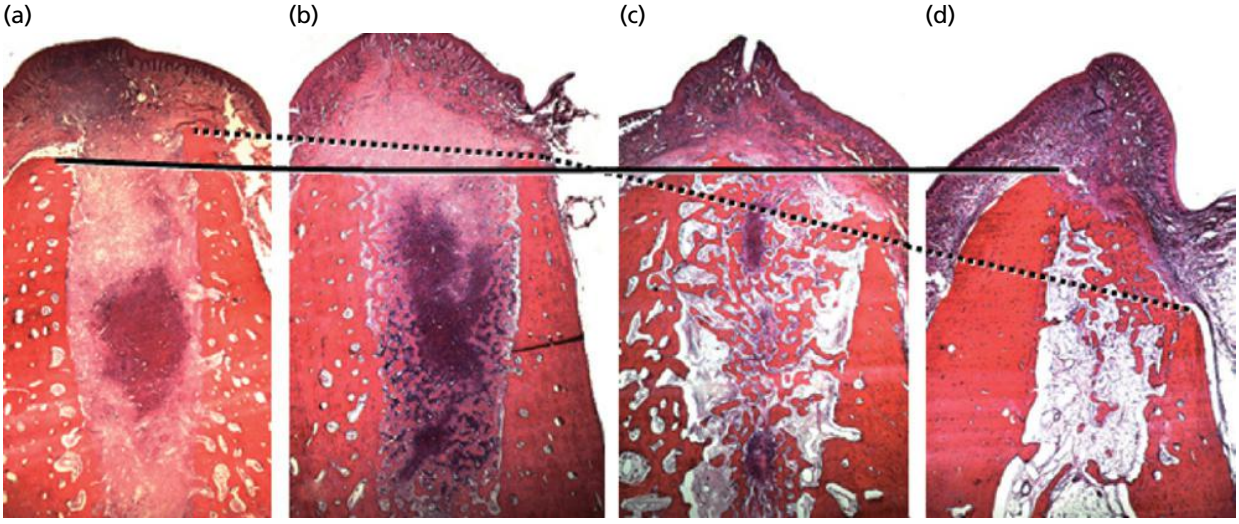

Fig. 3-26 Histologic sections (buccolingual aspects) showing the profile of the edentulous region in the dog after (a) 1, (b) 2, (c) 4, and (d) 8 weeks of healing following tooth extraction. While the marginal level of the lingual wall was maintained during the process of healing (solid line), the crest of the buccal wall was displaced >2 mm in the apical direction (dotted line).

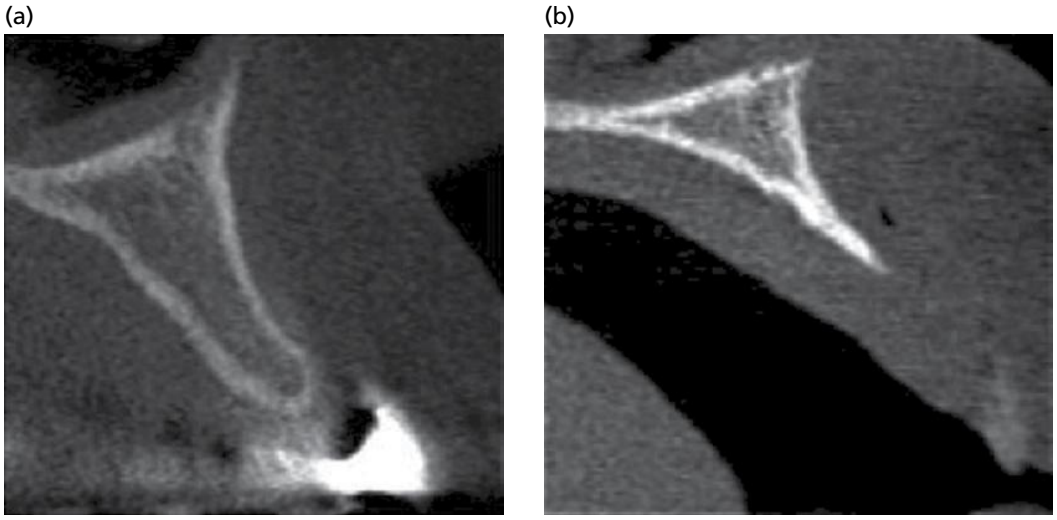

Fig. 3-27 Cone-beam computed tomograms that illustrate edentulous incisor sites of the maxilla with (a) large amounts of remaining hard tissue (cortical bone as well as trabecular bone) and (b) minute remnants of ridge tissue (only cortical bone).

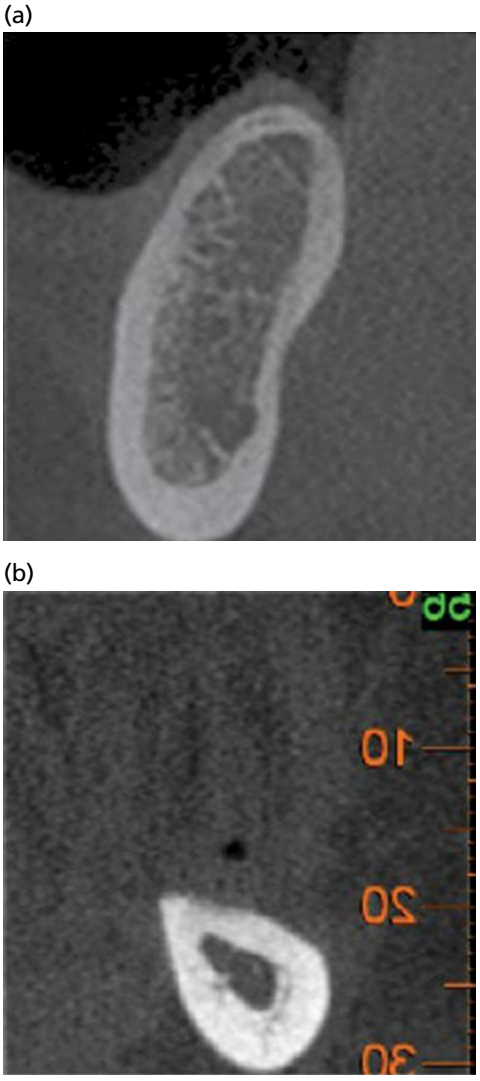

Fig. 3-28 Cone-beam computed tomograms illustrating edentulous regions of the first molar region of the mandible. (a) Remaining bone of the ridge is voluminous, is lined by dense cortical bone, and harbors large amounts of trabecular bone. (b) In this edentulous site, the entire alveolar process is lost and only the tissue of the corpus mandibulae remains.

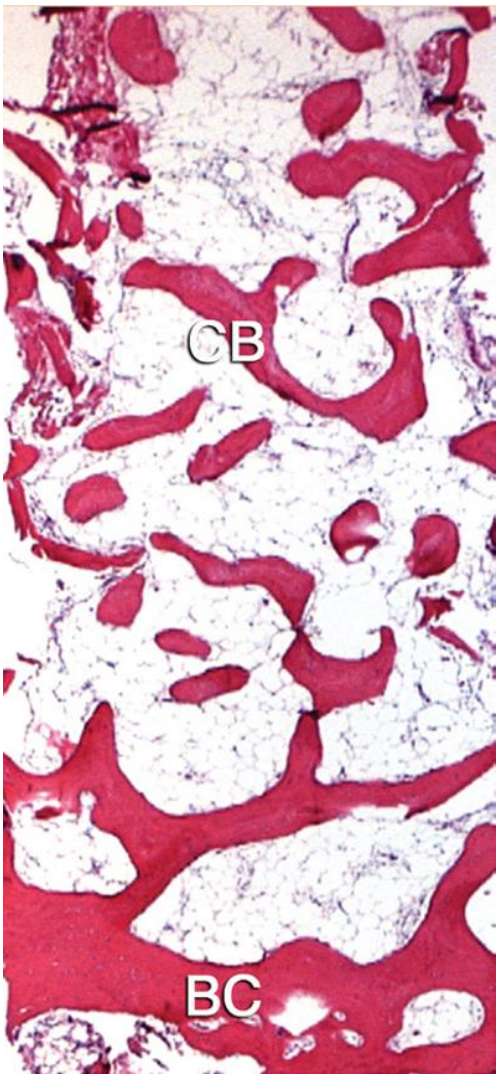

Fig. 3-29 Histologic section representing an edentulous maxilla. The biopsy was obtained >6 months post extraction. The marginal portion of the tissue (the bone crest [BC]) is comprised of dense lamellar bone, while more central portions harbor the cancellous bone (CB).

Chapter 4

The Mucosa at Teeth and Implants

Jan Lindhe, Jan L. Wennström, and Tord Berglundh

Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Gingiva

Biologic width

A term frequently used to describe the dimensions of the soft tissues that face the teeth is the *biologic width of the soft tissue attachment*. The development of the *biologic width concept* was based on studies and analyses by, among others, Gottlieb (1921), Orban and Köhler (1924), and Sicher (1959), who documented that the soft tissue attached to the teeth was comprised of two parts, one of fibrous tissue and one of epithelium. In a publication by Gargiulo *et al*. (1961) called "Dimensions and relations of the dentogingival junction in humans", sections from autopsy block specimens that exhibited different degrees of "passive tooth eruption" (i.e. periodontal tissue breakdown) were examined. Histometric assessments were made to describe the length of the sulcus (not part of the attachment), the epithelial attachment (today called the junctional epithelium), and the connective tissue attachment (Fig. 4-1). It was observed that the length of the connective tissue attachment varied within narrow limits (1.06–1.08 mm), while the length of the attached epithelium was about 1.4 mm at sites with normal periodontium, 0.8 mm at sites with moderate and 0.7 mm at sites with advanced periodontal tissue breakdown. In other words, (1) the biologic width of the attachment varied between about 2.5 mm in the normal case and 1.8 mm in the advanced disease case, and (2) the most variable part of the attachment was the length of the epithelial attachment (junctional epithelium).

Dimensions of the buccal tissue

The morphologic characteristics of the gingiva are related to the dimension of the alveolar process, the form (anatomy) of the teeth, events that occur during tooth eruption, and the eventual inclination and position of the fully erupted teeth (Wheeler 1961; O'Connor & Biggs 1964; Weisgold 1977). Oschenbein and Ross (1969) and Becker *et al*. (1997) proposed (1) that the anatomy of the gingiva is related to the contour of the osseous crest and (2) that two basic types of gingival architecture may exist, namely the "*pronounced scalloped*" and the "*flat*" biotype.

Subjects who belong to the "*pronounced scalloped*" biotype have long and slender teeth with tapered crown form, delicate cervical convexity, and minute interdental contact areas that are located close to the incisal edge (Fig. 4-2). The maxillary front teeth of such individuals are surrounded by a thin free gingiva, the buccal margin of which is located at or apical of the cementoenamel junction. The zone of gingiva is narrow, and the outline of the gingival margin is highly scalloped (Olsson *et al*. 1993). On the

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

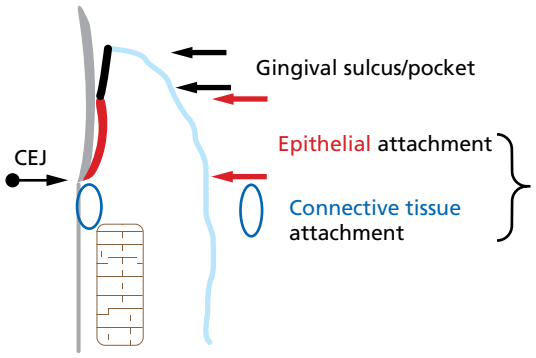

Fig. 4-1 Schematic drawing describing the "biologic width" of the soft tissue attachment at the buccal surface of a tooth with healthy periodontium. The combined length of the junctional epithelium (epithelial attachment) and the connective tissue attachment is considered to represent the "biologic width" of the soft tissue attachment. Note the gingival sulcus is *not* part of the attachment.

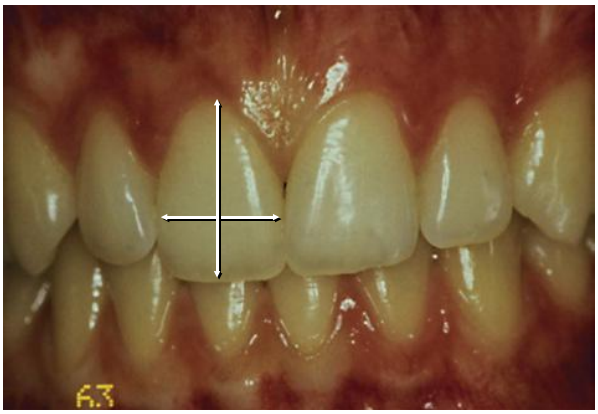

Fig. 4-2 Clinical photograph of a subject who belongs to the "pronounced scalloped" gingival biotype. The crowns of the teeth are comparatively long and slender. The papillae are comparatively long, the gingival margin is thin, and the zone of attached gingiva is short.

other hand, subjects who belong to the "*flat*" gingival biotype have incisors with squared crown form with pronounced cervical convexity (Fig. 4-3). The gingiva of such individuals is wider and more voluminous, the contact areas between the teeth are large and more apically located, and the interdental papillae are short. It was reported that subjects with a pronounced scalloped gingiva often exhibited more advanced soft tissue recession in the anterior maxilla than subjects with a flat gingiva (Olsson & Lindhe 1991).

Kan *et al*. (2003) measured the dimension of the gingiva – as determined by bone sounding – at the buccomesial and buccodistal aspects of maxillary anterior teeth. Bone sounding determines the distance between the soft tissue margin and the crest of the bone and, hence, provides an estimate that is about 1 mm greater than that obtained in a regular probing pocket depth measurement. The authors reported that the thickness of the gingiva varied between subjects of different gingival biotypes. Thus, the height of the gingiva at the buccal-approximal surfaces in subjects who belonged to the flat biotype was, on average, 4.5 mm, while in subjects belonging

Fig. 4-3 Clinical photograph of a subject who belongs to the "flat" gingival biotype. The crowns of the teeth are comparatively short but wide. The papillae are comparatively short but voluminous and the zone of attached gingiva is wide.

to the pronounced scalloped biotype the corresponding dimension (3.8 mm) was significantly smaller. This indicates that subjects who belong to the flat biotype have more voluminous soft buccal/approximal tissues than subjects who belong to the pronounced scalloped biotype.

Pontoriero and Carnevale (2001) evaluated the reformation of the gingival unit at the buccal aspect of teeth exposed to crown lengthening procedures using a denudation technique. At the 1-year follow-up examination after surgery, the regain of soft tissue – measured from the level of the denuded osseous crest – was greater in patients with a thick (flat) biotype than in those with a thin (pronounced scalloped) biotype (3.1 mm versus 2.5 mm). No assessment was made of the bone level change that had occurred between the baseline and the follow-up examination. It must, however, be anticipated that some bone resorption had taken place during healing and that the biologic width of the new connective tissue attachment had been re-established coronal to the level of the resected osseous crest.

The dimensions of the buccal gingiva may also be affected by the buccolingual position of the tooth within the alveolar process. A change of the tooth position in the buccal direction results in reduced dimensions of the buccal gingiva, while an increase is observed following a lingual tooth movement (Coatoam *et al*. 1981; Andlin-Sobocki & Brodin 1993). In fact, Müller and Könönen (2005) demonstrated in a study of the variability of the thickness of the buccal gingiva of young adults that most of the variation in gingival thickness was due to the tooth position and that the contribution of subject variability (i.e. flat and pronounced scalloped biotypes) was minimal.

Dimensions of the interdental papilla

The interdental papilla in a normal, healthy dentition has one buccal and one lingual/palatal component that are joined in the col region (see Chapter 1;

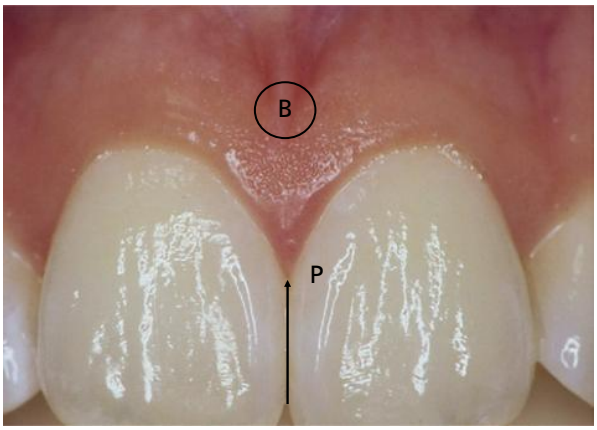

Fig. 4-4 Tarnow *et al.* (1992) measured the distance between the contact point (P) between the crowns of the teeth and the bone crest (B) using sounding (transgingival probing).

Figs. 1-1, 1-2, 1-3, 1-4, 1-5, 1-6, 1-7, 1-8, 1-9). Experiments performed in the 1960s (Kohl & Zander 1961; Matherson & Zander 1963) revealed that the shape of the papilla in the col region was not determined by the outline of the bone crest, but by the shape of the contact relationship that existed between adjacent teeth.

Tarnow *et al*. (1992) studied whether the distance between the contact point (area) between teeth and the crest of the corresponding interproximal bone could influence the degree of papilla fill that occurred at the site. Presence or absence of a papilla was determined visually in periodontally healthy subjects. If there was no space visible apical of the contact point, the papilla was considered complete. If a "black space" was visible at the site, the papilla was considered incomplete. The distance between the facial level of the contact point and the bone crest (Fig. 4-4) was measured by sounding. The measurement thus included not only the epithelium and connective tissue of the papilla, but in addition the entire supraalveolar connective tissue in the interproximal area (Fig. 4-5). The authors reported that the papilla was always complete when the distance from the contact point to the crest of the bone was ≤5 mm. When this distance was 6 mm, papilla fill occurred in about 50% of cases and when ≥7 mm, it was incomplete in about 75% of cases. Considering that the supracrestal connective tissue attachment is about 1 mm high, these data indicate that the papilla height may be limited to about 4 mm in most cases. Interestingly, papillae of similar height (3.2–4.3 mm) were found to reform following surgical denudation procedures (van der Velden 1982; Pontoriero & Carnevale 2001), but to a greater height in patients with a thick (flat) than in those with a thin (pronounced scalloped) biotype.

Summary

- *Flat gingival (periodontal) biotype*: the buccal marginal gingiva is comparatively thick, the papillae are often short, the bone of the buccal cortical wall is thick, and the vertical distance between the interdental bone crest and the buccal bone is short (about 2 mm).
- *Pronounced scalloped gingival (periodontal) biotype*: the buccal marginal gingiva is delicate and may often be located apical of the cementoenamel junction (receded), the papillae are high and slender, the buccal bone wall is often thin, and the vertical distance between the interdental bone crest and the buccal bone is long (>4 mm).

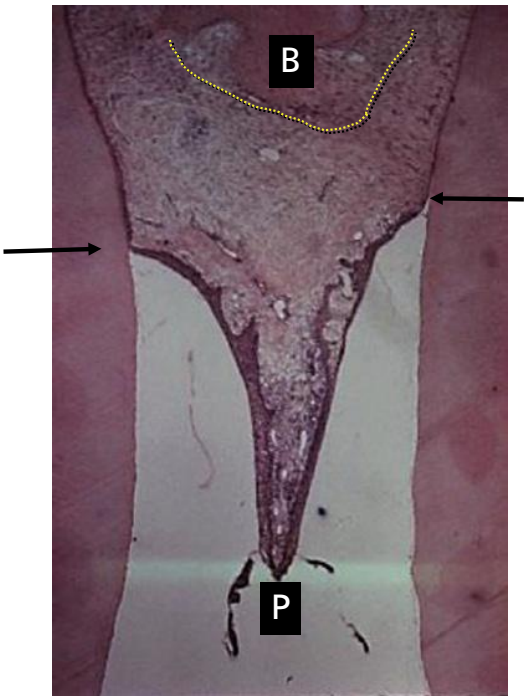

Fig. 4-5 Mesiodistal section of the interproximal area between the two central incisors. Arrows indicate the location of the cementoenamel junction. Dotted line indicates the outline of the marginal bone crest. The distance between the contact point (P) between the crowns of the teeth and the bone crest (B) indicates the height of the papilla.

Peri-implant mucosa

The soft tissue that surrounds dental implants is termed *peri-implant mucosa*. Features of the peri-implant mucosa are established during the process of wound healing that occurs subsequent to the closure of mucoperiosteal flaps following implant installation (one-stage procedure) or following abutment connection (two-stage procedure) surgery. Healing of the mucosa results in the establishment of a soft tissue attachment (transmucosal attachment) to the implant. This attachment serves as a seal that prevents products from the oral cavity reaching the bone tissue, and thus ensures osseointegration and the rigid fixation of the implant.

The peri-implant mucosa and the gingiva have several clinical and histologic characteristics in common. Some important differences, however, also exist between the gingiva and the peri-implant mucosa.

Biologic width

The structure of the mucosa that surrounds implants made of titanium has been examined in humans and several animal models (for review, see Berglundh 1999). In an early study in the dog, Berglundh *et al.* (1991) compared some anatomic features of the gingiva at teeth and the mucosa at implants. Details of the research model used in this study are briefly outlined here, as this model was used in subsequent experiments that will be described in this chapter.

The mandibular premolars on one side of the mandible were extracted, leaving the corresponding teeth in the contralateral jaw quadrant. After 3 months of healing following tooth extraction (Fig. 4-6), the fixture part of the implants (Brånemark System®; Nobel Biocare, Gothenburg, Sweden) were installed (Fig. 4-7) and submerged according to the guidelines in the manual for the system. Another 3 months later, abutment connection was performed (Fig. 4-8) in a second-stage procedure, and the animals were placed in a carefully monitored plaque-control program. Four months subsequent to abutment connection, the dogs were exposed to a clinical examination following which biopsy specimens of several tooth and all implant sites were harvested.

The clinically healthy gingiva and peri-implant mucosa had a pink color and a firm consistency (Fig. 4-9). On radiographs obtained from the tooth sites, it was observed that the alveolar bone crest was located about 1 mm apical of a line connecting the cementoenamel junction of neighboring premolars (Fig. 4-10). The radiographs from the implant sites disclosed that the bone crest was close to the junction between the abutment and the fixture part of the implant (Fig. 4-11).

Histologic examination of the sections revealed that the two soft tissue units, the gingiva and the peri-implant mucosa, had several features in common. The oral epithelium of the gingiva was well

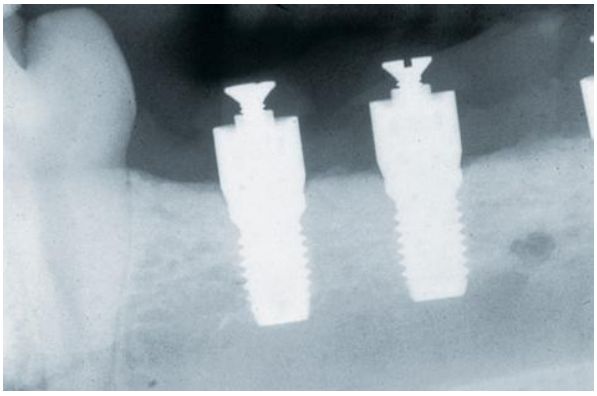

Fig. 4-11 Radiograph obtained of the implants in the right side of the mandible.

keratinized and continuous with the thin junctional epithelium that faced the enamel and that ended at the cementoenamel junction (Fig. 4-12). The supra-alveolar connective tissue was about 1 mm high and the periodontal ligament about 0.2–0.3 mm wide. The principal fibers were observed to extend from the root cementum in a fan-shaped pattern into the soft and hard tissues of the marginal periodontium (Fig. 4-13).

The outer surface of the peri-implant mucosa was also covered by a keratinized oral epithelium, which in the marginal border connected with a thin barrier epithelium (similar to the junctional epithelium at the teeth) that faced the abutment part of the implant (Fig. 4-14). It was observed that the barrier epithelium was only a few cell layers thick (Fig. 4-15) and that the epithelial structure terminated about 2 mm apical of the soft tissue margin (Fig. 4-14) and 1–1.5 mm from the bone crest. The connective tissue in the compartment above the bone appeared to be in direct contact with the surface (TiO_2) of the implant (Figs. 4-14, 4-15, 4-16). The collagen fibers in this connective tissue apparently originated from the periosteum of the bone crest and extended towards the margin of the soft tissue in directions parallel to the surface of the abutment.

The observation that the barrier epithelium of the healthy mucosa consistently ended at a certain

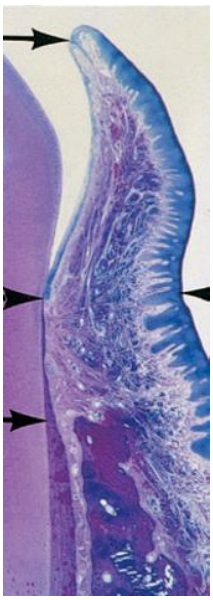

Fig. 4-12 Microphotograph of a cross-section of the buccal and coronal part of the periodontium of a mandibular premolar. Note the position of the soft tissue margin (top arrow), the apical cells of the junctional epithelium (center arrowheads), and the crest of the alveolar bone (bottom arrow). The junctional epithelium is about 2 mm long and the supracrestal connective tissue portion about 1 mm high.

distance (1–1.5 mm) from the bone is important. During healing following implant installation surgery, fibroblasts of the connective tissue of the mucosa apparently formed a biologic attachment to the TiO_2 layer of the "apical" portion of the abutment portion of the implant. This attachment zone was evidently not recognized as a wound and was therefore not covered with an epithelial lining.

In further dog experiments (Abrahamsson *et al.* 1996, 2002), it was observed that a similar mucosal attachment formed when different types of implant

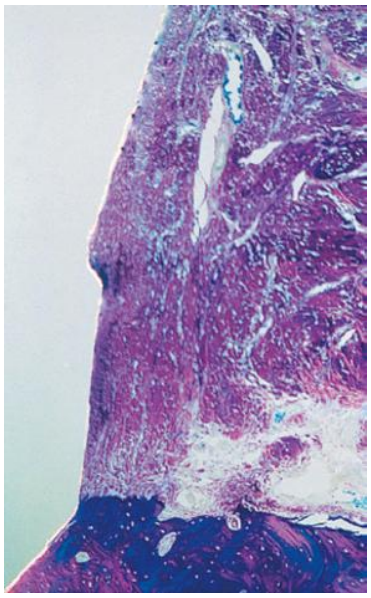

Fig. 4-16 Microphotograph of a section (buccolingual) of the implant–connective tissue interface of the peri-implant mucosa. The collagen fibers invest in the periosteum of the bone and project in directions parallel to the implant surface towards the margin of the soft tissue.

Fig. 4-17 Implants of three systems installed in the mandible of a Beagle dog. AstraTech Implants® Dental System (left), Brånemark System® (center) and ITI® Dental Implant System (right).

systems were used (e.g. AstraTech Implant System, AstraTech Dental, Mölndal, Sweden; Brånemark System®; Straumann® Dental Implant System, Straumann AG, Basel, Switzerland; 3i® Implant System, Implant Innovation Inc., West Palm Beach, FL, USA). In addition, the formation of the attachment appeared to be independent of whether the implants were initially submerged or not (Figs. 4-17, 4-18).

In subsequent studies (Abrahamsson *et al*. 1998; Welander *et al*. 2008), it was demonstrated that the material used in the abutment part of the implant was of decisive importance for the location of the connective tissue portion of the transmucosal attachment. Abutments made of aluminum-based sintered ceramic (Al_2O_3) and zirconium dioxide (ZrO_2) allowed for the establishment of a mucosal attachment similar to that which occurred at titanium abutments. Abutments made of a gold alloy or dental

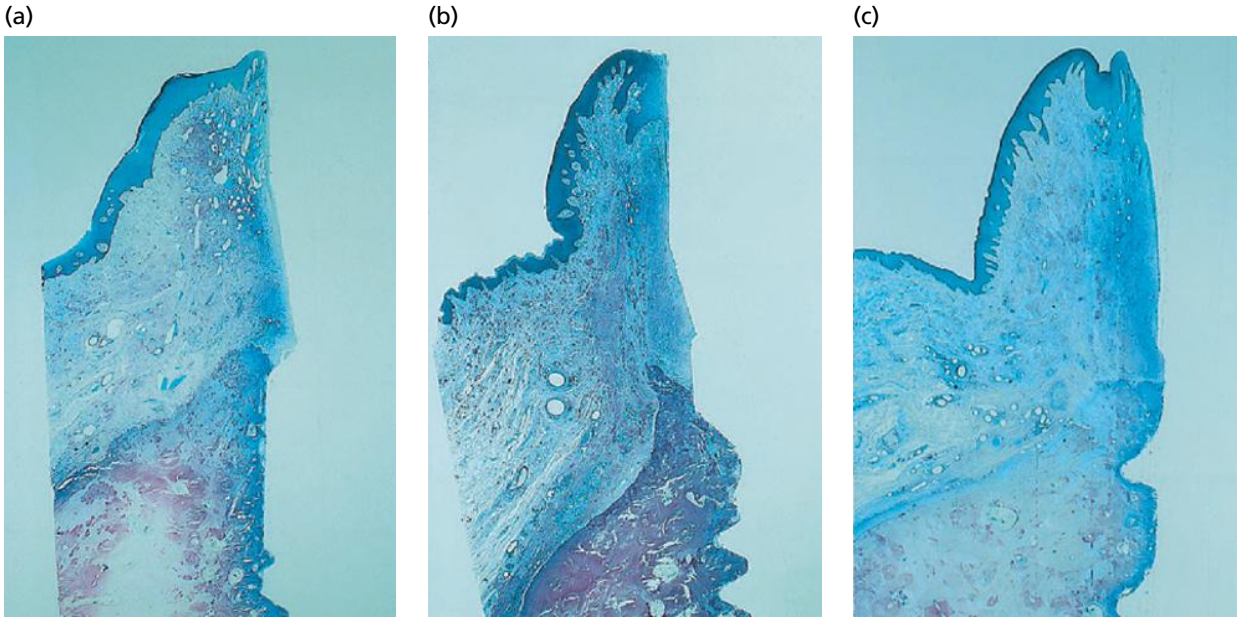

Fig. 4-18 Microphotographs illustrating the mucosa (buccolingual view) facing the three implant systems. (a) AstraTech Implants® Dental System. (b) Brånemark System®. (c) ITI® Dental Implant System.

porcelain, however, provided conditions for inferior mucosal healing. When such materials were used, the connective tissue attachment failed to develop at the abutment level. Instead, the connective tissue attachment occurred in a more apical location. Thus, during healing following the abutment connection surgery, some resorption of the marginal peri-implant bone took place to expose the titanium portion of the fixture (Brånemark System®) to which the connective tissue attachment eventually formed.

The location and dimensions of the transmucosal attachment were examined in a dog experiment by Berglundh and Lindhe (1996). Implants (fixtures) of the Brånemark System® were installed in edentulous premolar sites and submerged. After 3 months of healing, abutment connection was performed. On the left side of the mandible, the volume of the ridge mucosa was maintained, while on the right side the vertical dimension of the mucosa was reduced to 2 mm or less (Fig. 4-19) before the flaps were replaced and sutured. In biopsy specimens obtained after another 6 months, it was observed that the transmucosal attachment at all implants included a barrier epithelium component that was about 2 mm long and a zone of connective tissue that was about 1.3–1.8 mm high.

Further examination disclosed that at sites with a thin mucosa, wound healing had consistently included marginal bone resorption to establish space for a mucosa that eventually could harbor both the epithelial and the connective tissue components of the transmucosal attachment (Figs. 4-20, 4-21).

The dimensions of the epithelial and connective tissue components of the transmucosal attachment at implants are established during wound healing following implant surgery. As is the case for bone healing after implant placement (see Chapter 5),

the wound healing in the mucosa around implants is a delicate process that requires several weeks of tissue remodeling.

In an animal experiment, Berglundh *et al*. (2007) described the morphogenesis of the mucosa attachment to implants made of c.p. titanium. A non-submerged implant installation technique was used and the mucosal tissues were secured to the conical marginal portion of the implants (Straumann® Dental Implant System) with interrupted sutures. The sutures were removed after 2 weeks and a plaque-control program was initiated. Biopsies were performed at various intervals to provide healing periods extending from day 0 (2 hours) to 12 weeks. It was reported that large numbers of neutrophils infiltrated and degraded the coagulum that occupied the compartment between the mucosa and the implant during the initial phase of healing. The first signs of epithelial proliferation were observed in specimens representing 1–2 weeks of healing and a mature barrier epithelium was seen after 6–8 weeks. It was also demonstrated that the collagen fibers of the mucosa were organized after 4–6 weeks of healing. Thus, prior to this time interval, the connective tissue is not properly arranged.

Summary: The junctional and barrier epithelia are about 2 mm long and the zones of supra-alveolar connective tissue are between 1 and 1.5 mm high. Both epithelia are attached via hemi-desmosomes to the tooth/implant surface (Gould et al. 1984). The main attachment fibers (the principal fibers) invest in the root cementum of the tooth, but at the implant site the equivalent fibers run in a direction parallel to the implant and fail to attach to the metal body. The soft tissue attachment to implants is properly established several weeks following surgery.

Quality

The quality of the connective tissue in the supra-alveolar compartments at teeth and implants was examined by Berglundh *et al*. (1991). The authors observed that the main difference between the mesenchymal tissue present at a tooth and at an implant site was the occurrence of cementum on the root surface in the former. From this cementum (Fig. 4-22), coarse dentogingival and dentoalveolar collagen fiber bundles projected in lateral, coronal, and apical directions (see Fig. 4-13). At the implant site, the collagen fiber bundles were orientated in an entirely different manner. Thus, the fibers invested in the periosteum at the bone crest and projected in directions parallel to the implant surface (Fig. 4-23). Some of the fibers became aligned as coarse bundles in areas distant from the implant (Buser *et al*. 1992).

The connective tissue in the supracrestal area at implants was found to contain more collagen fibers, but fewer fibroblasts and vascular structures, than the tissue in the corresponding location at teeth. Moon *et al*. (1999), in a dog experiment, reported that the attachment tissue close to the implant (Fig. 4-24) contained only a few blood vessels, but a large number of fibroblasts that were orientated with their long axes parallel to the implant surface (Fig. 4-25). In more lateral compartments, there were fewer fibroblasts, but more collagen fibers and

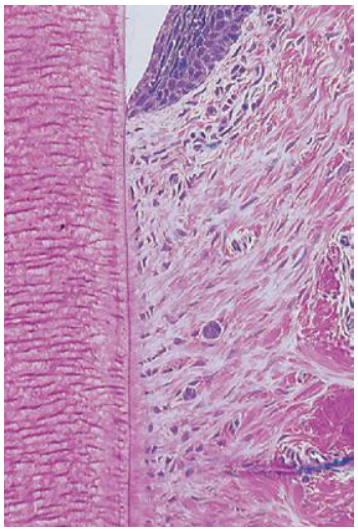

Fig. 4-22 Microphotograph of a tooth with marginal periodontal tissues (buccolingual section). Note on the tooth side the presence of an acellular root cementum with inserting collagen fibers. The fibers are orientated more or less perpendicular to the root surface.

Fig. 4-26 Buccolingual cleared section of a Beagle dog gingiva. The vessels have been filled with carbon (arrows). Note the presence of a supraperiosteal vessel on the outside of the alveolar bone, the presence of a plexus of vessels within the periodontal ligament, as well as vascular structures in the very marginal portion of the gingiva.

more vascular structures. From these and other similar findings, it may be concluded that the connective tissue attachment between the titanium surface and the connective tissue is established and maintained by fibroblasts.

Vascular supply

The vascular supply to the gingiva comes from two different sources (Fig. 4-26). The first source is represented by the large *supraperiosteal blood vessels* that put forth branches to form (1) the capillaries of the connective tissue papillae under the oral epithelium and (2) the vascular plexus lateral to the junctional epithelium. The second source is the *vascular*

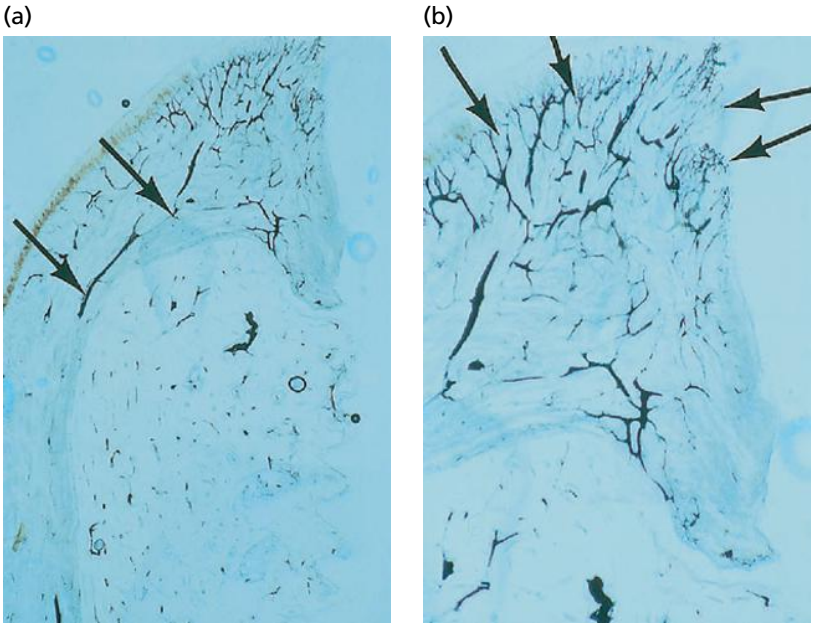

Fig. 4-27 (a) Buccolingual cleared section of a Beagle dog mucosa facing an implant (the implant was positioned to the right). Note the presence of a supraperiosteal vessel on the outside of the alveolar bone (arrows), but also that there is no vasculature that corresponds to the periodontal ligament plexus. (b) Higher magnification (of a) of the peri-implant soft tissue and the bone implant interface. Note the presence of a vascular plexus lateral to the junctional epithelium (arrows), but the absence of vessels in the more apical portions of the soft tissue facing the implant and the bone.

plexus of the periodontal ligament, from which branches run in a coronal direction and terminate in the supra-alveolar portion of the free gingiva. Thus, the blood supply to the zone of supra-alveolar connective tissue attachment in the periodontium is derived from two apparently independent sources (see Chapter 1).

Berglundh *et al.* (1994) observed that the vascular system of the peri-implant mucosa of dogs (Fig. 4-27) originated *solely* from the large *supraperiosteal blood vessel* on the outside of the alveolar ridge. This vessel gave off branches to the supra-alveolar mucosa and formed (1) the capillaries beneath the oral epithelium and (2) the vascular plexus located immediately lateral to the barrier epithelium. The connective tissue part of the transmucosal attachment to titanium implants contained only a few vessels, all of which could be identified as terminal branches of the *supraperiosteal blood vessels.*

Summary: The gingiva at teeth and the mucosa at dental implants shave some characteristics, but differ in the composition of the connective tissue, the alignment of the collagen fiber bundles, and the distribution of vascular structures in the compartment apical of the barrier epithelium.

Probing gingiva and peri-implant mucosa

It was assumed for many years that the tip of the probe in a pocket depth measurement identified the most apical cells of the junctional (pocket) epithelium or the marginal level of the connective tissue attachment. This assumption was based on findings by, for example, Waerhaug (1952), who reported that the "epithelial attachment" (e.g. Gottlieb 1921; Orban & Köhler 1924) offered no resistance to probing. Waerhaug (1952) inserted, "with the greatest caution", thin blades of steel or acrylic into the gingival pocket of various teeth of >100 young subjects without signs of periodontal pathology. In several sites the blades were placed in approximal pockets, "in which position radiograms were taken of them". It was concluded that the insertion of the blades could be performed without resulting in bleeding and that the device consistently reached the cementoenamel junction (Fig. 4-28). Thus, the epithelium or the epithelial attachment offered no resistance to the insertion of the device.

In subsequent studies it was observed, however, that the tip of a periodontal probe in a pocket depth measurement only identified the base of the dentogingival epithelium by chance. In the absence of an inflammatory lesion, the probe frequently failed to reach the apical part of the junctional epithelium (e.g. Armitage *et al.* 1977; Magnusson & Listgarten 1980). If an inflammatory lesion, rich in leukocytes and poor in collagen, was present in the gingival connective tissue, however, the probe penetrated beyond the epithelium to reach the apicolateral border of the infiltrate.

Probing depth measurements at *implant sites* was examined in various animal models. Ericsson and Lindhe (1993) used the model of Berglundh *et al.* (1991) referred to earlier and, hence, had both teeth and implants available for examination. The gingiva at mandibular premolars and the mucosa at correspondingly positioned implants (Brånemark System®) were, after extended periods of plaque control, considered clinically healthy. A probe with a tip diameter of 0.5 mm was inserted into the buccal "pocket" using a standardized force of 0.5 N. The probe was anchored to the tooth or to the implant and biopsies from the various sites were performed. The histologic examination of the biopsy material revealed that probing

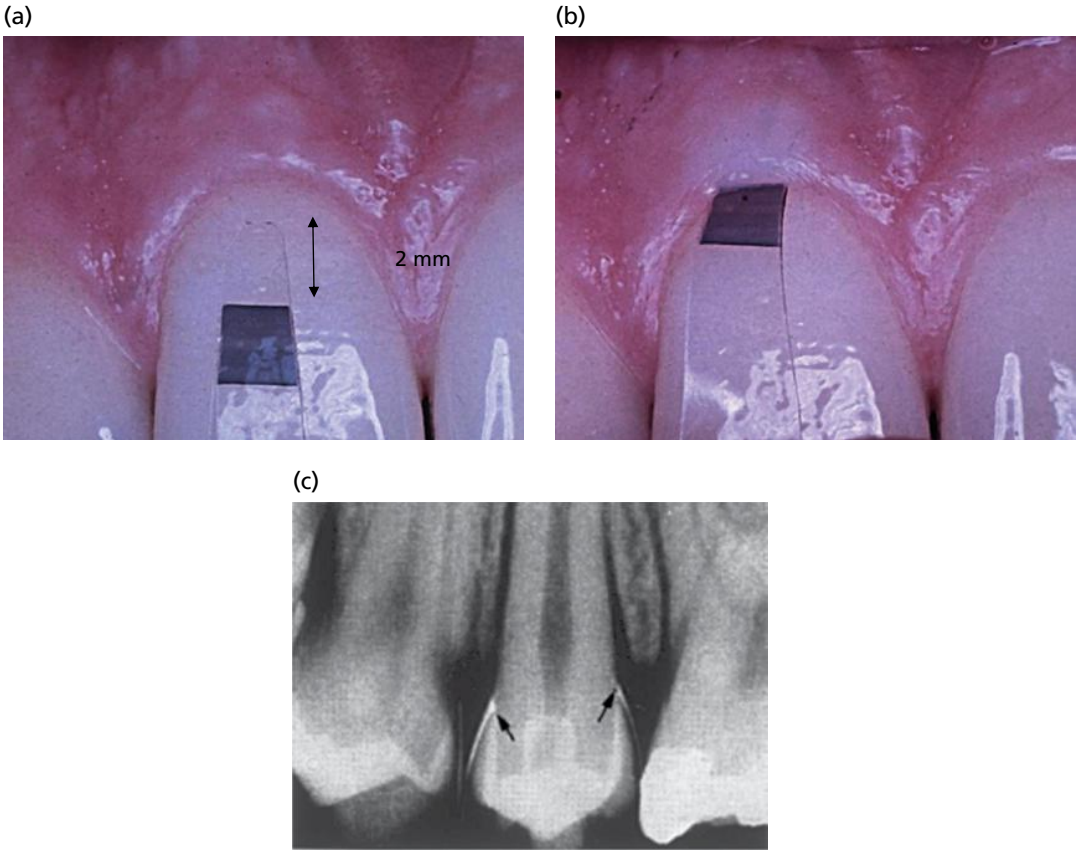

Fig. 4-28 Acrylic strip with a blue zone located 2 mm from the strip margin (a) prior to and (b) after its insertion into a buccal "pocket". With a light force the strip could be inserted 2 mm into the "pocket". (c) Thin blades of steel were inserted into pockets at approximal sites of teeth with healthy periodontal tissue. On radiographs, Waerhaug (1952) could observe that the blades consistently reached the cementoenamel junction.

the dentogingival interface had resulted in a slight compression of the gingival tissue. The tip of the probe was located coronal to the apical cells of the junctional epithelium. At the implant sites, probing caused both compression and a lateral dislocation of the peri-implant mucosa, and the average "histologic" probing depth was markedly deeper than at the tooth site: 2.0 mm versus 0.7 mm. The tip of the probe was consistently positioned deep in the connective tissue–abutment interface and apical of the barrier epithelium. The distance between the probe tip and the bone crest at the tooth sites was about 1.2 mm. The corresponding distance at the implant site was 0.2 mm. The findings presented by Ericsson and Lindhe (1993) regarding the difference in probe penetration in healthy gingiva and peri-implant mucosa are not in agreement with data reported in subsequent animal experiments.

Lang *et al*. (1994) used Beagle dogs and prepared the implant (Straumann® Dental Implant System) sites in such a way that on probing some were healthy, a few exhibited signs of mucositis, and some exhibited peri-implantitis. Probes with different geometry were inserted into the pockets using a standardized probing procedure and a force of only 0.2 N. The probes were anchored and block biopsy specimens were harvested. The probe locations were studied in histologic ground sections. The authors reported that the mean "histologic" probing depth at healthy sites was about 1.8 mm, that is similar to the depth (about 2 mm) recorded by Ericsson and Lindhe (1993). The corresponding depth at sites with mucositis and peri-implantitis was about 1.6 mm and 3.8 mm, respectively. Lang *et al*. (1994) further stated that at healthy and mucositis sites, the probe tip identified "the connective tissue adhesion level" (i.e. the base of the barrier epithelium), while at peri-implantitis sites, the probe exceeded the base of the ulcerated pocket epithelium by a mean distance of 0.5 mm. At such peri-implantitis sites, the probe reached the base of the inflammatory cell infiltrate.

Schou *et al*. (2002) compared probing measurements at implants and teeth in eight cynomolgus monkeys. Ground sections were produced from tooth and implant sites that were (1) clinically healthy, (2) slightly inflamed (mucositis/gingivitis), and (3) severely inflamed (peri-implantitis/periodontitis) and in which probes had been inserted. An electronic probe (Peri-Probe®) with a tip diameter 0.5 mm and a standardized probing force of 0.3–0.4 N was used. It was demonstrated that the probe tip was located at a similar distance from the bone in healthy tooth sites and implant sites. On the other hand, at implants exhibiting mucositis and peri-implantitis, the probe

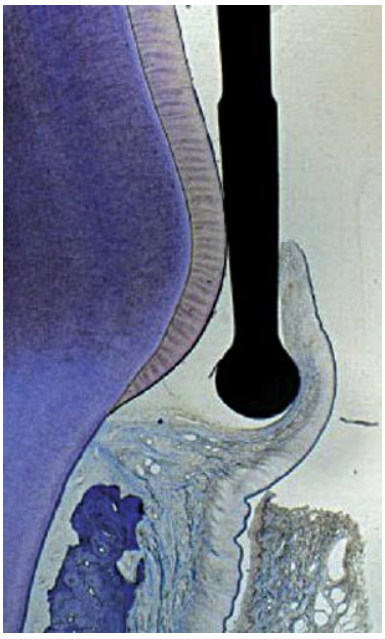

Fig. 4-29 Buccolingual ground section from a tooth site illustrating the probe tip position in relation to the bone crest. (Source: Abrahamsson & Soldini 2006. Reproduced with permission from John Wiley & Sons.).

tip was consistently identified at a more apical position than at corresponding tooth sites (gingivitis and periodontitis). The authors concluded that (1) probing depth measurements at implant and teeth yielded different information, and (2) small alterations in probing depth at implants may reflect changes in soft tissue inflammation rather than loss of supporting tissues.

Abrahamsson and Soldini (2006) evaluated the location of the probe tip in healthy periodontal and peri-implant tissues in dogs. It was reported that probing with a force of 0.2 N resulted in a probe penetration that was similar at implants and teeth. Furthermore, the tip of the probe was often at or close to the apical cells of the junctional/barrier epithelium. The distance between the tip of the probe and the bone crest was about 1 mm at both teeth and implants (Figs. 4-29, 4-30). Similar observations were reported from clinical studies in which different implant systems were used (Buser *et al*. 1990; Quirynen *et al*. 1991; Mombelli *et al*. 1997). In these studies, the distance between the probe tip and the bone was assessed in radiographs and was found to vary between 0.75 and 1.4 mm when a probing force of 0.25–0.45 N was used.

By comparing the findings from the studies reported above, it becomes apparent that probing depth and probing attachment level measurements are also meaningful at implant sites. When a "normal" probing force is applied to healthy tissues, the probe seems to reach similar levels at implant and tooth sites. Probing inflamed tissues at both tooth and implant sites will, however, result in a more advanced probe penetration and the tip of the probe may come closer to the bone crest.

Dimensions of the buccal soft tissue at implants

Chang *et al*. (1999) compared the dimensions of the periodontal and peri-implant soft tissues of 20 subjects who had been treated with an implant-supported single-tooth restoration in the esthetic zone of the maxilla and who had a non-restored natural tooth in the contralateral position (Fig. 4-31). In comparison to the natural tooth, the implant-supported crown was bordered by a thicker buccal mucosa (2.0 mm versus 1.1 mm), as assessed at a level corresponding to the bottom of the probeable pocket, and had a greater probing pocket depth (2.9 mm versus 2.5 mm) (Fig. 4-32). It was further observed that the soft tissue margin at the implant was more apically located (about 1 mm) than the gingival margin at the contralateral tooth.

Kan *et al*. (2003) studied the dimensions of the peri-implant mucosa at 45 single implants that had been placed in the anterior maxilla for an average of 33 months. Bone sounding measurements performed at the buccal aspect of the implants showed that the height of the mucosa was 3–4 mm in the majority of the cases. Less than 3 mm of mucosa height was found at only 9% of the implants. It was suggested that implants in this category (1) were found in subjects who belonged to a *thin periodontal biotype*, (2) had been placed too labially, and/or (3) had the emergence of an over-contoured facial prosthetic. A peri-implant soft tissue dimension of >4 mm was usually associated with a *thick periodontal biotype.*

Dimensions of the papilla between teeth and implants

In a study by Schropp *et al.* (2003), it was demonstrated that following single-tooth extraction the height of the papilla at the adjacent teeth was reduced by about 1 mm. Concomitant with this reduction (recession) of the papilla height, the pocket depth was reduced and some loss of clinical attachment occurred.

Following single-tooth extraction and subsequent implant installation, the height of the papilla in the tooth–implant site will be dependent on the attachment level of the tooth. Choquet *et al.* (2001) studied the papilla level adjacent to single-tooth dental implants in 26 patients and a total of 27 implant sites. The distance between the apical extension of the contact point between the crowns and the bone crest, as well as the distance between the soft tissue level and the bone crest, was measured on radiographs. The examinations were made 6–75 months after the insertion of the crown restoration. The authors observed that the papilla height consistently was about 4 mm and, depending on the location of the contact point between adjacent crown papilla, fill was either complete or incomplete (Fig. 4-33). The closer the contact point was to the incisal edge of the crowns (restorations), the less complete was the papilla fill.

Chang *et al.* (1999) studied the dimensions of the papillae at implant-supported single-tooth restorations in the anterior region of the maxilla and at non-restored contralateral natural teeth. They found that the papilla height at the implant-supported crown was significantly shorter and showed less fill of the embrasure space than the papilla at the natural tooth (Fig. 4-34). This was particularly evident for the distal papillae of implant-supported restorations in the central incisor position, both in comparison to the distal papilla at the contralateral tooth and to the papilla at the mesial aspect of the implant crown. This indicates that the anatomy of the adjacent natural teeth (e.g. the diameter of the root, the proximal outline/curvature of the cementoenamel junction/connective tissue attachment level) may have a profound influence on the dimension of the papilla lateral to an implant. Hence, the wider faciolingual root diameter and the higher proximal curvature of the cementoenamel junction of the maxillary central incisor – in comparison to corresponding dimensions of the lateral incisor (Wheeler 1966) – may favor the maintenance of the height of the mesial papilla at the single-implant–supported restoration.

Kan *et al.* (2003) assessed the dimensions of the peri-implant mucosa lateral to 45 single implants placed in the anterior maxilla and the 90 adjacent teeth using bone sounding measurements. The bone sounding measurements were performed at the mesial and distal aspects of the implants and at the mesial and distal aspects of the teeth. The authors reported that the thickness of the mucosa at the mesial/distal surfaces of the implant sites was on average 6 mm, while the corresponding dimension at the adjacent tooth sites was about 4 mm. It was further observed that the dimensions of the peri-implant mucosa of subjects who belonged to the *thick periodontal biotype* were significantly greater than those of subjects with a *thin biotype*.

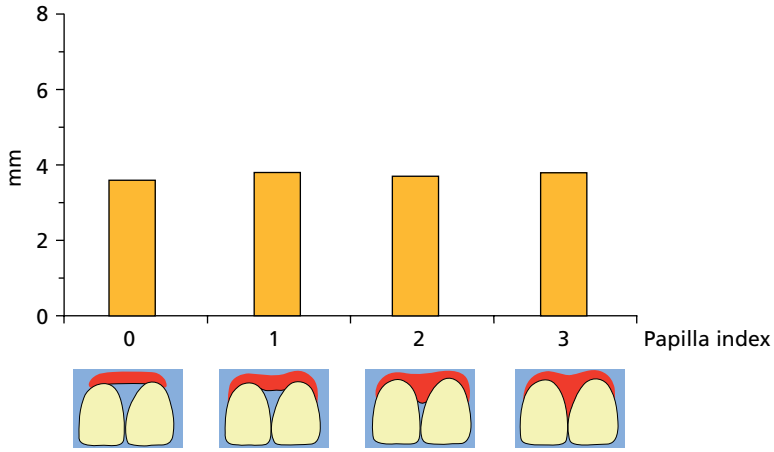

Fig. 4-33 Soft tissue height adjacent to single-tooth dental implants in relation to the degree of papilla fill. (Source: Choquet *et al*. 2001. Reproduced from the American Academy of Periodontology.)

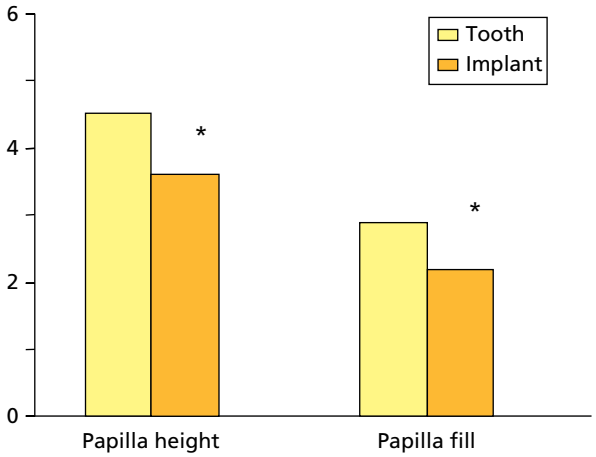

Fig. 4-34 Comparison of papilla height and papilla fill adjacent to single-implant restorations and the natural tooth in the contralateral position. (Source: Chang *et al*. 1999. Reproduced with permission from John Wiley & Sons.)

The level of the connective tissue attachment on the adjacent tooth surface and the position of the contact point between the crowns are obviously key factors that determine whether or not a complete papilla fill will be obtained at the single-tooth implant-supported restoration (Fig. 4-35). Although there are indications that the dimensions of the approximal soft tissue may vary between individuals having thin and thick periodontal biotypes, the height of the papilla at the single-implant restoration seems to have a biologic limit of about 4 mm (compare this with the dimension of the interdental papilla). Hence, to achieve a complete papilla fill of the embrasure space, a correct location of the contact area between the implant crown and the tooth crown is mandatory. In this respect it must also be recognized that the papilla fill at single-tooth implant restorations is unrelated to whether the implant is inserted according to a one- or two-stage protocol and whether a crown restoration is inserted immediately following surgery or delayed until the soft tissues have healed (Jemt 1999; Ryser *et al*. 2005).

(a)

(b)

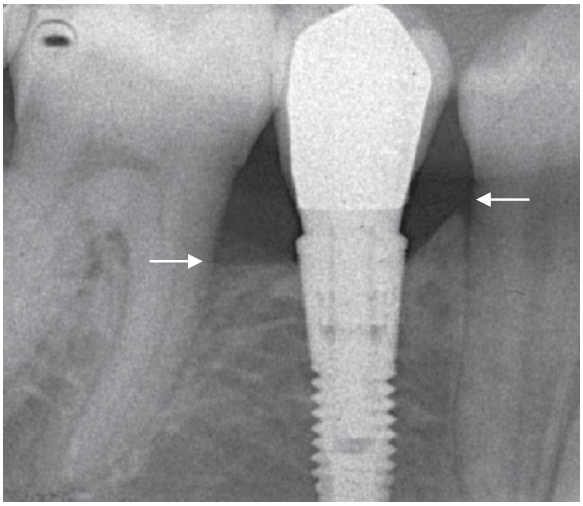

Fig. 4-35 Single implant in a mandibular premolar region. (a) Papilla fill between the implant and the first premolar is optimal, while the papilla fill between the implant and the molar is compromised and a black space is visible. (b) Radiograph from the same site showing the position of the cementoenamel junction (on the premolar) and the marginal bone level (on the molar) (arrows).

Dimensions of the "papilla" between adjacent implants

When two neighboring teeth are extracted, the papilla at the site will be lost (Fig. 4-36). Hence, at replacement of the extracted teeth with implant-supported

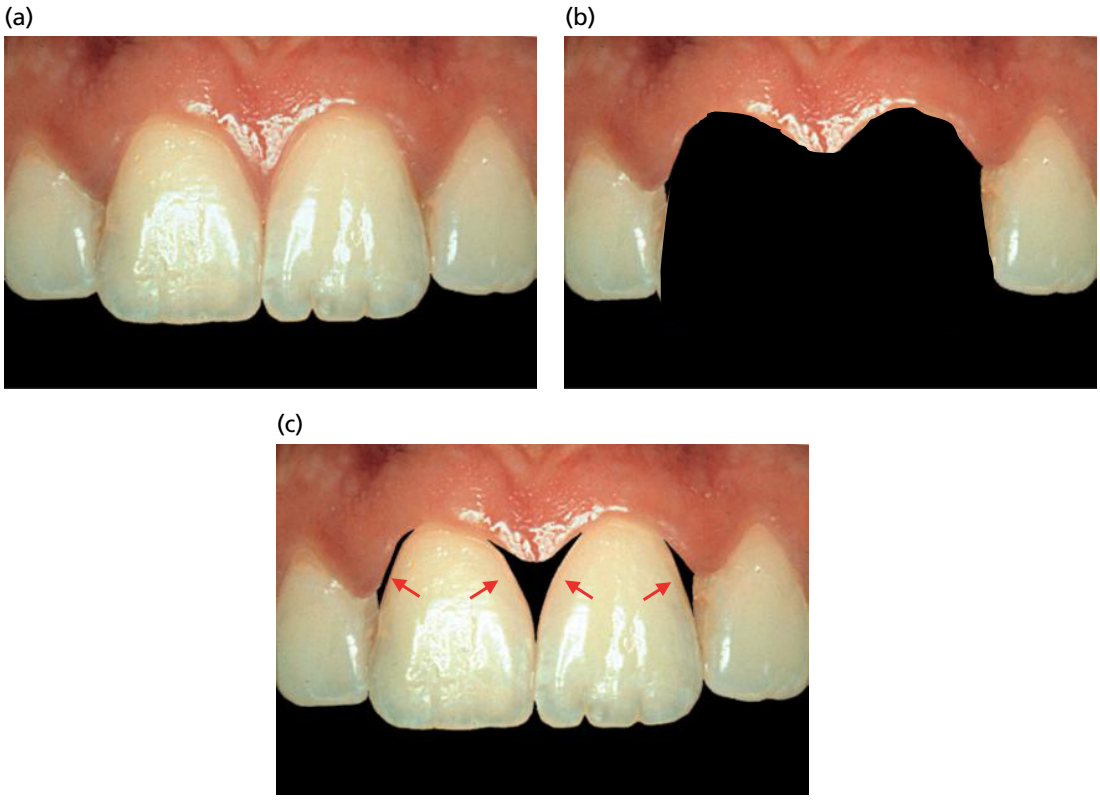

Fig. 4-36 See text for details. Arrows indicate the position of the soft tissue borders prior to the removal of the incisors.

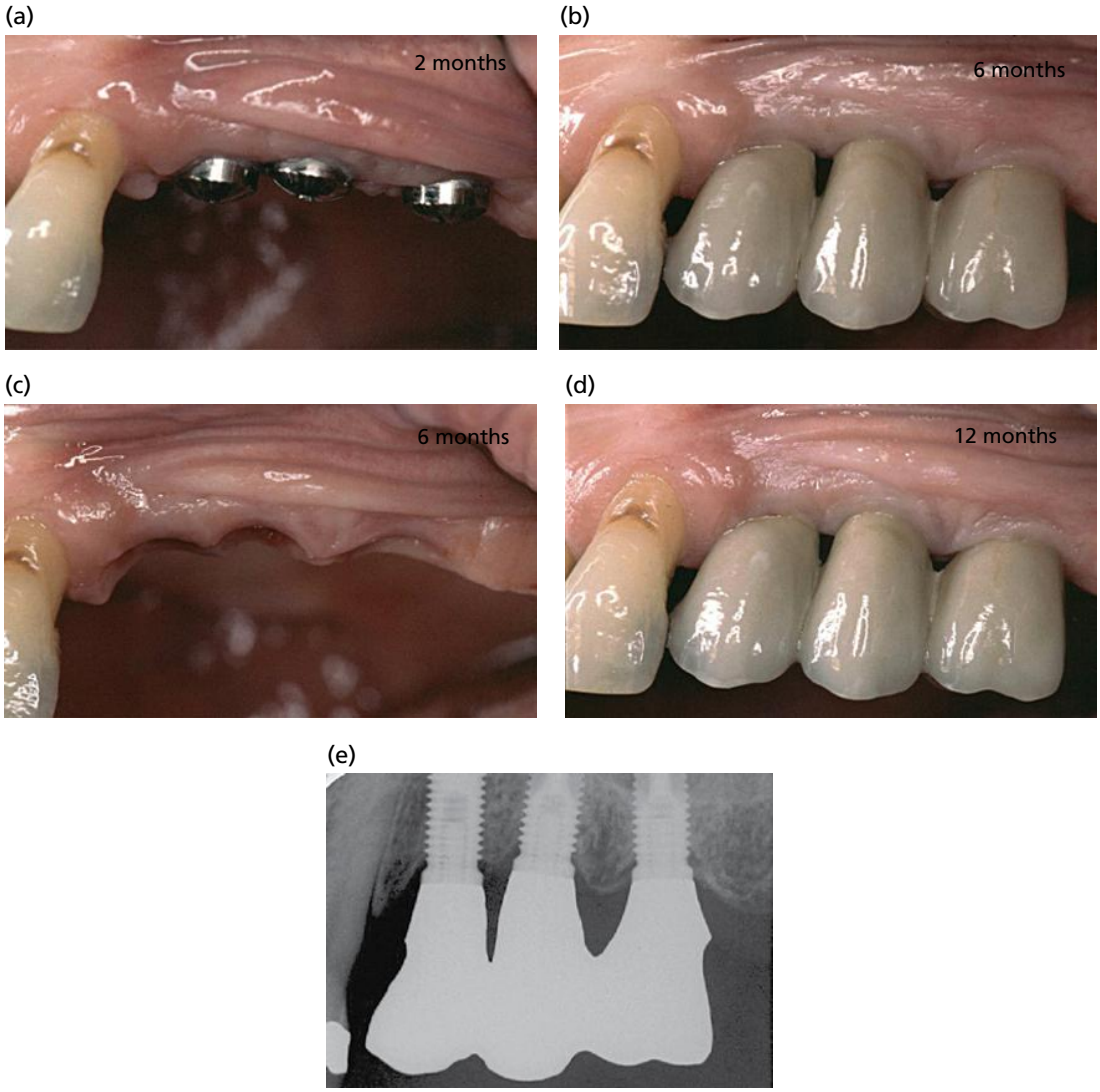

Fig. 4-37 See text for details.

restorations, the topography of the bone crest and the thickness of the supracrestal soft tissue portion are the factors that determine the position of the soft tissue margin in the interimplant area ("implant papilla"). Tarnow *et al*. (2003) assessed the height above the bone crest of the interimplant soft tissue ("implant papilla") by transmucosal probing at 136 anterior and posterior sites in 33 patients who had maintained implant-supported prostheses for at least 2 months. It was found that the mean height of the "papillae" was 3.4 mm, with 90% of the measurements in the range of 2–4 mm.

The dimension of the soft tissues between adjacent implants seems to be independent of the implant design. Lee *et al.* (2006) examined the soft tissue height between implants of two different systems (Brånemark Implant® and AstraTech Implant® systems), as well as the potential influence of the horizontal distance between implants. The height of the interimplant "papilla", that is the height of soft tissue coronal to the bone crest measured on radiographs, was about 3.1 mm for both implant systems. No difference was found regarding the "papilla" height for either of the implant systems at sites with a horizontal distance between the implants of <3 mm and those with a distance of 3 mm or greater. Gastaldo *et al.* (2004) evaluated the presence or absence of "papilla" at 96 interimplant sites in 58 patients. It was reported that the "papilla" filled the entire space between the implants only when the distance from the bone crest to the base of the contact point between the crown restorations, assessed by sounding, was <4 mm. Thus, taken together, these observations indicate that the soft tissue between two implants will have a maximum height of 3–4 mm, and that the location of the contact point between the crown restorations in relation to the bone crest level determines whether a complete soft tissue fill will be obtained in the embrasure space between two implants (Fig. 4-37).

Chapter 5

Osseointegration

Jan Lindhe,[1] Tord Berglundh,[1] and Niklaus P. Lang[2,3]

Introduction

The fully healed site of the edentulous ridge (see Chapter 3) is most often covered by a masticatory mucosa that is about 2–3 mm thick. The masticatory mucosa is covered by a keratinized epithelium and includes a connective tissue rich in collagen fibers and fibroblasts that are firmly attached to the bone via the periosteum. The outer walls of the edentulous ridge, the cortical plates, are comprised of lamellar bone and enclose the cancellous bone that contains trabeculae of lamellar bone that are embedded in bone marrow The bone marrow contains numerous vascular structures as well as adipocytes and pluripotent mesenchymal cells.

Different implant systems have been used to replace missing teeth, including subperiosteal implants, endosseous implants with fibrous encapsulation, and endosseous implants with direct bone contact (*osseointegrated*).

One definition of *osseointegration* [a term originally proposed by Brånemark *et al*. (1969)] was provided by Albrektsson *et al*. (1981) who suggested that this was "a direct functional and structural connection between living bone and the surface of a load carrying implant". Another definition was provided by Zarb and Albrektsson (1991) who proposed that *osseointegration* was "a process whereby clinically asymptomatic rigid fixation of alloplastic materials is achieved and maintained in bone during functional loading".

Schroeder *et al*. (1976, 1981, 1995) used the term *"functional ankylosis"* to describe the rigid fixation of the implant to the jaw bone, and stated that "new bone is laid down directly upon the implant surface, provided that the rules for atraumatic implant placement are followed and the implant exhibits primary stability".

Thus, in order to acquire proper conditions for osseointegration (or functional ankylosis), the implant must exhibit proper initial fixation (primary stability) following installation in the recipient site. This initial or primary stability is the result of the contact relationship or friction that is established between mineralized bone (often the cortical bone) at the recipient site and the metal device.

Implant installation

Tissue injury

Basic rule: The less traumatic the surgical procedure and the smaller the tissue injury (the damage) in the recipient site during implant installation, the more expeditious is the process through which new bone is formed and laid down on the implant surface.

The various steps used at implant installation, such as (1) *incision* of the mucosa, often but not always followed by (2) the elevation of *mucosal flaps* and the separation of the periosteum from the cortical plates, (3) the preparation of the *canal* in the cortical and

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

spongy (cancellous) bone of the recipient site, and (4) the insertion of the titanium device (the implant) into this canal, bring to bear a series of mechanical insults and injury to both the mucosa and the bone tissue. The host responds to this injury with an inflammatory reaction, the main objective of which is to eliminate the damaged portions of the tissues and prepare the site for regeneration or repair. To the above described injury to the hard tissues must be added the effect of the so-called "press fit", that is when the inserted implant is slightly wider than the canal prepared in the host bone. In such situations, (1) the mineralized bone tissue around the implant is compressed and exhibits a series of microfractures, (2) the blood vessels, particularly in the cortical portion, of the canal will collapse, (3) the nutrition to the bone in this portion is compromised, and (4) the affected tissues most often become non-vital.

The injury to the soft and hard tissues of the recipient site, however, also initiates the process of wound healing that ultimately ensures that (1) the implant becomes "ankylotic" with the bone, that is osseointegrated, and (2) a delicate mucosal attachment (see Chapter 4) is established and a soft tissue seal forms that protects the bone tissue from substances in the oral cavity.

Wound healing

The healing of the severed bone following implant installation is a complex process that apparently involves different events in different compartments of the surgical site.

In the *cortical bone compartment*, the non-vital mineralized tissue must first be removed (resorbed) before new bone can form. In the *spongy (cancellous) compartment* of the recipient site, on the other hand, the surgically inflicted damage (preparation of the canal and the installation of the implant) results mainly in soft tissue (marrow) injury that initially involves localized bleeding and clot (coagulum) formation. The coagulum is gradually resorbed and becomes replaced with granulation tissue; in-growth (from the walls of the prepared canal) of blood vessels, leukocytes, and mesenchymal cells. As a result of the continuous migration of mesenchymal cells from the surrounding marrow, the granulation tissue in turn is replaced with provisional connective tissue (provisional matrix) and eventually with osteoid. In the osteoid, deposition of hydroxyapatite crystals will occur in the collagen network around the newly formed vascular structures. Hereby, immature woven bone is formed (for detail see Chapter 3) and sequentially osseointegration occurs.

Cutting and non-cutting implants

In this chapter only screw-shaped implants made of c.p. titanium will be discussed. The design of the metal device and the installation protocol followed may influence the speed of the process that leads to osseointegration.

Fig. 5-1 "Non-cutting" implant (solid screw: Straumann® Implant System). (Courtesy of Institut Straumann AG.)

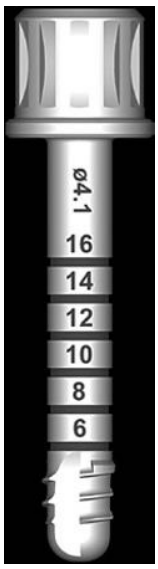

Fig. 5-2 Thread-tap (Straumann® Implant System) that is used to cut a track in the walls of the hard tissue canal. Following this preparation, the cavity in the host tissue and the implant are congruent. (Courtesy of Institut Straumann AG.)

"*Non-cutting*" implants (Fig. 5-1) require meticulous handling of the recipient site, including the preparation of a standardized track (thread) on the inside of the hard tissue canal. This track (thread) is prepared (precutting) using a thread-tap that is fitted with cutting edges (Fig. 5-2).

Figure 5.1 shows a "non-cutting" implant (e.g. solid screw, 4.1 mm: Straumann® Implant System) that is designed as a cylinder with a rounded "apical" base. The diameter of the cylinder is 3.5 mm. Pilot and twist drills of gradually increasing dimension are used to prepare the hard tissue canal of the recipient site to a final diameter of 3.5 mm. On the surface of the cylinder, the implant is designed with a helix-shaped pitch that is 0.3 mm high. The diameter of the entire screw-shaped device therefore becomes 4.1 mm.

In sites with a high bone density, a thread-tap (Fig. 5-2) is used to cut a 4.1-mm wide helix-shaped track in the walls of the hard tissue canal. The implant and the cavity prepared in the hard tissues of the recipient site become congruent. When the implant is

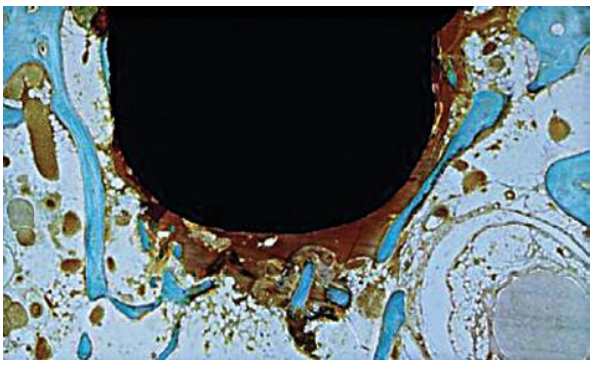

Fig. 5-4 Detail from the apical region of the implant described in Fig. 5-3. Note the presence of a coagulum in the bone marrow.

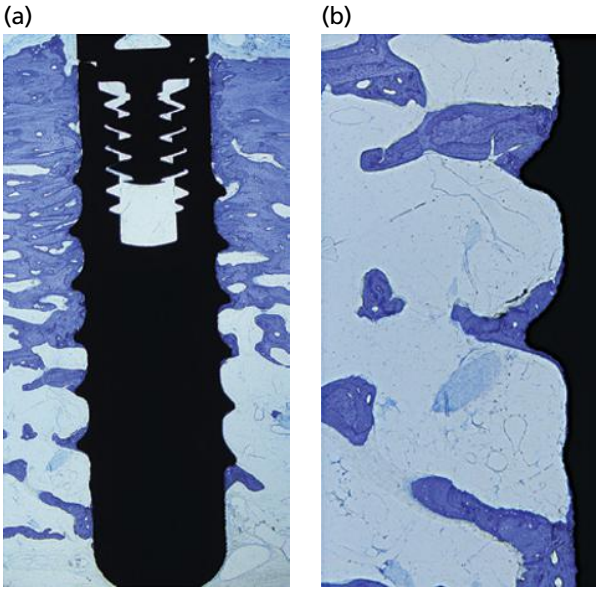

Fig. 5-5 (a) Ground section showing a "non-cutting" implant and surrounding bone after 16 weeks of healing. In the cortical portion of the recipient site, the bone density is high. (b) Detail of (a). In more apical areas, a thin coat of bone is present on the implant surface. Note also the presence of trabeculae of lamellar bone that extend from the implant into the bone marrow.

Fig. 5-6 "Cutting" implant (AstraTech® Implant System). Note the presence of cutting edges in the "apical" portion of the implant. During insertion this implant will cut a 0.3-mm wide chip from the lateral border of the canal prepared in the recipient site. (Courtesy of AstraTech.)

installed, the pitch on the device will capture and follow the helix-shaped track on the walls of the hard tissue canal and thereby guide the implant with a minimum of force into the preprepared position (Fig. 5-3).

Figure 5-3 illustrates a "non-cutting" Straumann® solid screw with surrounding tissues in a biopsy sampled 24 hours after implant installation. Proper initial fixation (stability) of the implant was obtained by the large contact area that was achieved between the metal screw and the buccal and lingual bone walls in the cortical compartment of the recipient site. During site preparation and placement of the implant, bone trabeculae in the spongy compartment of the site were obviously dislocated into the bone marrow. Blood vessels in the marrow compartment were severed, bleeding provoked, and a coagulum formed (Fig. 5-4).

After 16 weeks of healing (Fig. 5-5) the marginal portions of the "non-cutting" implant are surrounded by dense lamellar bone that is in direct contact with the rough surface of the metal device. Also, in the apical portion of the implant, a thin coat of mature bone can be seen to contact the implant surface and to separate the titanium screw from the bone marrow.

Cutting or self-tapping implants (e.g. AstraTech® Implant System, diameter 4.0 mm) (Fig. 5-6) are designed with cutting edges placed in the "apical" portion of the screw-shaped device. The threads of the screw are prepared during manufacturing by cutting

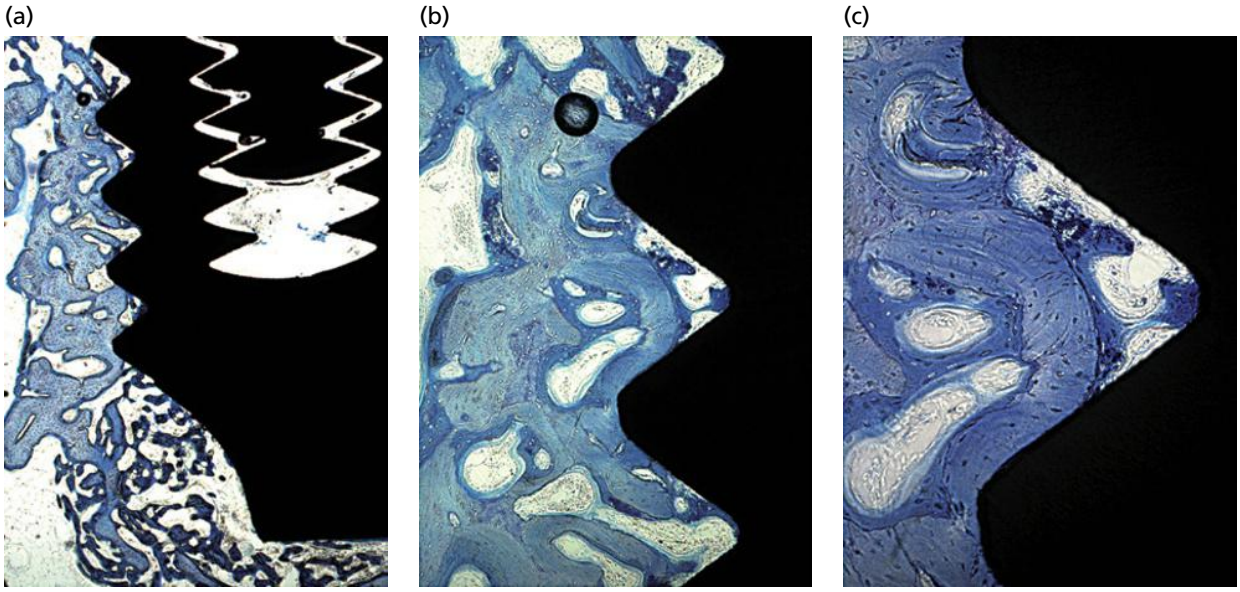

Fig. 5-7 (a) Ground section of an implant (AstraTech® Implant System) site from a biopsy sampled after 2 weeks of healing. In the apical area, large amounts of woven bone have formed. (b) Detail of (a). In the threaded region, newly formed bone can be seen to reach contact with the implant surface. (c) Higher magnification of (b). Newly formed bone extends from the old bone and reaches the titanium surface in the invagination between two consecutive "threads".

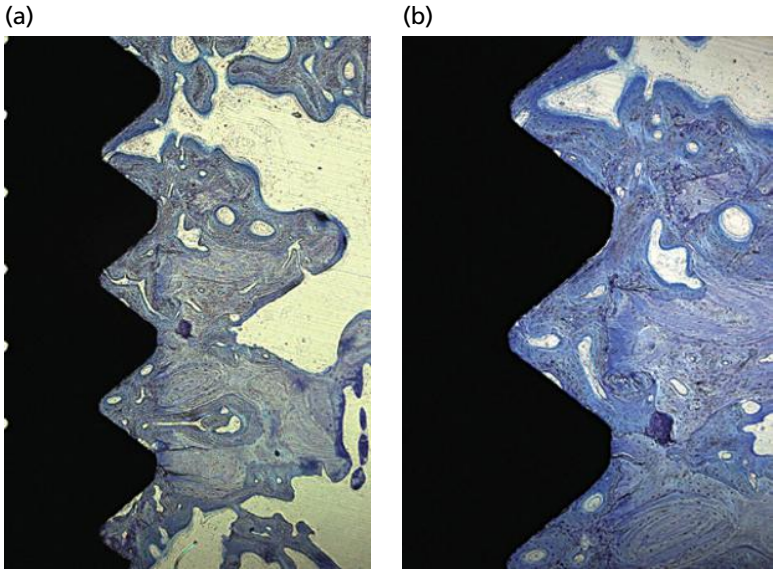

Fig. 5-8 Ground section of an implant site (AstraTech® self-tapping implant) from a biopsy specimen obtained after 6 weeks of healing. (a) In the marginal area, a continuous layer of bone covers most of the TiOblast® surface. (b) Higher magnification. Note the zone of newly formed (darker stained) bone that is in direct contact with the implant surface.

a continuous groove into the body of the titanium cylinder. When a self-tapping 4.0-mm wide implant is to be placed, the recipient site is first prepared with pilot and twist drills to establish a hard tissue canal that may have a final diameter of 3.7 mm. During insertion, the cutting edges in the "apical" portion of the implant create a 0.3-mm wide track in the walls of the canal and thereby establish the final 4.0 mm dimension. When the implant has reached its insertion depth, contact has been established between the outer portions of the threads and the mineralized bone in the cortical compartment (initial or primary fixation is thereby secured) and with the severed bone marrow tissue in the spongy (cancellous) bone compartment.

Figure 5-7 illustrates a recipient site with a self-tapping implant (AstraTech® implant). This implant is designed with a rough surface modification. The biopsy was harvested 2 weeks after installation surgery. The outer portion of the thread is in contact with the "old" bone, while new bone formation is the dominant feature in the invaginations between the threads and in areas lateral to the "apical" portions of the implant. Thus, discrete areas of newly formed bone can be seen also in direct contact with the implant surface. In sections representing 6 weeks of healing (Fig. 5-8), it was observed that a continuous layer of newly formed bone covers most of the rough implant surface. This newly formed bone is also in contact with the old, mature bone that is present in the periphery of the recipient site. After 16 months of healing (Fig. 5-9), the bone tissue in the zone of osseointegration has remodeled and the entire hard tissue bed for the implant is comprised of lamellar bone including both concentric and interstitial lamella.

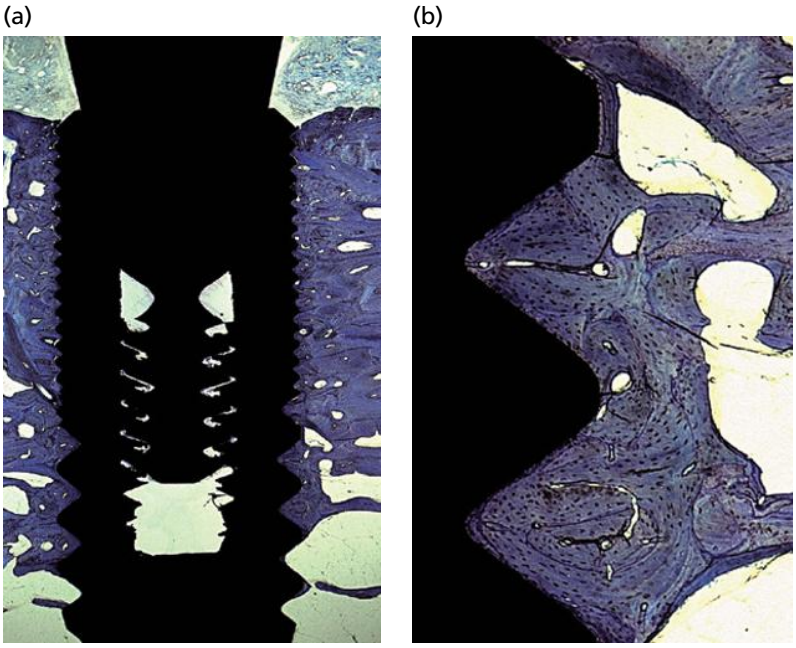

Fig. 5-9 Ground section of an implant site representing 16 months of healing. (a) The implant is surrounded by dense lamellar bone. (b) Higher magnification.

Process of osseointegration

De novo bone formation in the severed alveolar ridge following implant placement was studied in experiments in various experimental animal models (for review see Schroeder *et al*. 1995).

More recently, Berglundh *et al*. (2003) and Abrahamsson *et al*. (2004) described various steps involved in bone formation and osseointegration to implants placed in the mandible of dogs.

The device: Custom-made implants (made of c.p. titanium) in the shape of a solid screw and configured with a rough surface topography were utilized (Fig. 5-10). In the implant device, the distance between two consecutive profiles of the pitch (i.e. the threads in a vertical cross-section) was 1.25 mm. A 0.4-mm deep U-shaped circumferential trough had been prepared within the thread region during manufacturing (Fig. 5-11). The tip of the pitch was left untouched. Following the installation of the non-cutting device (Fig. 5-12), the pitch was engaged in the hard tissue walls prepared by the cutting/tapping device. This provided initial or primary fixation of the device. The void between the pitch and the body of the implant established a geometrically well-defined wound chamber (Fig. 5-13). Biopsies were performed to provide healing periods extending from 2 hours following implant insertion to 12 weeks of healing. The biopsy specimens were prepared for ground sectioning as well as for decalcified sectionings.

The wound chamber: Figure 5.13 illustrates a cross-section (ground section) of an implant with surrounding soft and hard tissues from a biopsy specimen sampled 2 hours after installation of the metal device. The peripheral portions of the pitch were in contact with the invaginations of the track prepared by the tap in the cortical bone. The wound

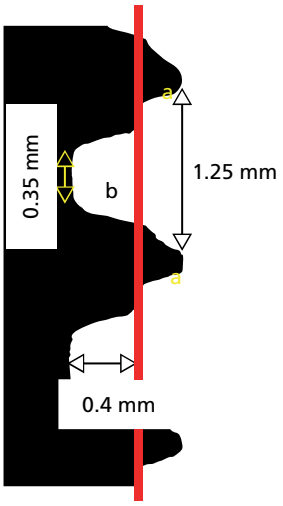

Fig. 5-11 The device. Schematic drawing illustrating the dimensions of the "wound chamber".

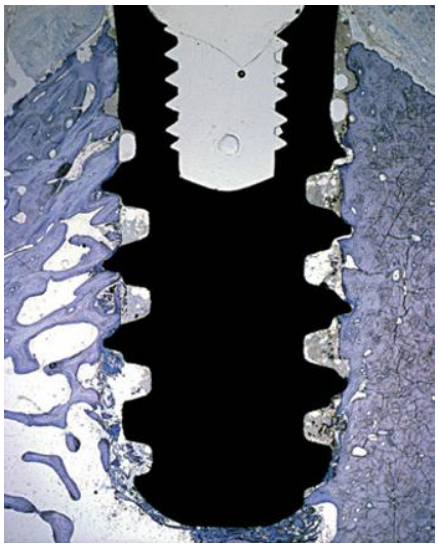

Fig. 5-12 Ground section showing the implant and adjacent tissues immediately after implant installation. The pitch region is engaged in the hard tissue walls. The void between two consecutive pitch profiles includes the wound chamber.

Fig. 5-13 Detail of Fig. 5-12. The wound chamber was filled with blood and a coagulum has formed.

chambers (Fig. 5-14a) were occupied with a blood clot in which erythrocytes, neutrophils, and monocytes/macrophages occurred in a network of fibrin (Fig. 5-14b). The leukocytes were apparently engaged in the wound cleansing process.

Fibroplasia: Figure 5-15a illustrates a device with surrounding tissues after 4 days of healing. The coagulum had in part been replaced with granulation tissue that contained numerous mesenchymal cells, matrix components, and newly formed vascular structures (angiogenesis) (Fig. 5-15b). A *provisional connective tissue (matrix)* had been established.

Bone modeling: After 1 week of healing, the provisional connective tissue in the wound chambers was rich in vascular structures and contained numerous mesenchymal cells (Fig 5-16a). The number of remaining inflammatory cells was relatively small. In several compartments of the chamber, a cell-rich immature bone (woven bone) was seen in the provisional connective tissue that surrounded the blood vessels. Woven bone formation occurred in the center of the chamber as well as in discrete locations that apparently were in direct contact with the surface of the titanium device (Fig. 5-16b). This was considered to represent the very first phase of osseointegration; contact between the implant surface and newly formed woven bone.

After 2 weeks of healing, woven bone formation appeared to be pronounced in all compartments, apical as well as lateral, surrounding the implant (Fig. 5-17a). Large areas of woven bone were found in the bone marrow regions "apical" of the implant. In the wound chamber, portions of the newly formed woven bone apparently extended from the old bone into the provisional connective tissue (Fig. 5-17b) and had in many regions reached the surface of the titanium device. At this interval, most of the implant surface was occupied by newly formed bone and a more comprehensive and mature osseointegration had been established (Fig. 5-17c). In the pitch regions, there were signs of ongoing new bone formation (Fig. 5-17d). Thus, areas

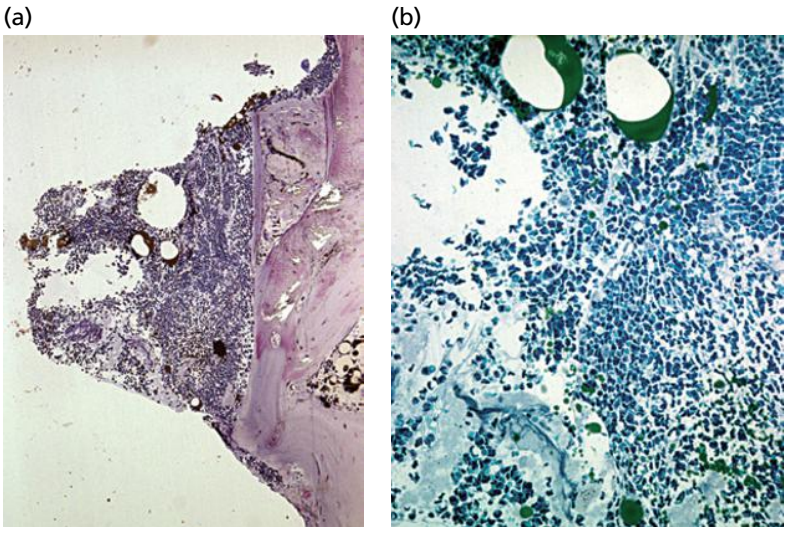

Fig. 5-14 Wound chamber 2 hours after implant installation. Decalcified sections. (a) The wound chamber is filled with blood. (b) Erythrocytes, neutrophils, and macrophages are trapped in a fibrin network.

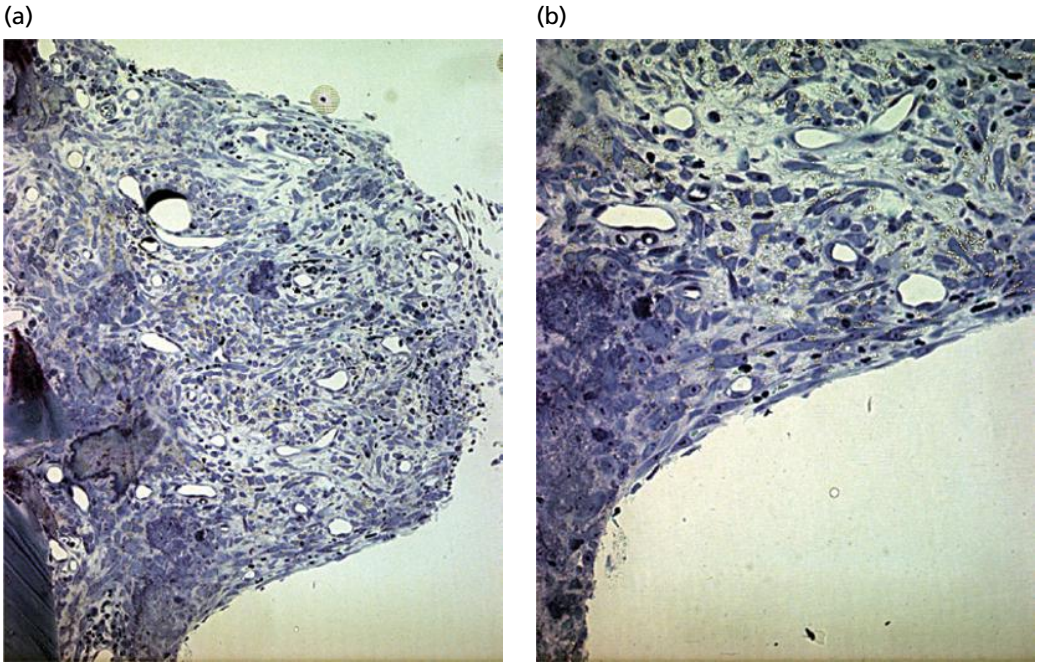

Fig. 5-15 Wound chamber after 4 days of healing (decalcified sections). (a) Most portions of the wound chamber are occupied by granulation tissue (fibroplasia). (b) In some areas of the chamber, provisional connective tissue (matrix) is present. This tissue includes large numbers of mesenchymal cells.

of the recipient site located lateral to the device, that were in direct contact with the host bone immediately following installation surgery and provided initial fixation for the implant, had undergone resorption and were also involved in new bone formation after 2 weeks of healing.

At 4 weeks (Fig. 5-18a), the newly formed mineralized bone extended from the cut bone surface into the chamber and a continuous layer of cell-rich, woven bone covered most of the titanium wall of the chamber. The central portion of the chamber was filled with a primary spongiosa (Fig. 5-18b), rich in vascular structures and a multitude of mesenchymal cells.

Remodeling: After 6–12 weeks of healing, most of the wound chambers were filled with mineralized bone (Fig. 5-19). Bone tissue, including primary and secondary osteons, could be seen in the newly formed tissue and in the mineralized bone that made contact with the implant surface. Bone marrow that contained

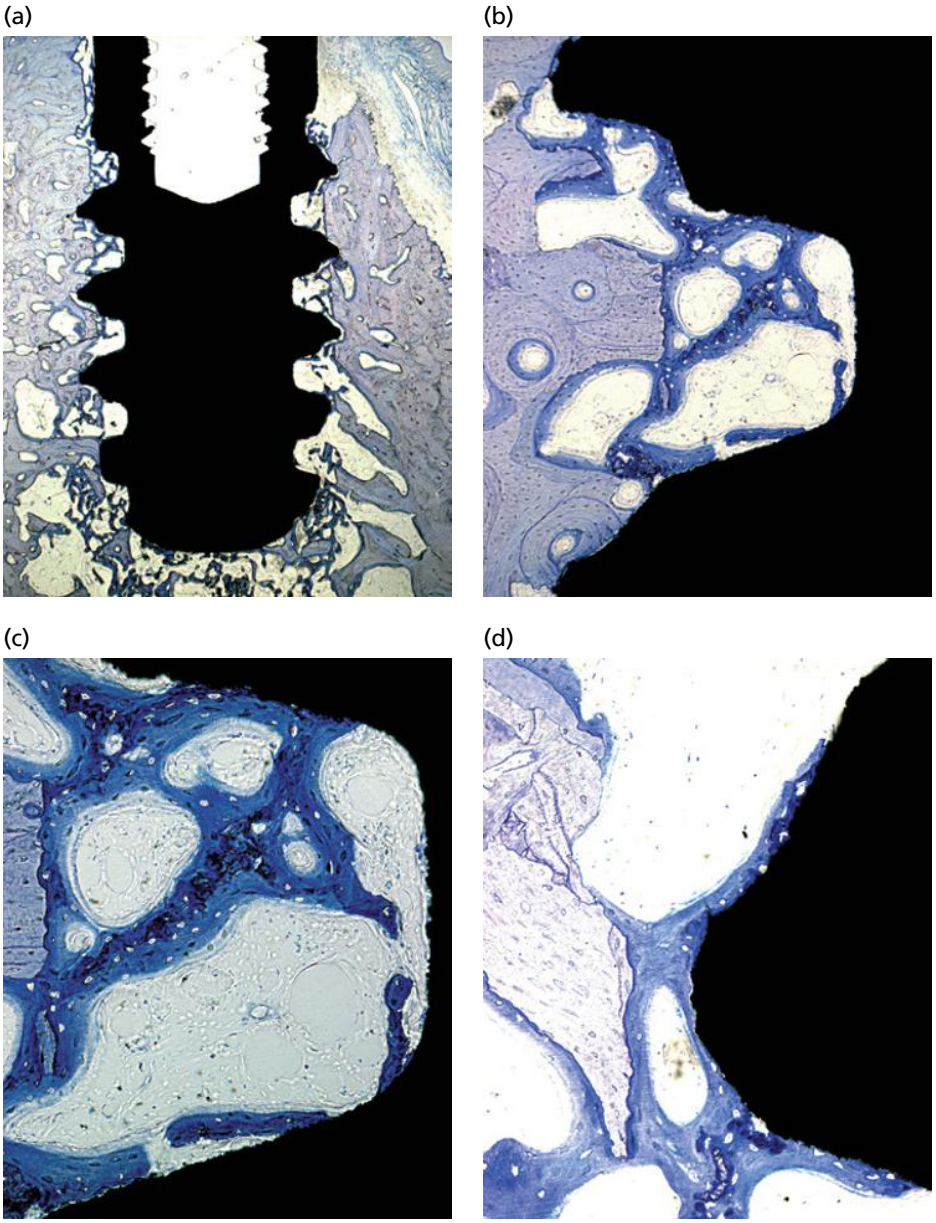

Fig. 5-17 Ground sections showing, in various magnifications, the tissues in the wound chamber after 2 weeks of healing. (a) Darker stained woven bone is observed in the apical area of the metal device. (b–d) Most portions of the implant surface are coated with bone.

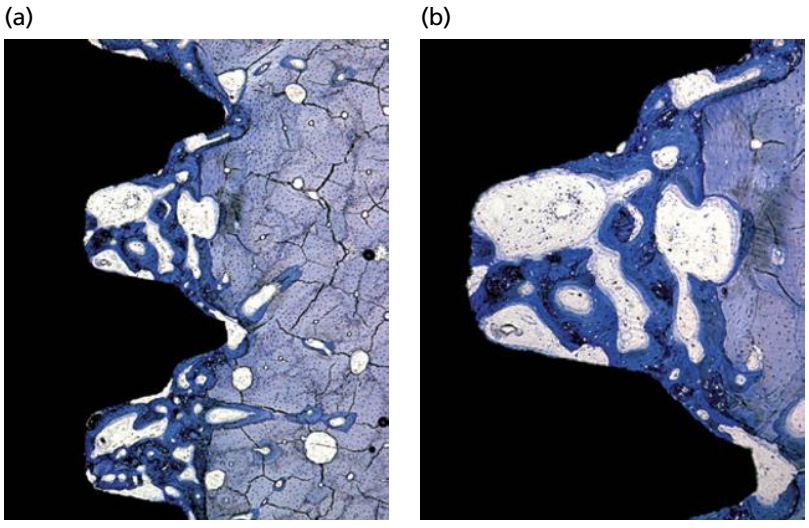

Fig. 5-18 Ground sections representing 4 weeks of healing. (a) Newly formed bone (dark blue) extends from the "old" bone into the wound chamber. (b) Appositional growth. Note the presence of primary osteons.

Fig. 5-19 Ground section representing 12 weeks of healing. The woven bone is being replaced with lamellar bone and marrow. Note the formation of secondary osteons.

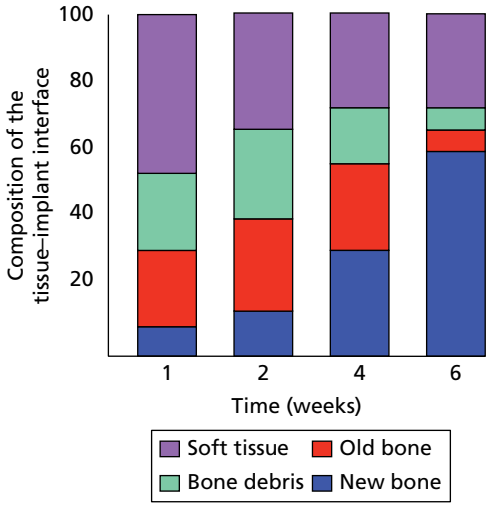

Fig. 5-20 Histogram showing the percentages of new bone, old bone, bone debris, and soft tissue in the "tissue–implant interface" after 1, 2, 4, and 6 weeks of healing. Note that the percentage of old bone, soft tissue, and bone debris that was present in the zone next to the implant surface decreased over time and that the amount of newly formed bone increased. There are reasons to suggest that (1) the contact between old bone and the implant established the initial "mechanical" stablility of the titanium device while (2) the newly formed bone subsequently achieved osseointegration. (Courtesy of D.D. Bosshardt.)

blood vessels, adipocytes, and mesenchymal cells was observed to surround the trabeculae of mineralized bone.

Summary: The wound chambers were first occupied with a coagulum. With the in-growth of vessels and migration of leukocytes and mesenchymal cells, the coagulum was replaced with granulation tissue. The migration of mesenchymal cells continued and the granulation tissue was replaced with a provisional matrix, rich in vessels, mesenchymal cells, and fibers. The process of *fibroplasia* and angiogenesis had started. Formations of newly formed bone could be recognized already during the first week of healing; the newly formed woven bone projected from the lateral wall of the cut bony bed (appositional bone formation; distance osteogenesis) (Davies 1998), but *de novo* formation of new bone could also be seen on the implant surface, that is at a distance from the parent bone (contact osteogenesis) (Davies 1998). During subsequent weeks, the trabeculae of woven bone were replaced with mature bone, that is lamellar bone and marrow (bone remodeling).

Morphogenesis of osseointegration

A series of publications have described the process of osseointegration of titanium implants placed in human volunteers (Bosshardt *et al*. 2011; Donos *et al*. 2011; Ivanovski *et al*. 2011; Lang *et al*. 2011). In these studies, solid screw devices (Institute Straumann AG, Basel, Switzerland) with a moderately rough surface were placed in the retromolar region of the mandible and submerged healing conditions were established. Biopsies including the implant with surrounding tissues were retrieved with the use of a trephine drill after 1, 2, 4, and 6 weeks. The examination of the samples included histologic and morphometric measurements and particular attention was paid to tissue elements that were in direct contact with or close to the implant surface (the tissue–implant interface), for example old bone, osteoid, newly formed bone, and non-mineralized mesenchymal soft tissue. In addition, at all examination intervals bone debris and solid bone particles were present in the wound lateral to the implant. Such constituents were obviously remnants of the drilling procedure used to prepare the hard tissue canal into which the implant was subsequently introduced.

Overall pattern of implant integration

Figure 5-20 describes the changes in the morphometric measurements in the tissue–implant interface region during the course of the study. After 1 week of healing, about 40% of the interface region was made up of soft tissue (granulation tissue, provisional connective tissue) and an additional 45% of bone debris and old bone. After 2 weeks, the amount of newly formed bone was still small, but the amount of soft tissue was markedly reduced. In the interval between 2 and 4 weeks, new bone formation was apparently pronounced in the interface zone. Thus, in this interval, newly formed bone increased from about 10% to about 30%, while the amount of hard tissue debris was markedly reduced. Also, in the period between 4 and 6 weeks, new bone formation was pronounced (from 30% to about 60%) and the diminution of old bone and bone debris markedly decreased. In other words, in humans the process of osseointegration appears to be most active in the interval between 2 and 6 weeks.

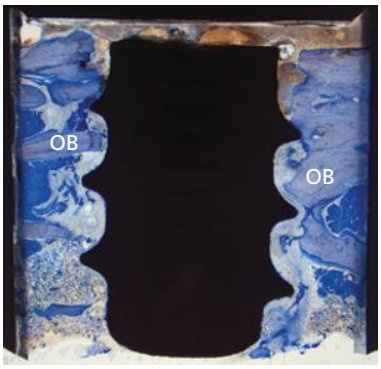

Fig. 5-21 Longitudinal ground section through a biopsy including a solid screw implant device. While compact old bone (OB) is found in contact with the coronal portion of the implant, the apical portion is comprised of less dense tissues and debris.

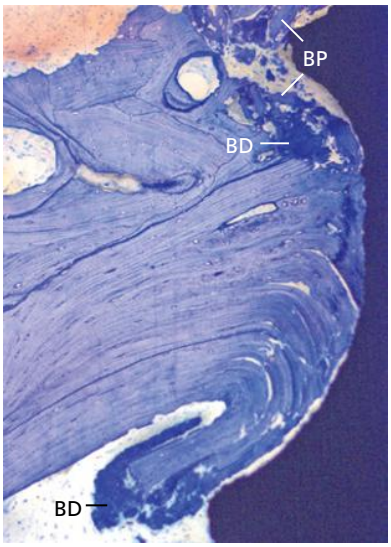

Fig. 5-22 Compact bone in direct contact with the implant surface in the coronal portion after 1 week of healing. Note the presence of bone particles (BP) and bone debris (BD) of varying size close to the implant surface. (Courtesy of D.D. Bosshardt.)

Summary: During the 6 weeks of healing that was monitored in this particular study in humans, it was observed that while the amount of old bone, bone debris, and soft tissue that initially occurred in close proximity to the implant gradually decreased, the amount of newly formed bone increased (Fig. 5-20). This pattern of healing that eventually resulted in osseointegration is in close agreement with the results obtained from the animal experiments reported earlier in this chapter.

Biopsy sample observations

Early wound

An implant with surrounding tissues sampled in the early phase after the surgical installation of the device is shown in Fig. 5-21. Note the presence of old bone, particularly in the cortical (marginal) region of the site. This old compact bone appeared to be in direct contact with the implant and obviously facilitated the initial mechanical stability of the device. Note also that more apical portions of the implant were surrounded by non-mineralized tissue, bone debris, and bone particles.

Healing process

After *1 week of healing*, substantial amounts of old bone occupied the marginal portion of the surgically prepared site. This bone tissue appeared to be in close contact with the implant device (Fig. 5-22). As stated above, this close fit between the remaining old bone and the titanium device was most likely a prerequisite for initial implant stability and of importance in establishing optimal healing conditions in the hard tissue wound. At this early interval, newly formed bone occurred on the surface of old bone tissue (Fig. 5-23), while areas of bone resorption could be identified in adjacent regions of the tissue wound. In other words, phenomena such as hard tissue apposition and resorption characterized the healing process in this early phase.

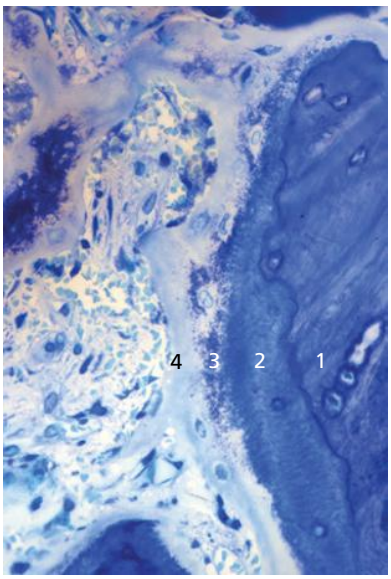

Fig. 5-23 Initial stage of bone apposition onto the surface of old bone occurring at a distance from the implant surface after 1 week of healing. 1, old bone; 2, new mineralized bone matrix; 3, mineralization foci at the mineralization front; 4, osteoid lined by osteoblasts.

Bone debris, bone particles, soft mesenchymal tissue as well as thin layers of osteoid tissue were also frequently found on or close to the implant surface (Figs. 5-24, 5-25).

At the *2-week interval*, remnants of old bone apparently still remained in the marginal portion of the implant site. Areas of hard tissue resorption (Howship´s lacunae; Fig. 5-26) could be found immediately adjacent to as well as at a distance from the implant. In addition, minute areas of newly formed bone occurred on or immediately lateral to the surface of the implant device. This formation of woven bone was the first sign of what may be called

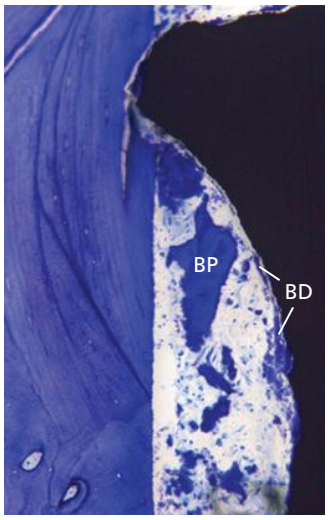

Fig. 5-24 After 1 week of healing, a considerable amount of bone debris (BD) and larger bone particles (BP) are present in the gap between the implant surface and the cut bone bed. (Courtesy of D.D. Bosshardt.)

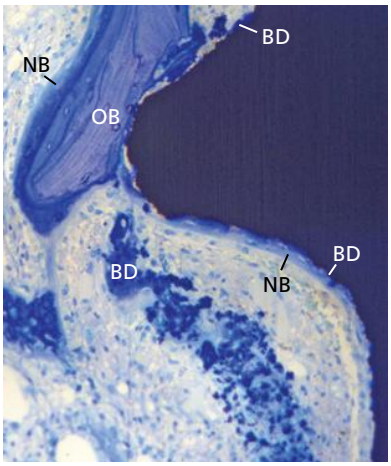

Fig. 5-25 After a healing period of 1 week, old bone (OB) is still in contact with the pitch of the implant thread. Newly formed bone (NB) is present (1) on the ledges of old bone and (2) on the implant surface. Bone debris (BD) is found adhering to the implant surface, but is also embedded in the adjacent mesenchymal soft tissue. The newly formed bone mainly consists of a partly mineralized osteoid lined by osteoblasts.

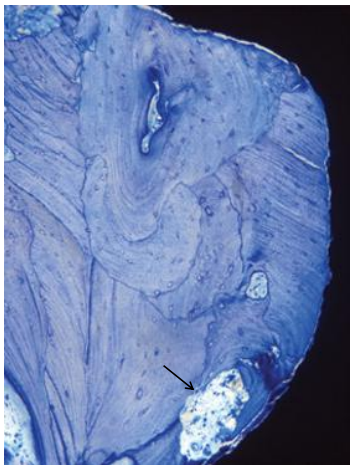

Fig. 5-26 Area of compact old bone in contact with the most coronal portion of the implant after a healing period of 2 weeks. Note the presence of bone resorption at the bottom of the micrograph (arrow).

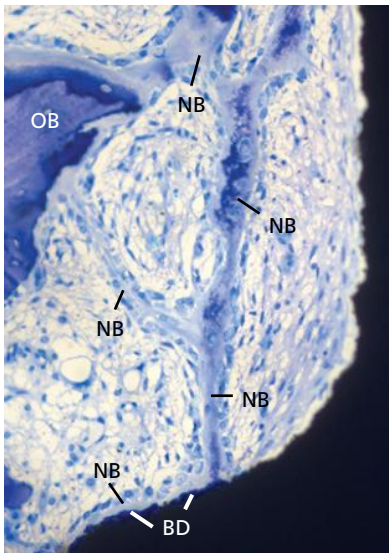

Fig. 5-27 Site characterized by active tissue modeling, in other words woven bone formation. The newly formed trabeculae of woven bone extend from old bone into the provisional connective tissue. (OB, old bone; NB, new bone; BD, bone debris.)

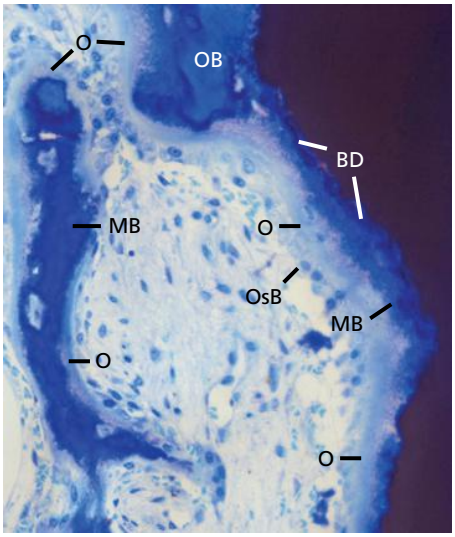

Fig. 5-28 Micrograph showing the implant–tissue interface of an implant site after 2 weeks of healing. The area is filled with a provisional connective tissue matrix and zones of new bone are discernible as well as osteoid tissue on the implant surface. Note the presence of bone debris (BD) on the surface of the implant. Tissue elements, including mineralized matrix of immature bone (MB) as well as osteoid tissue (O) and old bone (OB), are in contact with the implant surface. OsB, bodet between osteoid and connective tissue. (Courtesy of D.D. Bosshardt.)

osseointegration (Figs. 5-27, 5-28). Furthermore, at this interval, tiny ledges of newly formed woven bone apparently connected old bone to the titanium screw device (Fig. 5-28) .

At the *4-week interval*, the healing process features of modeling and remodeling were pronounced. Thus, in some areas close to the implant surface resorptive processes were discernible, while in adjacent areas woven bone had formed (Fig. 5-29).

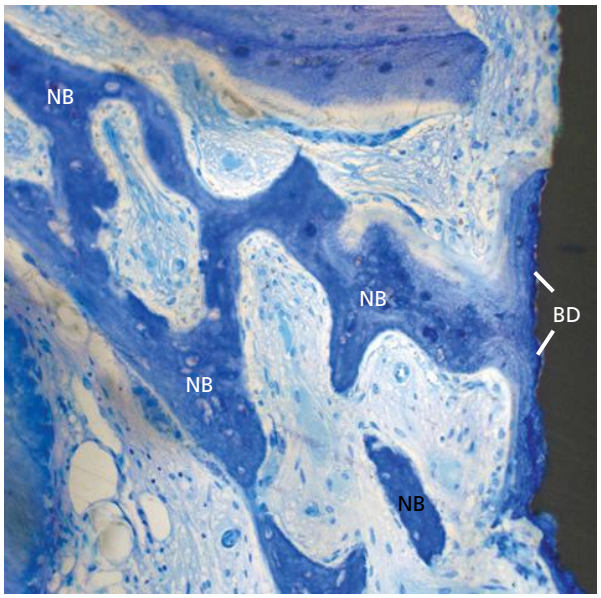

Fig. 5-29 Micrograph showing the implant–tissue interface and the peri-implant tissues of an implant after 4 weeks of healing. The newly formed bone (NB) forms a tiny trabecular network connecting the surface of the old bone with the implant surface. Deposition of new bone on the implant surface was associated with the presence of bone debris (BD). (Courtesy of D.D. Bosshardt.)

At the *6-week interval*, large amounts of newly formed woven bone (Fig. 5-30), but also lamellar bone and marrow, were present in close proximity to the implant device. This kind of newly formed hard tissue was apparently part of a more stable "bone–implant contact", in other words osseointegration.

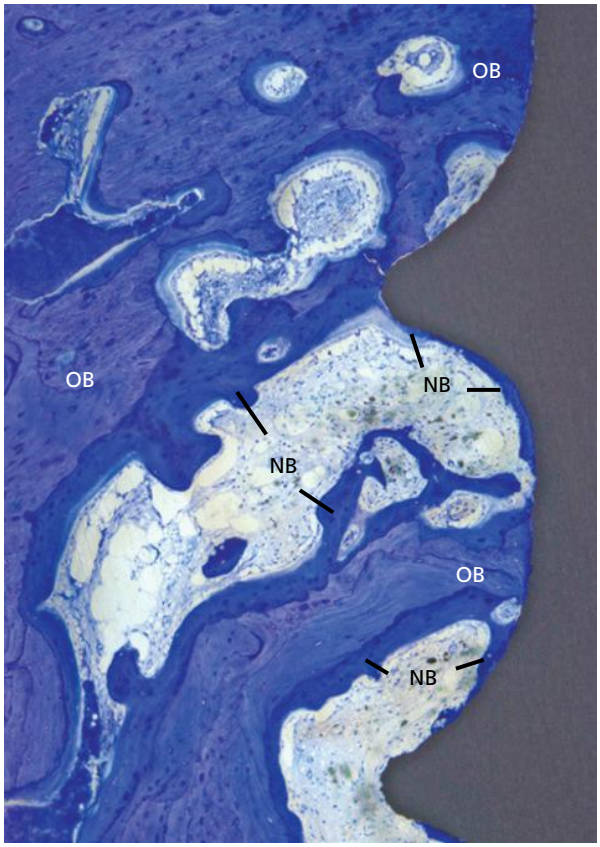

Fig. 5-30 Microphotograph showing the implant–tissue interface after 4–6 weeks of healing. New bone (NB) is found on the surface of old bone (OB) and on the implant surface. (Courtesy of D.D. Bosshardt.)

Chapter 6

From Periodontal Tactile Function to Peri-implant Osseoperception

Reinhilde Jacobs

Laboratory of Oral Physiology, Department of Periodontology, and Oral Imaging Center, Faculty of Medicine, Catholic University of Leuven, Leuven, Belgium

Introduction

Perception is the ability to detect external stimuli through vision, audition, balance, somatic function, taste or smell (Martin 1991). In this chapter, only perception via the somatosensory system is explored. The preponderance of this system is illustrated by its major representation, along with that of the hand, in the sensory homunculus proposed by Penfield (Penfield & Rasmussen 1950). Generally speaking, the somatosensory function is essential for the fine-tuning of limb movements.

Likewise, tactile function of teeth plays a crucial role in refinement of jaw motor control. Periodontal mechanoreceptors and especially those located in the periodontal ligament, are extremely sensitive to external mechanical stimuli (Jacobs & van Steenberghe 1994). The periodontal ligament can thus be considered as a keystone for masticatory and other oral motor behaviors. Any condition that may influence periodontal mechanoreceptors could alter the sensory feedback pathway and thus affect tactile function and fine-tuning of jaw motor control (e.g. periodontal breakdown, bruxism, re-implantation, anesthesia).

The most dramatic change may occur after extraction of teeth, as this eliminates all periodontal ligament receptors. This condition may persist after implant placement, as functional re-innervation has not yet been proven in humans. Surprisingly, patients with implant-supported prostheses often seem to function quite well. The underlying mechanism of this so-called "osseoperception" phenomenon remains a matter of debate, but the response of assumed peri-implant receptors might help to restore the proper peripheral feedback pathway. This hypothesized physiologic integration might thus lead to better acceptance, improved psychological integration, and more natural functioning.

This chapter will unravel periodontal tactile function and guide the reader through the mysteries of peri-implant osseoperception in order to find neuroanatomic, histologic, physiologic, and psychophysical evidence to confirm the hypothesis.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Neurophysiologic background

Trigeminal neurosensory pathway

The sensory inputs of the oral region are carried by the mandibular and maxillary divisions of the trigeminal nerve via the trigeminal ganglion to the brainstem. This is part of an important sensory feedback pathway that refines jaw movements. The afferent signals are transmitted either to the main sensory nucleus of the trigeminal nerve (responsive to tactile senses, light touch, and pressure) or to the descending spinal tract nuclei (responsive to sensation of oral mucosa, pain, temperature, and deep pressure). From these, signals are transferred across the midline and sent to the thalamus and, via thalamocortical projections, to the respective cortical areas involved in orofacial sensation, where they can result in conscious perception.

Neurovascularization of the jaw bones

The jaws are richly supplied by neurovascular structures, and it is thus of utmost importance to identify vital anatomic structures before carrying out a surgical procedure. During a radiographic preoperative planning procedure, neurovascular structures need to be precisely localized so that they can be avoided in surgical treatment. Studies reveal that edentulous and dentate anterior jaws present significant variation in jaw bone neurovascularization (for review see Jacobs *et al*. 2007). All these canal structures contain a neurovascular bundle whose diameter may be large enough to cause clinically significant trauma if damaged. Surgeons need to avoid the nervous structures to avoid this trauma, and also because these critical structures may be essential in the potential re-innervation of peri-implant bone. Indeed, the remaining neurovascular bundles in the edentulous jaw bone may support nerves that regenerate after tooth extraction and implant placement. This assumption is the basis of the so-called osseoperception phenomenon and will be further outlined below.

Mandibular neuroanatomy

The mandibular nerve runs forward through the mandibular canal. At the mental foramen it gives off the mental nerve. Additional mental foramina exist, with a reported prevalence of 9%. These canals are often smaller and located more posteriorly (Oliveira-Santos *et al*. 2011). Meanwhile, the mandibular nerve continues to run anteriorly as the mandibular incisive nerve (Mraiwa *et al*. 2003a, b) (Fig. 6-1). Conventional intraoral and panoramic radiographs often fail to show the so-called incisive canal (Jacobs *et al*. 2004). Cross-sectional imaging may, however, be used to locate the canal and as such protect it from the risk for neurovascular damage (Jacobs *et al*. 2002a) The mandibular incisive canal undeniably contains a true neurovascular bundle with nervous sensory structures (Fig. 6-2). Its existence in edentulous patients is underlined by reported surgical complications. Indeed, sensory disturbances, caused by direct trauma to the mandibular incisive canal bundle, have been reported after implant placement in the interforaminal region (Jacobs *et al*. 2007) (Fig. 6-3). Sensory disorders may also result from indirect trauma caused by a hematoma in the canal, and as the latter acts as a closed chamber, pressure is exerted on the mandibular incisive canal bundle and this spreads to the main mental branch (Mraiwa *et al*. 2003b).

Other anatomic landmarks to be noted are the superior and inferior genial spinal foramina and their bony canals, situated in the midline of the mandible in 85–99% of mandibles (Liang *et al*. 2005a, b; Jacobs *et al*. 2007) (Fig. 6-4). The superior genial spinal foramen has been found to contain a branch of the lingual artery, vein, and nerve. Furthermore, a branch of the mylohyoid nerve together with branches or anastomoses of sublingual and/or submental arteries and veins have been identified in the inferior genial spinal foramen. This artery can be of a size that, if it is damaged, a hemorrhage intraosseously or in the connective soft tissue can be provoked and may be difficult to control (Liang *et al*. 2005a, b) (Figs. 6-5, 6-6).

Fig. 6-1 These human dry mandibular bone sections illustrate the presence and dimensional importance of the mandibular incisive nerve, even in edentulism. The middle section actually shows the mandibular midline, confirming that there is no true connection between the left and right sections.

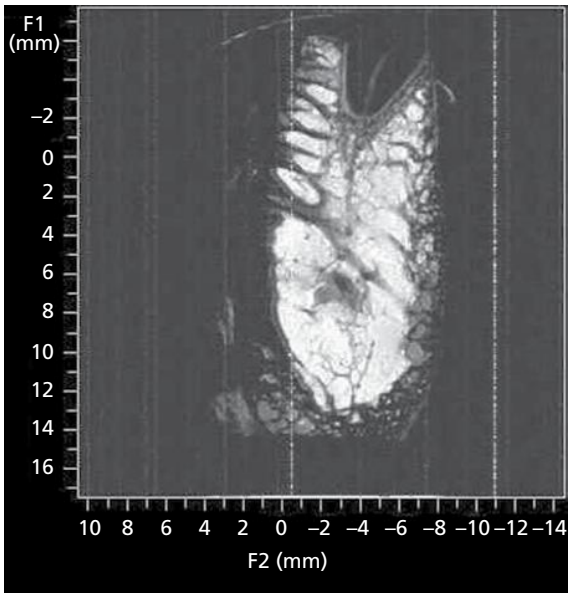

Fig. 6-2 Single cross-sectional slice of a high resolution MRI dataset localized at the incisor region of a dentate anterior human mandible, with the fatty marrow colored white. A black root-form structure corresponds to the root of an incisor tooth. It is surrounded by a small band of intermediate signal intensity, representing the periodontal ligament. Furthermore, the dental neurovascular supply is seen as a line of intermediate signal intensity in the middle of the root. The latter is descending to the level of a larger structure of intermediate signal intensity (incisive nerve) with a black oval area on top (vascular structure). (Source: Jacobs *et al*. 2007. Lambrichts, University of Hasselt.)

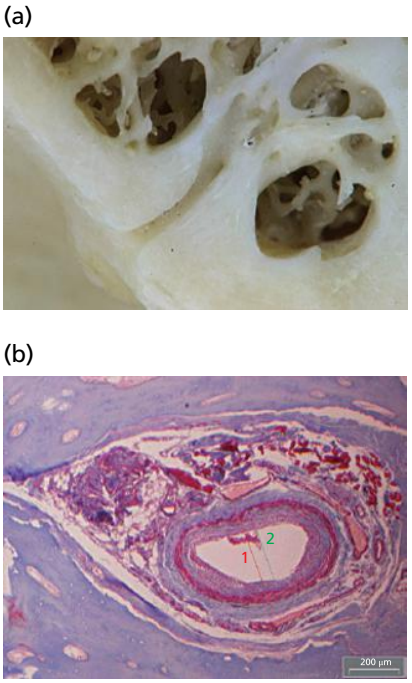

Fig. 6-5 (a) Stereomicroscopic image showing a single genial spinal canal section. (b) Neurovascular content of the canal is confirmed histologically. The artery in this image has a diameter of about 0.5 mm (red and green lines denote the inner and outer wall dimensions, respectively).

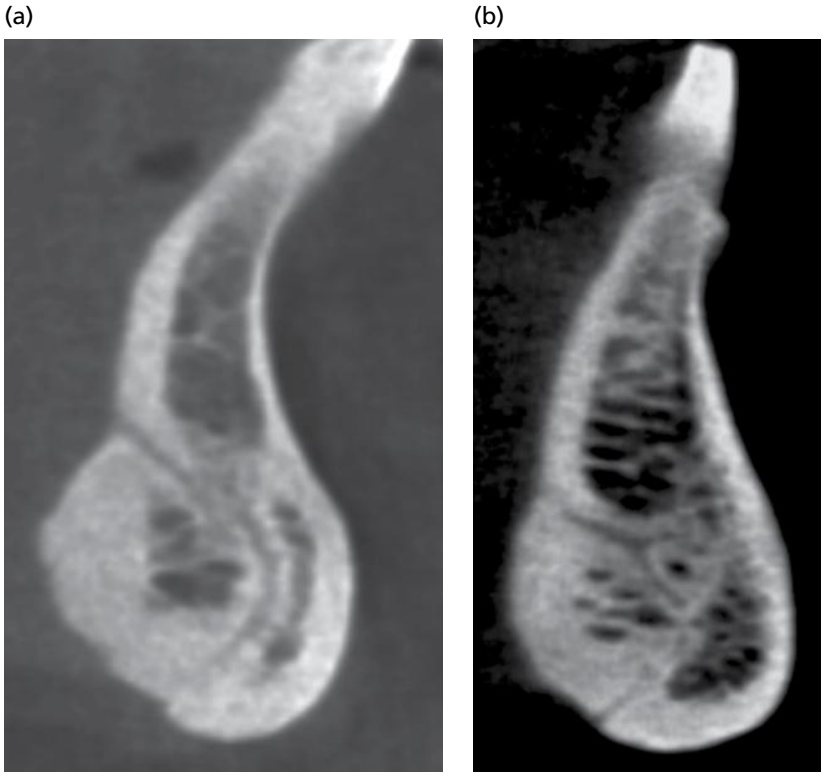

Fig. 6-6 Cone-beam CT cross-sectional images showing the relation and communication between the superior and inferior genial spinal canal (a) and the incisive canal (b).

The observation that immediate loading of implants in the anterior mandible, using the Brånemark Novum® concept rather than a conventional implant-supported overdenture, results in a significant reduction of tactile function could be explained by contact with the aforementioned neurovascular bundles in the anterior mandible (Abarca *et al*. 2006).

Maxillary neuroanatomy

The maxillary nerve is a sensory nerve, with its superior nasal and alveolar branches supplying the palate, nasal and maxillary sinus mucosa, upper teeth and their periodontium. The anterior superior alveolar nerve sometimes runs in a clearly defined canal, palatally of the canine (canalis sinuosus) (Shelley *et al*. 1999). Care should therefore be taken to avoid neurovascular trauma during canine implant installation. Another branch of importance during implant placement is the superior nasal branch, denoted the nasopalatine nerve. It descends to the roof of the mouth through the nasopalatine canal and communicates with the corresponding nerve of the opposite side and with the anterior palatine nerve (Mraiwa *et al*. 2004). Typically, it has been described as forming a Y-shape with the orifices of two lateral canals, and terminating at the nasal floor level in the foramina of Stenson (Fig. 6-7). Occasionally, two additional minor canals carry the nasopalatine nerves (foramina of Scarpa) (Fig. 6-7a). Mraiwa *et al*. (2004) point out a significant variability in both the dimensions and morphologic appearance of the nasopalatine canal. To avoid disturbing neurovascular bundles and causing further complications, implant placement in the maxillary incisor region should consider this important structure (Fig. 6-8).

Histologic background

Periodontal innervation

Periodontal receptors are located within the gingiva, jaw bone, periosteum, and periodontal ligament. Most receptors seem to have mechanoreceptive characteristics, contributing to a sophisticated exteroceptive tactile function. This tactile information is not primarily used for protective purposes, but rather to improve oral motor behavior and fine-tuning of biting and chewing (Trulsson 2006).

It is clear that periodontal ligament plays a predominant role in this dedicated mechanoreceptive function. It has an extremely rich sensory nerve supply, especially in those locations that are more prone to displacement (periapical, buccal, and lingual). It contains three types of nerve endings: free nerve endings, Ruffini-like endings, and lamelated corpuscles (Lambrichts *et al*. 1992). Free nerve endings stem from both unmyelinated and myelinated nerve fibers. Lamellated corpuscles are found in close contact with each other. Most mechanoreceptive endings are however Ruffini-like, and predominantly present in the apical part of the periodontal ligament. Morphologic studies indicate that these endings are in close contact with collagen fibers of the surrounding tissues

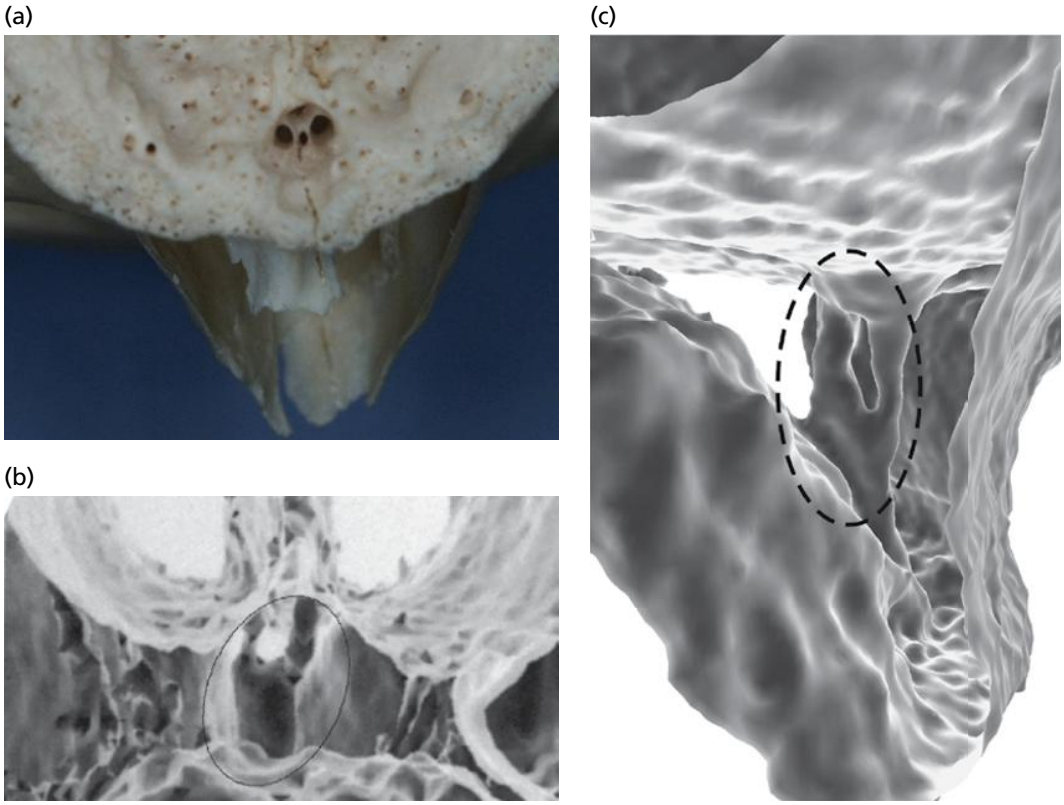

Fig. 6-7 Anatomy of the nasopalatine canal. (a) View from the palate of an edentulous dry skull showing the nasopalatine foramen, formed at the articulation of both maxillae, behind the incisor teeth. In the depth of the canal, the orifices of two lateral canals are seen. As an anatomic variant, two minor canals can be observed on the midline, one anterior and one posterior to the major nasopalatine canals. (b, c) Three-dimensional reconstruction of the palate and the floor of the nose, seen from a posterior angle (b) and from the side view (c). The outline of the common Y morphology of the nasopalatine canal is circled.

(Lambrichts *et al*. 1992) (Fig. 6-9). This particular association may explain their extremely high sensitivity upon loading a tooth. This results in low threshold levels for periodontal tactile function (≤10 µm), and is considered as the basis of an elaborate sensory apparatus that may be linked to a number of clinical phenomena.

The mechanoreceptive function of the periodontal ligament signals the differential information about the mechanical events that occur during biting and

chewing (Trulsson 2006). The detailed differential signaling allows the brain to analyze and characterize these specific mechanical events, enabling further processing for fine-tuning and resulting in an optimized masticatory sequence (Trulsson 2006). Considering this crucial role, it is clear that some sensory–motor interactions are impaired or even lost when the periodontal ligament is altered or damaged. When teeth are extracted and thus ligament receptors eliminated, tactile functioning may be hampered. Indeed, Haraldson (1983) described a similar muscle activity during the entire masticatory sequence in patients with implant-supported fixed prosthesis. In subjects with natural teeth, the chewing pattern gradually changes as the food bolus properties change. Jacobs and van Steenberghe (1995) identified a silent period in muscle activity (reflex response) when teeth or implants neighboring teeth, but not implants in a fully edentulous jaw bone, were tapped. These findings may illustrate the modulatory role of periodontal ligament input in jaw muscle activity.

Peri-implant innervation

Tooth extraction damages a large number of sensory nerve fibers and corresponds to an amputation, where the target organ and peripheral nervous structures have been destroyed (Mason & Holland 1993). After extraction of teeth, the myelinated fiber content of the inferior alveolar nerve is reduced by 20% (Heasman 1984). This finding indicates that fibers originally innervating the tooth and periodontal ligament are still present in the inferior alveolar nerve. Linden and Scott (1989) succeeded in stimulating nerves of periodontal origin in healed extractions sockets, which implies that some nerve endings remain functional. Nevertheless, most of the surviving mechanoreceptive neurons represented in the mesencephalic nucleus may lose some functionality (Linden & Scott 1989). These experiments have been the basis for a long-lasting debate on the presence and potential function of sensory nerves fibers in the bone and peri-implant environment. Histologic evidence indicates that there may be some re-innervation around osseointegrated implants (Wang *et al*. 1998; Lambrichts 1998) (Figs. 6-10, 6-11). Indeed, it has been shown that the surgical trauma from implantation of endosseous implants may lead to degeneration of surrounding neural fibers. Soon, however, new fibers are observed to sprout and the number of free nerve endings close to the bone–implant interface gradually increases during the first weeks of healing (Wada *et al*. 2001). A more recent study in the

dog succeeded in partially regenerating the periodontal ligament on an implant surface (Jahangiri *et al*. 2005). Whether such regeneration can also induce restoration of the peripheral feedback pathway needs further verification.

On the other hand, existing mechanoreceptors in the periosteum may also play a role in tactile function upon implant stimulation. It is evident that oral implants offer a different type of loading and force transfer from teeth, given the intimate bone–implant contact with elastic bone properties instead of the characteristic viscoelasticity of the periodontal ligament. Thus, forces applied to osseointegrated implants are directly transferred to the bone and bone deformation may lead to receptor activation in the peri-implant bone and, more specifically, in the neighboring periosteum.

Testing tactile function

Exteroceptive function can be examined by neurophysiologic as well as psychophysical methods.

Neurophysiologic assessment

Neurophysiologic investigations of the sensory function of the human trigeminal system are risky and therefore rarely reported (Johansson *et al*. 1988a, b; Trulsson *et al*. 1992). Alternatively, non-invasive approaches may be considered to evaluate oral tactile function. The first approach is the recording of the so-called trigeminal somatosensory evoked potentials (TSEPs) after stimulation of receptors in the oral cavity. Unfortunately, SEPs from the trigeminal branches are, in contrast to those recorded from limbs, weak and difficult to discriminate from the background noise. Advanced signal analysis is required to gain reliable information (van Loven *et al*. 2000, 2001). Another non-invasive method to assess sensory function is to visualize brain activities by functional magnetic resonance imaging (fMRI) (Borsook *et al*. 2006). This is a complex method, which has received hardly any attention in relation to tactile function of teeth and implants (Lundborg *et al*. 2006; Miyamoto *et al*. 2006; Habre-Hallage *et al*. 2010). When combining fMRI with other techniques such as psychophysics and TSEPs, it may offer a new non-invasive approach to evaluate human oral somatosensory function.

Psychophysical assessment

Sensory function can also be evaluated by psychophysical testing, relying on the patient's response. This technique has often been applied to test oral tactile function (Jacobs *et al*. 2002b–d). A major advantage of psychophysical testing is that it employs simple non-invasive techniques that may be performed in a clinical environment. When carried out under strictly standardized conditions, the psychophysical response can be directly linked to the neural receptor activation (Vallbo & Johansson 1984).

Periodontal tactile function: Influence of dental status

Oral tactile function is influenced by tooth position and dental status (Jacobs & van Steenberghe 2006). The tactile function of teeth is primarily determined by the presence of periodontal ligament receptors. Vital or non-vital teeth may show a comparable tactile function. However, when periodontal ligament receptors are reduced or eliminated (e.g. through periodontitis, bruxism, chewing, extraction, anesthesia), tactile function is impaired (Table 6-1). Clinically, this implies that a patient's ability to detect occlusal inaccuracies (e.g. induced by restorative treatment) is decreased in these situations. Indeed, exteroceptors inform the nervous system on the characteristics of the stimulus, which then allows modulation of the motor neuron pool to optimize jaw motor activity and avoid overloading. Elimination of these exteroceptors by tooth extraction may reduce the tactile function to an important extent (for review see Jacobs & van Steenberghe 2006). Even after rehabilitation with a prosthesis, tactile function remains impaired and inappropriate exteroceptive feedback may thus present a risk for overloading the prosthesis (Jacobs & van Steenberghe 2006). In comparison to the tactile function of natural dentitions, the active thickness detection threshold is seven to eight times higher for dentures, but only three to five times higher for implants (see Table 6-1). For the passive detection of forces applied to upper teeth, thresholds for dentures are increased 55 times and for implants 50 times (see Table 6-1). The large discrepancies between active and passive thresholds can be explained by the fact that several receptor groups may respond to active thickness detection, while the passive force

Table 6-1 Factors influencing the tactile function of teeth (for review see Jacobs *et al*. 2002b; Jacobs & van Steenberghe 2006)

Polyneuropathy	↑	↑

↑, increase in threshold level implies decrease in tactile function and hampered feedback.

application selectively activates only periodontal ligament receptors. The latter are eliminated after extraction, which may explain the reduced tactile function in edentulous patients.

After rehabilitation with a bone-anchored prosthesis however, edentulous patients seem to function quite well. These patients perceive mechanical stimuli exerted on osseointegrated implants in the jaw bone. Some even note a special sensory awareness with the bone-anchored prosthesis, coined "osseoperception". This can be defined as perception of external stimuli transmitted via the implant through the bone by activation of receptors located in the peri-implant environment, periosteum, skin, muscles, and/or joints, with periosteal innervation playing a key role (Jacobs 1998). From the existence of the osseoperception phenomenon it can be hypothesized that the feedback pathway to the sensory cortex is partly restored with a representation of the prosthesis in the sensory cortex, which modulates of the motor neuron pool, leading to a more natural functioning and avoidance of overload.

From periodontal tactile function to peri-implant osseoperception

Neurophysiologic evidence for the cortical plasticity with representation of the implant in the sensory cortex can be found in some experiments evoking TSEPs upon implant stimulation. By triggering sweeps in the electroencephalogram by means of an implant stimulation device and by cumulative and advanced analysis of the sweeps, significant waves can be noted (Fig. 6-12). These experiments indicate that endosseous and/or periosteal receptors around the implants convey the sensation (Van Loven *et al*. 2000). These mechanisms could be the basis for implant-mediated sensory–motor control, which may have important clinical implications for a more natural functioning with implant-supported prostheses.

Evidence for cortical plasticity may open the way to complete integration of implants in the human body. Henry *et al*. (2005) extracted lower incisors in mole rats and with fMRI analysis showed a reorganization of the orofacial representation in the *primary sensory cortex* 5–8 months later. This study may indicate that a cortical representation of teeth may lead to significant restructuring after tooth loss. Likewise, an fMRI study by Lundborg *et al*. (2006) demonstrated that upon tactile stimulation of an osseointegrated prosthetic thumb, the primary somatosensory cortex is bilaterally activated in an area corresponding to that of the hand. As only stimulation of the healthy thumb would be expected to activate the contralateral cortex, the presence of bilateral cortical activation upon implant stimulation may be explained by some compensatory mechanism that recruits additional sensory areas after amputation (Lundborg *et al*. 2006). Following the stimulation protocol of Habre-Hallage *et al*. (2010) with 1-Hz punctuate tactile stimuli applied to teeth and implants, this group recently found that upon stimulation of implants and teeth, the somatosensory cortex was activated (Habre-Hallage 2011). The implant activated a larger bilateral cortical network outside the somatosensory areas. This novel study demonstrates that punctuate mechanical stimulation of oral implant activates cortical somatosensory areas and induces brain plasticity (Habre-Hallage 2011) (Fig. 6-13). This activation may represent the underlying mechanism of osseoperception and confirms that some related cortical plasticity may truly exist.

However, the central neural pathways and neural characteristics contributing to implant-mediated sensory–motor control remain unclear. Future research should therefore try to visualize cortical plasticity after tooth extraction and further functional rehabilitation with implants in humans. It should be considered that an extraction and immediate implant rehabilitation protocol might induce a different cortical remodeling from that with a traditional two-stage implant rehabilitation protocol. An interesting phenomenon with respect to sensory–motor integration of osseointegrated implants may be the so-called phantom tooth (after extraction) or phantom limb (after amputation), allowing perception of lost body parts (Jacobs *et al*.

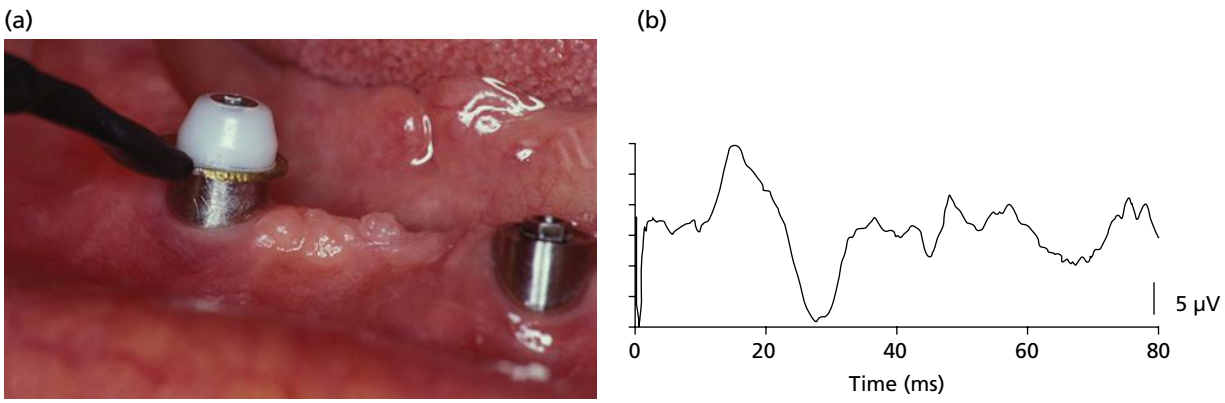

Fig. 6-12 (a) Electrical stimulation of an osseointegrated implant using a ring-shaped stimulation electrode fixed by a cover screw. (b) Trigeminal evoked potential elicited by electrical stimulation of an osseointegrated implant in the mandible. A similar potential could be maintained after topical anesthesia of the peri-implant soft tissues, indicating that the trigeminal potentials originated from other peri-implant structures such as bone and periosteal receptors.

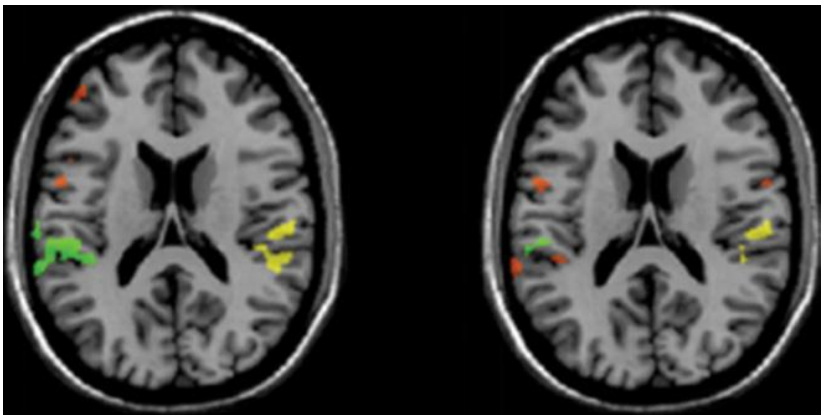

Fig. 6-13 Functional MRI showing cortical activation during tactile stimulation (1 Hz) of implant 21 (a) and tooth 23 (b) in the same subject (random effect analysis of subject sample). The primary somatosensory area is displayed in green, the secondary somatosensory area in yellow, and the other foci of activation in orange. (Source: Habre-Hallage *et al*. 2012, with permission of Pascale Habre, KU Leuven.)

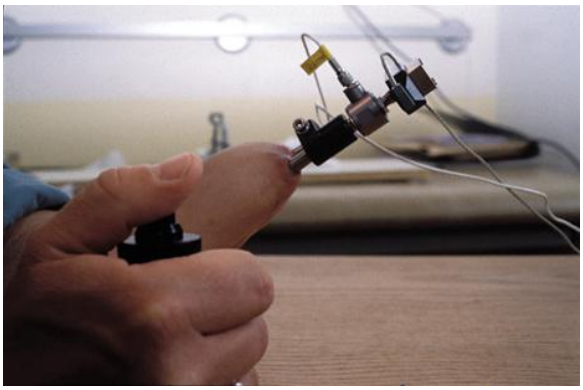
2002c). In fact, it could be assumed that such a phantom feeling of the lost limb may overlap with or enforce the feeling of a bone-anchored prosthetic limb (Jacobs *et al*. 2000). In this way, phantom sensations might contribute to physiologic integration of a bone-anchored prosthesis in the human body.

Once neuroplasticity after amputation and osseointegration is fully unraveled, it may be a consideration during treatment as it could optimize adaptation to oral rehabilitation and implant placement (Feine *et al*. 2006).

From osseoperception to implant-mediated sensory–motor interactions

During the last few decades, millions of patients have been rehabilitated by means of osseointegrated implants. Even though part of the peripheral feedback mechanism is lost after tooth extraction, edentulous patients seem to function quite well, especially when rehabilitated with a prosthesis retained by or anchored to osseointegrated implants (Jacobs 1998). These findings correspond well to those in amputees rehabilitated with a bone-anchored prosthesis rather than a socket prosthesis. During skeletal reconstruction, psychophysical testing reveals an improved tactile and vibrotactile capacity with osseointegrated implants and bone-anchored prosthetic limbs (Fig. 6-14). Furthermore, both edentulous patients and amputees seem to report an improved awareness and special feeling with the implant-supported prosthesis, suggesting the hypothesis that the peripheral feedback pathway is partially restored with a representation of the artificial limb feeling in the sensory cortex (Lundborg *et al*. 2006). If this hypothesis can be confirmed, osseointegrated implants in the jaw or other skeletal bones might contribute to implant-mediated sensory motor control, allowing physiologic integration of the implant into the human body and as a result, a more natural functioning (Jacobs & van Steenberghe 2006).

(a)



(b)

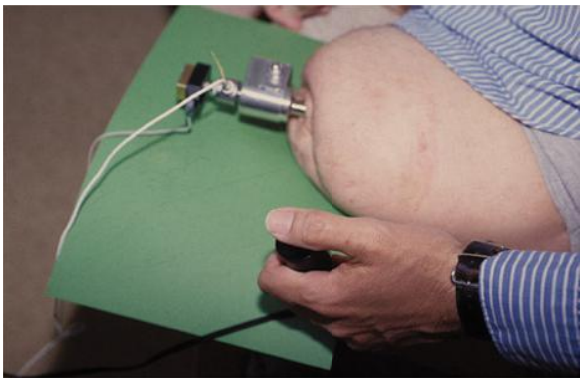


Fig. 6-14 Psychophysical test set-up using patient-controlled remote control for a vibrotactile stimulator fixed to a radial (a) and femoral (b) osseointegrated implant. This particular test set-up yields a superior perception for implants and bone-anchored prosthetic limbs as compared to socket prostheses. (Source: Jacobs *et al*. 2000. Reproduced with permission from Sage.)

Clinical implications of implant-mediated sensory–motor interactions

Psychophysical testing of various bone-anchored prostheses confirms an improved tactile function leading to a better physiologic integration of the limb. If perception upon implant stimulation is working well, peripheral feedback mechanism may be

restored and help fine-tune motor control. This implant-mediated sensory–motor interaction may thus help to achieve a more natural function with the bone-anchored prosthesis. Osseointegrated thumb prostheses even allow patients to perform the activities of daily life without any problem, which can be attributed to bone-anchorage and bilateral cortical representation after prosthesis stimulation. Considering the increased tactile threshold level for oral implant stimulation, a few clinical implications should be considered. During rehabilitation by means of implant-supported prostheses, a dentist should not rely on the patient's perception of occlusion. In this respect, the dentist should also be aware of the gradually increasing tactile function during the healing period after implant placement. This may be of particular importance when dealing with immediate loading protocols. To avoid any overloading related to suboptimal feedback mechanisms, patients should be encouraged to limit chewing forces by eating only soft foods during the healing period. Furthermore, parafunctional habits such as grinding or clenching might have a negative impact during the implant healing phase, but further research is needed to confirm this assumption (Lobbezoo *et al*. 2006). Until further evidence is available, bruxism may be considered as a relative contraindication to immediate loading protocols (Glauser *et al*. 2001).

Conclusion

Sensory feedback plays an essential role in the fine-tuning of jaw and limb motor control. Periodontal mechanoreceptors, and more specifically those located in the periodontal ligament, are extremely sensitive to external mechanical stimuli. These receptors play the key role in tactile function of teeth, yielding detection thresholds of a thickness of about 20 µm between antagonistic teeth and 1–2 g upon tooth loading. It is the sensory characteristics and related peripheral feedback that dedicate the periodontal ligament receptors to the fine-tuning of masticatory and other oral motor behaviors.

It is clear that any condition that may influence periodontal mechanoreceptors may also alter the sensory feedback pathway, and thus influence tactile function and modulation of jaw motor control (e.g. periodontal breakdown, bruxism, re-implantation, anesthesia). After extraction of teeth, the periodontal ligament is lost and so are its mechanoreceptors. After placement of oral implants, detection thresholds are increased to a thickness of at least 50-100 µm and 50–100 g upon tooth loading.

Surprisingly, patients rehabilitated by means of osseointegrated implants seem to function quite well and/or sense even better. In accordance with this, amputated patients rehabilitated with a lower limb prosthesis anchored to the bone by means of an osseointegrated implant have reported that they could sense the type of surface they were walking on, and those with a bone-anchored thumb prosthesis had a conscious perception of fingers.

The underlying mechanism of this so-called "osseoperception" phenomenon remains a matter of debate, but it is assumed that mechanoreceptors in the peri-implant bone and neighboring periosteum may be activated upon implant loading. Histologic, neurophysiologic, and psychophysical evidence of osseoperception has been amassed, making the assumption more likely that a proper peripheral feedback pathway can be restored when using osseointegrated implants. This implant-mediated sensory–motor control may have important clinical implications, because a more natural functioning can be attempted with implant-supported prostheses. This may open doors for physiologic and psychophysical integration of implants in the human body.

Introduction

The term epidemiology is of Hellenic origin; it consists of the preposition "epi", which means "among" or "against", and the noun "demos", which means "people". As denoted by its etymology, epidemiology is defined as "the study of the distribution of disease or a physiological condition in human populations and of the factors that influence this distribution" (Lilienfeld 1978). A more inclusive description by Frost (1941) emphasizes that "epidemiology is essentially an inductive science, concerned not merely with describing the distribution of disease, but equally or more with fitting it into a consistent philosophy". Thus, the information obtained from an epidemiologic investigation should extend beyond a mere description of the distribution of the disease in different populations (*descriptive* epidemiology). It should be further expanded to (1) elucidate the etiology of a specific disease by combining epidemiologic data with information from other disciplines such as genetics, biochemistry, microbiology, sociology, etc. (*etiologic* epidemiology); (2) evaluate the consistency of epidemiologic data with hypotheses developed clinically or experimentally (*analytical* epidemiology); and (3) provide the basis for developing and evaluating preventive procedures and public health practices (*experimental* epidemiology).

Based on the above, epidemiologic research in periodontology must (1) fulfil the task of providing data on the *prevalence* of periodontal diseases (the frequency of their occurrence) in different populations, as well as on the *severity* of such conditions, that is the amount of pathologic changes; (2) elucidate aspects related to the *etiology* and the *determinants* of these diseases (*causative* and *risk* factors); and (3) provide documentation concerning the effectiveness of preventive and therapeutic measures on a population basis.

Methodologic issues

Examination methods: Index systems

Examination of the periodontal status of a given individual includes clinical assessments of inflammation in the gingiva, recordings of probing depths and clinical attachment levels, as well as radiographic assessments of the amount of loss of supporting alveolar bone. A variety of index systems for the scoring of these parameters have been developed, some of which were designed exclusively for examination of patients in a dental practice set-up, while others were developed for use in epidemiologic research. The design of the index systems and the definition

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

of the various scores inevitably reflect the knowledge of the etiology and pathogenesis of periodontal diseases at the time these systems were introduced, as well as concepts related to the contemporary therapeutic approaches and strategies. This section will not provide a complete list of all available scoring systems, but rather give a brief description of a limited number of indices that are either currently used or are likely to be encountered in the recent literature. For a description of earlier scoring systems and a historical perspective of their development, the reader is referred to Ainamo (1989).

Assessment of inflammation of the periodontal tissues

Presence of inflammation in the gingiva is usually recorded by the use of a probe, and often according to the principles of the Gingival Index System outlined by Löe (1967). According to this system, absence of visual signs of inflammation in the gingival unit is scored as 0, while a slight change in color and texture is scored as 1. Visual inflammation and bleeding tendency from the gingival margin right after a periodontal probe is briefly run along the gingival margin is scored as 2, while overt inflammation with a tendency for spontaneous bleeding is scored as 3. A parallel index scores plaque deposits (Plaque Index System) on a scale from 0 to 3 (Silness & Löe 1964): the absence of plaque is scored as 0, plaque disclosed after running the periodontal probe along the gingival margin as 1, visible plaque as 2, and abundant plaque as 3. Simplified variants of both the Gingival and the Plaque indices (Ainamo & Bay 1975) have been extensively used, assessing presence/absence of inflammation or plaque, respectively, in a binomial fashion (*dichotomous scoring*). In such systems, bleeding from the gingival margin and visible plaque correspond to a score of 1, while absence of bleeding and no visible plaque correspond to a score of 0.

Bleeding after probing to the base of the probeable pocket (Gingival Sulcus Bleeding Index) has been a common way of establishing the occurrence of subgingival inflammation, characterized by the presence of an inflammatory infiltrate adjacent to the ulcerated pocket epithelium (Mühlemann & Son 1971). In this dichotomous registration, cases where bleeding emerges within 15 seconds after probing are scored as 1.

Assessment of loss of periodontal tissue support

One of the early indices providing indirect information on the loss of periodontal tissue support was the Periodontal Index (PI) developed in the 1950s by Russell (1956), and until the 1980s it was the most widely used index in epidemiologic studies of periodontal disease. Its criteria are applied to each tooth and the scoring is as follows: a tooth with healthy periodontium scores 0, a tooth with gingivitis around only part of the tooth circumference scores 1, a tooth with gingivitis encircling the tooth scores 2, pocket formation scores 6, and loss of function due to excessive tooth mobility scores 8. Due to the nature of the criteria used, the PI is a reversible scoring system; in other words, after treatment, a tooth or an individual can have the score lowered or reduced to 0.

In contrast to the PI system, the Periodontal Disease Index (PDI), developed by Ramfjord (1959), is a system designed to assess *destructive* disease; it measures *loss of attachment* instead of *pocket depth* and is, therefore, an irreversible index. The scores, ranging from 0 to 6, denote periodontal health or gingivitis (scores 0–3) and various levels of attachment loss (scores 4–6).

In contemporary epidemiologic studies, loss of periodontal tissue support is assessed by measurements of probing pocket depth (PPD) and probing attachment level (PAL). PPD is defined as the distance from the gingival margin to the apical location of the tip of a periodontal probe that is inserted into the pocket using a moderate probing force. Likewise, PAL or clinical attachment level (CAL) is defined as the distance from the cementoenamel junction (CEJ) to the location of the probe tip. Probing assessments are usually carried out at several locations along the tooth circumference (buccal, lingual, mesial, and distal). The number of probing assessments per tooth has varied in epidemiologic studies from two to six, while the examination may include either all teeth present (*full-mouth*) or a subset of *index* teeth (*partial-mouth* examination).

Carlos *et al*. (1986) proposed an index system which records loss of periodontal tissue support. The index was denoted the Extent and Severity Index (ESI) and consists of two components (*bivariate* index): (1) the *Extent*, describing the proportion of tooth sites of a subject showing signs of destructive periodontitis, and (2) the *Severity*, describing the amount of PAL at the diseased sites, expressed as a mean value. An attachment loss threshold of >1 mm was set as the criterion that qualified a tooth site as affected by the disease. The introduction of a threshold value serves a dual purpose: (1) it readily distinguishes the fraction of the dentition affected by disease at levels exceeding the error inherent in the clinical measurement of attachment loss; and (2) it prevents unaffected tooth sites from contributing to the individual subject's mean attachment loss value. In order to limit the number of measurements to be performed, a partial examination comprising the mid-buccal and mesiobuccal aspects of the upper right and lower left quadrants was recommended. It has to be emphasized that the system was designed to assess the cumulative effect of destructive periodontal disease rather than the presence of the disease itself. The bivariate nature of the index facilitates a

rather detailed description of attachment loss patterns: for example, an ESI of (90, 2.5) suggests a generalized but rather mild form of destructive disease, in which 90% of the tooth sites are affected by an average attachment loss of 2.5 mm. In contrast, an ESI of (20, 7.0) describes a severe, localized form of disease. Validation of various partial extent and severity scoring systems against the full-mouth estimates has been performed (Papapanou *et al*. 1993).

Radiographic assessment of alveolar bone loss

The potential and the limitations of intraoral radiography to describe loss of supporting periodontal tissues were reviewed in classical publications (Lang & Hill 1977; Benn 1990) and recent reports (Vandenberghe *et al*. 2010). Radiographs have been commonly employed in cross-sectional epidemiologic studies to evaluate the result of periodontal disease on the supporting tissues rather than the presence of the disease itself, and are thought to provide valid estimates of the extent and severity of destructive periodontitis (Pitiphat *et al*. 2004). Radiographic assessments have been particularly common as screening methods for detecting subjects suffering from juvenile periodontitis as well as a means for monitoring periodontal disease progression in longitudinal studies. Assessments of bone loss in intraoral radiographs are usually performed by evaluating a multitude of qualitative and quantitative features of the visualized interproximal bone, including (1) the presence of an intact lamina dura, (2) the width of the periodontal ligament space, (3) the morphology of the bone crest ("even" or "angular" appearance), and (4) the distance between the CEJ and the most coronal level at which the periodontal ligament space is considered to exhibit normal width. The threshold for bone loss (the CEJ–bone crest distance considered to indicate that bone loss has occurred) varies between 1 and 3 mm in different studies. Radiographic data are usually presented as (1) mean bone loss scores per subject (or group of subjects) and (2) number or percentage of tooth surfaces per subject (or group of subjects) exhibiting bone loss exceeding certain thresholds. In early studies, bone loss was frequently recorded using "ruler" devices, describing the amount of lost or remaining bone as a percentage of the length of the root or the tooth (Schei *et al*. 1959; Lavstedt *et al*. 1975).

Assessment of periodontal treatment needs

An index system aimed at assessing the need for periodontal treatment in large population groups was developed, on the initiative of the World Health Organization (WHO), by Ainamo *et al*. (1982). The principles of the Community Periodontal Index for Treatment Needs (CPITN) can be summarized as follows:

1. The dentition is divided into six *sextants* (one anterior and two posterior tooth regions in each dental arch). The treatment need in a sextant is recorded when two or more teeth not intended for extraction are present. If only one tooth remains in the sextant, the tooth is included in the adjoining sextant.
2. Probing assessments are performed either around all teeth in a sextant or around certain index teeth (the latter approach has been recommended for epidemiologic surveys). Only the most severe measure in the sextant is chosen to represent the sextant.
3. The periodontal conditions are scored as follows:
   - *Code 0* is given to a sextant with no pockets, calculus or overhangs of fillings and no bleeding on probing
   - *Code 1* is given to a sextant with no pockets, calculus or overhangs of fillings, but in which bleeding occurs after gentle probing in one or several gingival units
   - *Code 2* is assigned to a sextant if there are no teeth with pockets exceeding 3 mm, but in which dental calculus and plaque-retaining factors are identified subgingivally
   - *Code 3* is given to a sextant that harbors teeth with 4–5-mm deep pockets
   - *Code 4* is given to a sextant that harbors teeth with pockets that are 6 mm deep or deeper.
4. The treatment needs (TNs) scores range from 0 to 4 and are based on the most severe periodontal condition code in the entire dentition, recorded as above. Thus, TN 0 indicates no need for periodontal therapy in the presence of gingival health (*Code 0*), TN 1 need for improved oral hygiene (*Code 1*); TN 2 need for scaling, removal of overhangs, and improved oral hygiene (*Codes 2 + 3*); and TN 3 more advanced treatment needs (*Code 4*).

Although not designed for epidemiologic purposes, this index system has been extensively used, and CPITN-based studies have often been the sole source of epidemiologic information on periodontal conditions, particularly those from developing countries. A later modification of the index, termed Community Periodontal Index (WHO 1997), places more emphasis on the assessment of periodontal conditions rather than the assessment of periodontal treatment needs. A substantial amount of data generated by the use of CPITN/CPI have been accumulated in the WHO Global Oral Data Bank (Miyazaki *et al*. 1992; Pilot & Miyazaki 1994; Petersen & Ogawa 2005; Petersen *et al*. 2010) and are accessible electronically through servers maintained at the WHO Collaborating Centers at the Niigata University, Japan and the University of Malmö, Sweden.

Periodontitis "case definition" in epidemiologic studies

A fundamental prerequisite for any meaningful comparative assessment of prevalence is a valid and accurate definition of the disease under investigation.

Unfortunately, no uniform criteria have been established in periodontal research for this purpose. Epidemiologic studies have employed, in an inconsistent manner, a wide array of symptoms, including gingivitis, probing pocket depth, clinical (or probing) attachment level, and radiographically assessed alveolar bone loss. Considerable variation characterizes the threshold values employed for defining periodontal pockets as "deep" or "pathologic", or the clinical attachment level and alveolar bone scores required for assuming that loss of periodontal tissue support has in fact occurred. In addition, the number of "affected" tooth surfaces required for assigning an individual subject as a "case", that is as suffering from periodontal disease, has varied. These inconsistencies in the definitions inevitably affect the data describing the distribution of the disease (Papapanou 1996; Kingman & Albandar 2002; Demmer & Papapanou 2010) and, consequently, the identification of risk factors (Borrell & Papapanou 2005). Any review of the literature charged with the task of comparing disease prevalence or incidence in different populations or at different time periods must first confront the interpretation of the published data and literally "decode" them in order to extract relevant information that is amenable to inter-study comparisons. These problems have been addressed in the literature and three specific aspects have attracted special attention, namely (1) the ability of partial recordings to reflect full-mouth conditions, (2) the use of the CPITN system in studies of periodontal disease, and (3) the definition of a "periodontitis case" in epidemiologic studies.

It is clear that an optimal examination of periodontal conditions should include circumferential probing assessments around all teeth. Nevertheless, the majority of epidemiologic studies have, for practical reasons, employed partial recording methodologies. The rationale for the use of partial examinations has been the assumption that (1) the time required for carrying out a partial recoding is significantly decreased, resulting in lower cost and better patient acceptance, and (2) the amount of information lost is kept to a minimum, assuming that the examined segments adequately reflect the periodontal condition of the entire dentition. However, attempts to accurately quantify the amount of information lost through the different partial recording systems made by several investigators (Diamanti-Kipioti *et al*. 1993, Eaton *et al*. 2001; Susin *et al*. 2005a; Kingman *et al*. 2008) have revealed that the discrepancy between the findings obtained by means of partial- and full-mouth surveys may be substantial. These studies have typically employed full-mouth data for a series of periodontal parameters and compared them with the values obtained by assessments of a subset of teeth or tooth surfaces. Their results suggest that:

1. High correlations between full-mouth and half-mouth clinical attachment loss scores should be expected in adult populations, due to the apparent symmetry of periodontal conditions around the midline.
2. The performance of a partial recording system is directly dependent on the actual prevalence and extent of periodontal disease in the population in question and, consequently, on the age of the subjects examined; the less frequent the disease is in the population and the lower the number of sites that are affected in each individual, the more difficult it becomes for the partial examination to accurately portray the full-mouth periodontal status.
3. A full-mouth examination provides the best means of accurately assessing the prevalence and severity of periodontal disease in a population.

The use of the CPITN system in epidemiologic studies of periodontal disease was critically evaluated in a number of publications (Schürch *et al*. 1990; Butterworth & Sheiham 1991; Baelum *et al*. 1993a, b, 1995; Baelum & Papapanou 1996; Benigeri *et al*. 2000). At the time the system was designed, the conversion from periodontal health to periodontitis was thought to follow a continuum of conditions of increasing severity, ranging from health to gingivitis, calculus deposition, formation of deep pockets, and destructive, progressive disease. Consequently, treatment approaches were primarily focused on probing depths to determine the choice between non-surgical and more complex, surgical periodontal therapy. As mentioned earlier, the CPITN system was originally intended for population screening in order to determine treatment needs and to facilitate preventive and therapeutic strategies; it was not meant to describe the prevalence, extent, and severity of periodontal disease and several studies have questioned the suitability of the CPITN for such purposes. For example, Butterworth and Sheiham (1991) examined the ability of CPITN to reflect changes in periodontal conditions in patients of a general dental practice before and after periodontal therapy. Despite a substantial improvement in periodontal status, that is a reduction in gingivitis, calculus scores, and deep pockets, the CPITN scores were only marginally improved. Furthermore, in a rural Kenyan subject sample, Baelum *et al*. (1993b) refuted the validity of the *hierarchical principle* of the CPITN, that is the assumption that a tooth with calculus is assumed to be also positive for bleeding on probing, or that a tooth with deep pockets is assumed to be positive for both calculus and bleeding. In a companion paper, results from a full-mouth examination were compared with those generated by the use of the ten index teeth recommended by the WHO for surveys of adults (Baelum *et al*. 1993a). The study revealed that the partial CPITN methodology seriously underestimated the more severe periodontal conditions both in terms of prevalence and severity, by failing to detect a substantial proportion of subjects with periodontal pockets. Finally, an examination of the relationship

between CPITN findings and the prevalence and severity of clinical attachment loss demonstrated that the CPITN scores do not consistently correlate with clinical attachment loss measures, but tend to overestimate prevalence and severity among younger subjects and underestimate such parameters in elderly populations (Baelum *et al*. 1995). Collectively, the above data call for caution in the interpretation of epidemiologic studies based on the CPITN/CPI systems.

As mentioned earlier, a concise "case definition" is essential for assessing disease prevalence and incidence and to generate comparable data across populations. The currently used classification of periodontal diseases was introduced by the 1999 International Workshop for a Classification of Periodontal Diseases and Conditions and encompasses eight main categories, namely:

I Gingival diseases
II Chronic periodontitis
III Aggressive periodontitis
IV Periodontitis as a manifestation of systemic diseases
V Necrotizing periodontal diseases
VI Abscesses of the periodontium
VII Periodontitis associated with endodontic lesions
VIII Developmental or acquired deformities and conditions.

According to the above scheme, the principal forms of periodontitis, which this chapter will mainly focus on, fall under categories II and III, that is *chronic* and *aggressive periodontitis*. *Chronic periodontitis* is the more "common" form that occurs primarily in adults, progresses at a relatively slow rate, resulting in an extent and severity of periodontal tissue loss that is largely commensurate with the presence of local etiologic factors. In contrast, *aggressive periodontitis* is less frequent, affects primarily, but not exclusively, young, systemically healthy individuals, progresses rapidly, and results in substantial loss of periodontal tissue support that may be disproportionate to the occurrence of local etiology. Importantly, *aggressive periodontitis* shows *familial aggregation*, that is it appears to affect parents and siblings within the same family, indicating that genetic predispositions and common environmental exposures are important determinants of the disease. However, none of the three primary features of *aggressive periodontitis* (systemically healthy patient; rapid attachment loss and bone loss; familial aggregation) (Lang 1999) can facilitate the differential diagnosis between *chronic* and *aggressive periodontitis* in the setting of an epidemiologic study: the first because it is entirely non-specific; the second because it requires at least two examinations over time to determine how "rapidly" the periodontal destruction has occurred; and the third because it is subject to *reporting bias*, and requires extensive interviewing and verification to ascertain reliably. As a result, very sparse epidemiologic data have been generated to date by strictly adhering to the primary criteria of these principal forms of periodontitis. Instead, several studies have reported periodontitis prevalence data using the periodontitis case definition introduced by a working group from the Centers for Disease Control (CDC) and the American Academy of Periodontology (AAP) that is based on a combination of probing depth and clinical attachment level assessments (Page & Eke 2007). The CDC/AAP case definition does not distinguish chronic and aggressive forms of periodontitis, but defines (1) *severe periodontitis* as the presence of two or more interproximal sites with ≥6 mm of clinical attachment loss, not on the same tooth, *and* the presence of at least one interproximal site with a ≥5-mm probing depth; and (2) *moderate periodontitis* as the presence of two or more interproximal sites with ≥4 mm of clinical attachment loss occurring at two or more different teeth *or* two or more interproximal sites with a ≥5-mm probing depth, not on the same tooth. An alternative, two-level periodontitis case definition for use in epidemiologic studies was developed by a working group of the 5th European Workshop in Periodontology (Tonetti & Claffey 2005), and consisted of a *sensitive* definition (proximal attachment loss of ≥3 mm in two or more non-adjacent teeth) and a *specific* definition (proximal attachment loss of ≥5 mm in ≥30% of the teeth present). The former definition aimed at capturing incipient forms of the disease, while the latter was meant to reflect periodontitis of substantial extent and severity. Lastly, Demmer and Papapanou (2010) recently proposed a method for differentiating chronic and aggressive forms of periodontitis in epidemiologic studies of young individuals (≤35 years old) based on a combination of *age* and *extent/severity* of periodontitis. Specifically, these authors suggested that for those aged ≤25 years, the presence of two or more interproximal, non-adjacent sites with ≥4 mm of attachment loss at a minimum of two different teeth, and accompanied by bleeding on probing, signifies the presence of *aggressive periodontitis*, while a more demanding threshold of attachment loss (≥6 mm) is required to arrive at the same diagnosis in individuals aged between 26 and 35 years. In other words, according to this classification approach, extent and severity of periodontal disease exceeding the above thresholds in a young individual is incompatible with a diagnosis of *chronic periodontitis*, as the *de facto* substantial loss of periodontal tissue support early in life indicates rapid progression of the disease and thus justifies its diagnosis as *aggressive periodontitis*. This age-adjusted approach obviously fails to facilitate the differential diagnosis between severe chronic and aggressive periodontitis in a subject over the age of 35 years. Access to disease progression data derived from sequential examinations and/or confirmation of familial aggregation according to the 1999 consensus report are therefore necessary in

order to distinguish the two forms of periodontitis in older patients, but the feasibility of such an approach in the setting of an epidemiologic study remains highly questionable.

Given the lack of universal consensus on the definitions of periodontitis and the continuously evolving epidemiologic approaches, in the following text we have opted to summarize the available data on the prevalence and progression of periodontal disease according to the age range of the examined cohorts. We thus first present findings from epidemiologic studies in adults, including studies exclusively targeting elderly populations, followed by corresponding findings derived from children, adolescents, and young adults. This strategy was adopted under the assumption that the former studies primarily reflect features of *chronic periodontitis*, while the latter studies largely refer to *aggressive periodontitis*.

Prevalence of periodontal diseases

Periodontitis in adults

It is important to briefly mention some older epidemiologic studies to acquire some historical perspective and appreciate how the concepts of both the descriptive and the analytical epidemiology of periodontitis have evolved over the years. Starting with a study performed during the 1950s in India, Marshall-Day *et al*. (1955) used assessments of alveolar bone height to distinguish gingivitis and destructive periodontal disease in 1187 dentate subjects. The authors reported (1) a decrease in the percentage of subjects with "gingival disease without any bone involvement" with increasing age concomitant with an increase in the percentage of subjects with "chronic, destructive periodontal disease", and (2) a 100% occurrence of destructive periodontitis after the age of 40 years. Findings from other epidemiologic studies from the same period verified a high prevalence of destructive periodontal disease in the adult population in general, and a clear increase in disease prevalence with age. In the 1960s, Scherp (1964) reviewed the available literature on the epidemiology of periodontal disease and concluded that (1) periodontal disease appears to be a major, global public health problem affecting the majority of the adult population after the age of 35–40 years; (2) the disease starts as gingivitis in youth, which, if left untreated, leads to progressive destructive periodontitis; and (3) >90% of the variance of the periodontal disease severity in the population can be explained by age and oral hygiene. These notions, based on established concepts of the pathogenesis of periodontal disease of that time, dominated the periodontal literature until the late 1970s.

Studies performed during the 1980s provided a more thorough description of the site-specific features of periodontal disease and the high variation in periodontal conditions between and within different populations. Contrary to previous custom, the prevalence issue was no longer addressed through assigning individuals simply to a "periodontitis-affected" or a "disease-free" group, based on presence or absence of attachment or alveolar bone loss. Instead, studies began to unravel details concerning the *extent* to which the dentition was affected by destructive disease (i.e. the percentage of tooth sites involved) and the *severity* of the defects (expressed as the magnitude of the tissue support lost due to the disease). The traditional description of pocket depth and attachment loss scores in terms of *subject mean values* was soon complemented by *frequency distributions*, revealing percentages of tooth sites exhibiting probing depth or attachment level of varying severity. Such an additional analysis appeared necessary after it became clear that mean values offer a crude description of periodontal conditions and fail to reflect the variability in the severity of periodontal disease within and between individuals. In an article presenting different methods of evaluating periodontal disease data in epidemiologic research, Okamoto *et al*. (1988) proposed the use of *percentile plots* in the graphic illustration of attachment loss data. As exemplified by Fig. 7-1, such plots make it possible to illustrate simultaneously both the proportion of subjects exhibiting attachment loss of different levels and the severity of the loss within the subjects. Similar plots

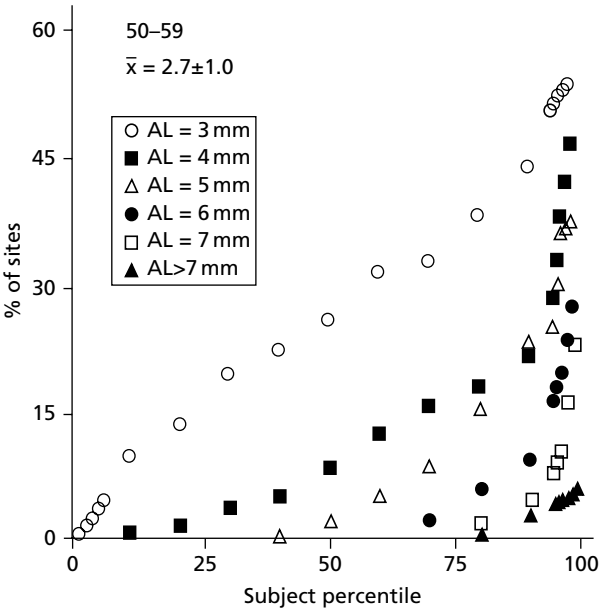

Fig. 7-1 Attachment loss in a group of Japanese subjects aged 50–59 years. The mean value of attachment level and the standard deviation are shown in the top of the figure. The x-axis represents the subject percentile and the y-axis represents the percentage of sites in the subjects showing attachment loss of 3, 4, 5, 6, 7, and >7 mm (represented by 8). Subjects with no or only minor signs of attachment loss are reported to the left and subjects with increasing amounts of periodontal destruction are reported to the right of the graph. For example, the median subject (50th percentile) exhibited 5-mm attachment loss at 2%, 4-mm loss at 8%, and 3-mm loss at 25% of its sites. (Source: Okamoto *et al*. 1988. Reproduced with permission from John Wiley & Sons.)

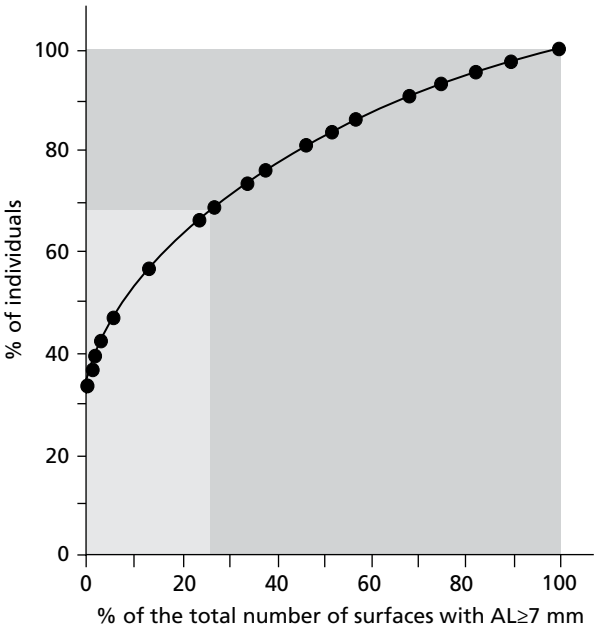

Fig. 7-2 Cumulative distribution of individuals aged ≥50 years according to the cumulated proportion of surfaces with attachment loss (AL) of ≥7 mm. All individuals are arranged according to increasing number of surfaces with AL of ≥7 mm present in each individual. Thus, individuals with few such surfaces are represented on the left side of the diagram and those with many such surfaces on the right side. It is seen that 31% (69–100%) of the individuals account for 75% (25–100%) of the total number of surfaces with AL of ≥7 mm present (shaded area). (Source: Baelum *et al*. 1986. Reproduced with permission from John Wiley & Sons.)

may be produced for other parameters, such as gingivitis, probing depths, and gingival recession, and may provide a comprehensive description of both the prevalence and the severity of periodontal disease in a given sample.

Baelum *et al*. (1986) described cross-sectional findings for dental plaque, calculus, gingivitis, loss of attachment, periodontal pockets, and tooth loss in a sample of adult Tanzanians aged 30–69 years. Despite the fact that the subjects examined exhibited large amounts of plaque and calculus, pockets deeper than 3 mm and attachment loss of >6 mm occurred at <10% of the tooth surfaces. Edentulism was virtually nonexistent, and a very small percentage of subjects had experienced major tooth loss. Of particular interest was the analysis of the distribution of sites within subjects (Fig. 7-2). This analysis revealed that 75% of the tooth sites with attachment loss of >6 mm were found in 31% of the subjects, indicating that a subset of the sample was responsible for the majority of the observed periodontal breakdown. In other words, advanced periodontal disease was not evenly distributed in the population and not readily correlated to supragingival plaque levels; instead, the majority of the subjects examined exhibited negligible periodontal problems, while a limited group was affected by advanced disease.

In a study of similar design performed in Kenya, the same investigators analyzed data from 1131 subjects aged 15–65 years and confirmed their earlier observations (Baelum *et al*. 1988a). Poor oral hygiene in the sample was reflected by high plaque, calculus, and gingivitis scores. However, pockets ≥4 mm deep were found in <20% of the surfaces and the proportion of sites per individual with deep pockets and advanced loss of attachment revealed a pronounced skewed distribution. The authors suggested that "destructive periodontal disease should not be perceived as an inevitable consequence of gingivitis which ultimately leads to considerable tooth loss" and called for a more specific characterization of the features of periodontal breakdown in those individuals who seem particularly susceptible.

At approximately the same time, Löe *et al*. (1986) published data from a longitudinal study that showed distinct patterns for the *progression* of untreated periodontitis. In a population never exposed to any preventive or therapeutic intervention related to oral diseases in Sri Lanka, a cohort of 480 14–31-year-old male tea-plantation laborers was recruited in 1970 and underwent subsequent follow-up examinations. A total of 161 individuals among those originally enrolled were re-examined in 1985, essentially generating data on the natural history of periodontal disease between the ages of 14 and 46 years. Despite poor plaque control and virtually ubiquitous gingival inflammation in the entire sample, three distinct patterns of progression of periodontitis were observed over the follow-up period, based on interproximal longitudinal attachment loss and tooth mortality rates: one group, comprising approximately 8% of the total, exhibited rapid progression of periodontal disease (RP); another group (approximately 11%) exhibited no progression (NP) of periodontal disease beyond gingivitis; and a third group between these two extremes (approximately 81%) exhibited moderate progression (MP). The mean loss of attachment in the RP group was 9 mm and 13 mm at the ages of 35 and 45 years, respectively, as opposed to 1 mm and 1.5 mm in the NP group, and 4 mm and 7 mm in the MP group. As a result, the annual rate of longitudinal attachment loss in the RP group varied between 0.1 and 1.0 mm, in the MP group between 0.05 and 0.5 mm, and in the NP group between 0.05 and 0.09 mm. Thus, this study clearly demonstrated huge variability in progression of periodontitis in a seemingly homogeneous population, and suggested that variables other than age, plaque, and gingival inflammatory status are important determinants of periodontal deterioration over time.

Several more recent epidemiologic studies verify the above principals. In these studies, periodontal disease has been assessed by means of clinical examination of the periodontal tissues (Brown *et al*. 1990; Albandar *et al*. 1999; Susin *et al*. 2004a; Thomson *et al*. 2006); radiographic assessments of alveolar bone loss (Papapanou *et al*. 1988; Jenkins & Kinane 1989; Salonen *et al*. 1991; Diamanti-Kipioti *et al*. 1995); or a combination of clinical and radiographic means (Papapanou *et al*. 1990; Hugoson *et al*. 1992, 1998a, 2005).

Table 7-1 Selected prevalence studies of periodontitis in adults.

Authors/country	Sample/methodology	Findings
Löe *et al*. (1978) Norway/Sri Lanka	Two samples, one comprising 565 Norwegian students and academicians and the other 480 Sri Lankan tea laborers, in ages 16–30+ years; assessments of plaque, gingivitis, calculus, PD, and AL at the mesial and facial aspects of all teeth	Norwegian group: excellent oral hygiene, negligible amounts of plaque and gingivitis, virtually no deep pockets and minimal attachment loss; mean AL at the age of 30 years <1 mm Sri Lankan group: poor oral hygiene, abundant plaque and calculus, attachment loss present at the age of 16 years, increasing with age; mean AL at the age of 30 years ≈ 3 mm, a substantial number of teeth with AL of >10 mm
Baelum *et al*. (1988a) Kenya	A stratified random sample of 1131 subjects, 15–65 years; full-mouth assessments of tooth mobility, plaque, calculus, bleeding on probing (BoP), PD, and AL	Plaque in 75–95% and calculus in 10–85% of all surfaces PD ≥4 mm in <20% of sites AL of ≥1 mm in 10–85% of sites Percentage of sites/subjects with PD or AL of ≥4 mm or ≥7 mm conspicuously skewed
Brown *et al*. (1990) USA	A sample of 15 132 subjects, stratified by geographic region, representing 100 million employed adults aged 18–64 years; probing assessments at mesial and buccal sites in one upper and one lower quadrant; mesial assessments performed from the buccal aspect of the teeth; assessments of gingivitis, PD, AL, and gingival recession	44% of all subjects had gingivitis at an average of 2.7 sites/subject and at <6% of all sites assessed Pockets 4–6 mm were observed in 13.4% of subjects at an average of 0.6 sites/person and at 1.3% of all sites assessed; corresponding figures for pockets ≥7 mm were 0.6%, 0.01, and 0.03% AL ≥3 mm was prevalent in 44% of subjects (increasing with age from 16% to 80%) affecting an average of 3.4 sites/subject; corresponding figures for AL ≥5 mm were 13% (2–35%) and 0.7 sites/subject
Salonen *et al*. (1991) Sweden	A random sample of 732 subjects, 20–80+ years, representing 0.8% of the population of a southern geographic region; full-mouth radiographic examination; alveolar bone level expressed as a percentage of the root length (B:R ratio); B:R of ≥80% represents intact periodontal bone support	Age group of 20–29 years: 38% of subjects had no sites with a B:R of <80% and 8% of subjects had ≥5 sites below this threshold Corresponding figures for the age group 50–59 years: 5% and 75%; after the age of 40, women displayed more favorable B:R ratios than men
Hugoson *et al*. (1998) Sweden	Three random samples of 600, 597, and 584 subjects aged 20–70 years, examined in 1973, 1983, and 1993, respectively; full-mouth clinical and radiographic examination; based on clinical and radiographic findings, the subjects were classified according to severity of periodontal disease in five groups, where group 1 (G1) included subjects with close to faultless periodontal tissues and group 5 (G5) subjects with severe disease	Edentulism decreased over the 20-year period from 11% to 8% to 5%; percentage distribution of the subjects in the five groups in 1973, 1983, and 1993 respectively was: G1 8%, 23%, 22%; G2 41%, 22%, 38%; G3 47%, 41%, 27%; G4 2%, 11%, 10%; G5 1%, 2%, 3%; the increase in the prevalence of subjects with severe disease was apparently due to the increased number of dentate subjects at the older ages
Albandar *et al*. (1999) USA	A nationally representative, multistage probability sample comprising 9689 subjects, 30–90 years old (NHANES III study); probing assessments at mesial and buccal sites in one upper and one lower quadrant; mesial assessments performed on the buccal aspect of the teeth; assessments of gingivitis, PD, and location of the gingival margin in relation to the CEJ	Pockets ≥5 mm were found in 8.9% of all subjects (7.6% in non-Hispanic Caucasians, 18.4% in non-Hispanic Blacks, and 14.4% in Mexican Americans) AL ≥5 mm occurred in 19.9% of all subjects (19.9% in non-Hispanic Caucasians, 27.9% in non-Hispanic Blacks, and 28.34% in Mexican Americans)
Schürch & Lang (2004) Switzerland	A total of 1318 subjects, randomly selected based on community rosters in seven regions, aged 20–89 years; probing assessments of PD and AL for all teeth present; assessments of plaque and gingivitis for index teeth	7.1% of subjects were edentulous; mean number of teeth present in dentate subjects was 21.6 Mean values of PD reached a plateau of 3 mm by the age of 49 years AL increased dramatically after the age of 50 years and paralleled a marked loss of teeth
Susin *et al*. (2004a) Brazil	A sample of 853 dentate individuals, selected by multistage probability sampling, aged 30–103 years; full-mouth examination of AL at six sites/tooth	Moderate AL (≥5 mm) and advanced AL (≥7 mm) occurred in 70% and 52% of the subjects, affecting an average of 36% and 16% of their teeth, respectively; in comparison to 30–39 year olds, 40–49 year olds had 3x increased risk for moderate and 7.4x increased risk for advanced AL; corresponding figures for ≥50 year olds were 5.9x and 25.4x, respectively

Table 7-1 *Continued.*

Authors/country	Sample/methodology	Findings
Dye *et al*. (2007) USA	NHANES 1999–2004 study, nationally representative sample comprising 10 312 individuals in four age cohorts (35–49, 50–64, 65–74, and 75+ years; partial-mouth examination in two randomly selected quadrants (one maxillary and one mandibular) at the mesio-facial and mid-facial sites of all fully erupted teeth excluding third molars	Prevalence of AL ≥3 mm in the four age cohorts was 36.1%, 53.4%, 67.2%, and 75.5% respectively Corresponding figures for PD ≥4 mm were 11.9%, 13.2%, 11.3%, and 12.1% respectively
Wang *et al*. (2007) China	A sample of 1590 dentate subjects with ≥14 teeth present, aged >25 years, from four geographic regions, equally farmers and urban professionals; partial-mouth examination at six sites in each of six index teeth	Average of 40% of sites bled on probing in the rural group as compared to 35% in the urban group Prevalence of AL ≥4 mm was approximately 10% in ages 25–34 years, increasing to 31%, 53%, and 70% in ages 35–44, 45–59, and >60 years, respectively, in the rural group; corresponding figures were 18%, 38%, and 57% in the urban group
Holtfreter *et al*. (2010) Germany	The fourth German Dental Health Survey examined a total of 1965 individuals aged 35–44 years (adult sample) and 65–74 years (senior sample); partial-mouth examination of PD and AL at three sites in each of 12 index teeth	AL ≥3 mm was prevalent in 95% of the adults and 99.2% of the seniors (68.7% and 91.4% of teeth affected, respectively) PD ≥4 mm was prevalent in 70.9% and 87.4% of the adult and senor cohorts, respectively
Eke *et al*. (2012) USA	NHANES 2009–2010 study, nationally representative sample comprising 3742 individuals in four age cohorts (30–34, 35–49, 50–64, 65+ years); full-mouth examination at six sites per tooth at all fully erupted teeth excluding third molars	Prevalence of AL ≥3 mm in the four age cohorts was 64.1%, 83.1%, 92.0%, and 96.7%, respectively Corresponding figures for PD ≥4 mm were 29.6%, 35.5%, 47.5%, and 49.3%, respectively Prevalence of severe periodontitis, according to the CDC/AAP definition (Page & Eke 2007) was 1.9% in ages 30–34 years, 6.7% in ages 35–49 years, 11.7% in ages 50–64 years, and 11.2% in ages 65 years and above

PD, probing depth; AL, attachment level; CEJ, cemento-enamel junction; NHANES, National Health and Nutrition Examinations Surveys; CDC/AAP, Centers for Disease Control/American Academy of Periodontology.

Table 7-1 summarizes the design and main findings from a number of cross-sectional studies in adults from geographically divergent areas and involving samples of a relatively large size. Several included studies focused on assessments of prevalence of "advanced periodontitis", the definition of which is, however, far from identical across the different reports, rendering comparisons difficult. Nevertheless, it appears that severe forms of periodontitis affect a relatively limited portion of the population in the industrialized countries, usually not exceeding 10–15%. This fraction increases considerably with age and appears to reach its peak at the age of 50–60 years. The increased loss of periodontally affected teeth occurring after this age appears to account for the subsequent decline in prevalence. It is worth pointing out that studies employing full-mouth examination protocols generally generate higher prevalence estimates, underscoring the decisive impact of the methodology. An interesting issue is also the apparent disparity in the extent and severity of periodontitis across different populations. In an earlier report by Baelum *et al*. (1996), the authors recalculated their own data from a Kenyan (Baelum *et al*. 1988a) and a Chinese (Baelum *et al*. 1988b) adult population to conform with the examination methodology and data presentation utilized in each of six other surveys: from Japan (Yoneyama *et al*. 1988), Norway (Löe *et al*. 1978), New Mexico (Ismail *et al*. 1987), Sri Lanka (Löe *et al*. 1978), and two South Pacific islands (Cutress *et al*. 1982). Among the samples included in this analysis, only the Sri Lankan and the South Pacific island subjects appeared to suffer severe periodontal tissue breakdown, while the distribution of advanced disease was strikingly similar in six of the eight samples, despite marked differences in oral hygiene conditions. Hence, the data failed to corroborate the traditional generalization that the prevalence and severity of periodontitis is markedly increased in African and Asian populations. On the other hand, data from the National Health and Nutrition Examinations Surveys (NHANES) (Albandar *et al*. 1999; Dye *et al*. 2007; Eke *et al*. 2012), which examined large nationally representative, stratified, multistage probability samples in the US, clearly showed that the prevalence of deep pockets and advanced attachment loss was more pronounced in non-Hispanic black than in non-Hispanic white subjects. This observation was consistent even when several alternative thresholds defining advanced disease were employed. Thus, current evidence suggests that the prevalence of severe periodontitis is not

Table 7-2 Selected prevalence studies of periodontitis in elderly subjects.

Authors/country	Sample/methodology	Findings
Baelum *et al*. (1988b) China	544 persons, aged 60+ years, from two urban and one rural area of the Beijing area; assessments of plaque, calculus, gingivitis, loss of attachment, pocket depth and tooth mobility	0–29% edentulous; mean number of teeth 6.9–23.9, depending on age and sex ≈50% of all surfaces with plaque and calculus 50% of all sites with AL of ≥4 mm <15% with PD ≥4 mm Conspicuously skewed percentage of sites/persons with AL of ≥7 mm and PD ≥4 mm
Locker & Leake, (1993a) Canada	907 subjects, aged 50–75+ years, living independently in four communities; probing assessments at mesio-buccal and mid-buccal aspects of all teeth; mid-palatal and mesio-palatal probing assessments in upper molars; 23% of subjects edentulous; calculation of Extent and Severity Index (ESI) with AL threshold set at ≥2 mm; "severe disease": >4 sites with AL ≥5 mm and PD ≥4 mm at ≥1 of those sites	59% of subjects with PD of ≥4 mm, 16% with ≥6 mm, and 3% with ≥8 mm 86% of subjects with AL of ≥4 mm, 42% with ≥6 mm, and 16% with ≥8 mm; 20% of the subjects with a mean PAL of ≥4 mm Severe disease in 22% of subjects; mean ESI: 77, 2.44
Beck *et al*. (1990) USA	690 community dwelling adults, aged 65+ years; probing assessments at mesio-buccal and mid-buccal surfaces, all teeth; "advanced disease": ≥4 sites with AL of ≥5 mm and PD ≥4 mm at ≥1 of those sites	Mean ESI in Blacks: 78, 4; in Caucasians: 65, 3.1 Advanced disease in 46% of Blacks and 16% of Caucasians
Gilbert & Heft (1992) USA	671 dentate subjects, aged 65–97 years, attending senior activity centers; probing assessments at mesial and buccal surfaces of one upper and one lower quadrant; questionnaire data; calculation of ESI	Average of 17.0 teeth/subject 50.7% of subjects with most severe mesial PD of 4–6 mm and 3.4% with PD of ≥7 mm 61.6% with most severe AL of 4.6 mm and 24.2% with AL of ≥7 mm ESI increased with age: 84.8, 3.6 (65–69 years); 88.7, 3.8 (75–79 years); 91.2, 3.9 (85+ years)
Douglass *et al*. (1993) USA	1151 community-dwelling elders, aged 70+ years; probing assessments at ≥3 sites/tooth, all teeth; 57% of the sample female, predominantly Caucasian (95%); 37.6% edentulous; mean number of teeth present between 21.5 and 17.9, depending on age	85% of subjects with BOP 66% with 4–6-mm deep pockets affecting an average of 5.3 teeth/subject; 21% with pockets of >6 mm affecting an average of 2.2 teeth 39% with AL of 4–6 mm at 6.7 sites/subject and 56% with AL of >6 mm at 2.7 teeth/subject
Kiyak *et al*. (1993) USA	1063 residents in 31 nursing homes, aged 72–98 years; visual inspection of the oral cavity; periodontal status assessed indirectly through registration of intraoral swelling or suppuration, sore or bleeding gums, increased tooth mobility, and poor oral hygiene	42% of subjects with remaining natural teeth; 43% had sore or bleeding gums, 18% with significant tooth mobility, 6% with intraoral swelling or suppuration, and 72% with poor oral hygiene
Weyant *et al*. (1993) USA	650 long-term residents of nursing home care units, mean age 72 years; probing assessments at mesial and buccal surfaces, all teeth; demographic, oral and general health data recorded; sample predominantly male and Caucasian; calculation of ESI scores	42% edentulous 60% of subjects with PD of >3 mm at an average of 5.8 sites/person; 3.7% with PD of ≥6 mm at <1 site/person Overall mean mesial ESI of 74, 2.91
Bourgeois *et al*. (1999) France	603 non-institutionalized elderly, aged 65–74 years; stratified sample with respect to gender, place of residence and socioeconomic group; periodontal conditions assessed by CPITN	16.3% edentulous 31.5% of subjects had pockets ≥4 mm; 2.3% had pockets ≥6 mm
Levy *et al*. (2003) USA	From a sample of 449 community dwelling elders, mean age 85 years, 342 (76%) were dentate and 236 were examined with respect to PD and AL at four sites/tooth in all teeth present	91% of ubjects had ≥1 site with ≥4 mm AL, 45% ≥1 site with ≥6 mm AL, and 15% ≥1 site with ≥8 mm AL
Mack *et al*. (2004) Germany	1446 randomly selected subjects aged 60–79 years; half-mouth examination of PD and AL at four sites/ tooth; plaque calculus and BoP were assessed at index teeth	16% of the 60–65-year olds and 30% of the 75–79-year olds were edentulous Among the 70–79-year olds, median BoP was 37.5% in men and 50% in women Prevalence of PD ≥6 mm was 31.8% and 28.5% in men and women, respectively Prevalence of AL ≥5 mm was 71.9% and 66.9% in men and women, respectively
Syrjälä *et al*. (2010) Finland	1460 individuals aged ≥65 years, participants in the nationally representative Health 2000 Survey; full-mouth examination at four sites/tooth at all erupted teeth except third molars	44.3% edentulous 31% of dentate participants had no pockets >3 mm; 28% had 1–3 teeth with ≥4 mm pockets, 15% had 4–6 and 26% ≥7 affected teeth 73% showed BoP at ≥1 sextant

PD, probing depth; AL, attachment level; BoP, bleeding on probing; CEJ, cemento-enamel junction; ESI, Extent and Severity Index; CPITN, Community Periodontal Index of Treatment Needs.

uniformly distributed among various races, ethnicities or socioeconomic groups.

The limitations of the findings from studies using the CPITN system were discussed earlier. However, a substantial part of the available information from developing countries has been collected using this particular system. An article providing a summary of almost 100 CPITN surveys from >50 countries performed over the period 1981–89 for the age group 35–44 years was published by Miyazaki *et al*. (1991b). These studies indicate a huge variation in the percentage of subjects with one or several deep (≥6 mm) pockets, both between and within different geographic areas. The percentage of subjects with such deep pockets ranged between 1% and 74% in Africa (data from 17 surveys), 8% and 22% in North and South America (four surveys), 2% and 36% in the Eastern Mediterranean (six surveys), 2% and 40% in Europe (38 surveys), 2% and 64% in South-East Asia, and 1% and 22% in the Western Pacific area (17 surveys). The average number of sextants per subject with ≥6-mm deep pockets also varied considerably and ranged between 0 and 2.1 in Africa, 0.1 and 0.4 in North and South America, 0.1 and 0.6 in the Eastern Mediterranean, 0.1 and 0.8 in Europe, 0.1 and 2.1 in South-East Asia, and 0 and 0.4 in the Western Pacific area. However, it is difficult to assess the extent to which these values reflect true differences in the periodontal conditions given the methodologic limitations of the CPITN system.

Table 7-2 summarizes a number of prevalence studies of periodontal disease in elderly subjects. In four studies (Beck *et al*. 1990; Gilbert & Heft 1992; Locker & Leake 1993b; Weyant *et al*. 1993), data on attachment loss were used to calculate ESI scores, which appear to be relatively consistent between the surveys. It is evident that attachment loss of moderate magnitude was frequent and widespread in these subject samples; however, severe disease was again found to affect relatively limited proportions of the samples and usually only a few teeth per subject. It must be realized, however, that (1) edentulism is high in elderly subjects, and (2) the remaining teeth in elderly individuals are likely those least affected by periodontitis. As discussed later, tooth loss results in an underestimation of the "true" extent and severity of periodontitis in elderly individuals.

Periodontitis in children and adolescents

The form of periodontal disease that affects the *primary* dentition, the condition formerly termed *prepubertal periodontitis*, has been reported to appear in both a generalized and a localized form (Page *et al*. 1983). Information about this disease has mainly been provided by clinical case reports and no data on the prevalence and the distribution of the disease in the general population are available. However, a small number of studies involving samples of children have provided limited data on the frequency with which deciduous teeth may be affected by attachment loss. The criteria used in these studies are by no means uniform; hence the prevalence data vary significantly. In an early study, Jamison (1963) examined the "prevalence of destructive periodontal disease" (indicated by PDI scores >3) in a sample of 159 children in Michigan, USA and reported prevalences of 27% for 5–7-year-old children, 25% for 8–10-year olds, and 21% for 11–14-year olds. Shlossman *et al*. (1986) used an attachment level value of ≥2 mm as a cut-off point and reported prevalences of 7.7% in 5–9-year olds and 6.1% in 10–14-year olds in a sample of Pima Indians. Sweeney *et al*. (1987) examined radiographs obtained from 2264 children, aged 5–11 years, who were referred to a university clinic for routine dental treatment, and reported that a distinct radiographic bone loss was evident at one or more primary molars in 19 children (0.8%), 16 of whom were black, two Caucasian, and one Asian.

In contrast, relatively uniform criteria have been used in epidemiologic studies of periodontitis in teenagers and young adults, although, as discussed earlier, the vast majority of studies have not employed the diagnostic criteria of the current classification. Nevertheless, the clinical phenotype of *localized aggressive periodontitis* (LAP) in young individuals, the condition formerly termed *localized juvenile periodontitis* (LJP), that is the severe and disproportionate involvement of incisors and first molars, has facilitated more standardized detection methodologies. Typically, a two-stage approach has been adopted in these studies: first, bitewing radiographs are used to screen for bone loss adjacent to molars and incisors, and then a clinical examination is performed to verify the diagnosis. As illustrated by the data in Table 7-3, the prevalence of LAP varies in geographically and/or racially different populations. In Caucasians, the disease appears to affect females more frequently than males and the prevalence is low (approximately 0.1%). In other races, and in particular in Blacks, the disease is more prevalent, probably at levels over 1%, and the sex ratio appears to be reversed, since males are affected more frequently than females. Smoking and low socioeconomic status have been confirmed to be associated with *aggressive periodontitis* in various populations (Lopez *et al*. 2001; Susin & Albandar 2005; Levin *et al*. 2006).

Epidemiologic studies of periodontal conditions in adolescents have been also carried out using the CPITN system. Miyazaki *et al*. (1991a) presented an overview of 103 CPITN surveys of subjects aged 15–19 years from over 60 countries. The most frequent finding in these groups was the presence of calculus, which was much more prevalent in subjects from non-industrialized than industrialized countries. Probing pocket depths of 4-5 mm were present in about two-thirds of the populations examined. However, the occurrence of deep pockets (≥6 mm) was relatively infrequent: score 4 quadrants were

Table 7-3 Selected prevalence studies of periodontitis in adolescents and young adults.

Authors/Country	Sample/methodology	Findings
Saxén (1980) Finland	A random sample of 8096 16-year olds; radiographic and clinical criteria (bone loss adjacent to first molars without any obvious iatrogenic factors and presence of pathologic pockets)	Prevalence of LAP 0.1% (8 subjects, 5 of whom were females)
Kronauer *et al*. (1986) Switzerland	A representative sample of 7604 16-year olds; two step examination (radiographic detection of bone lesion on bite-wing radiographs, clinical verification of presence of pathologic pockets)	Prevalence of LAP of 0.1%; 1:1 gender ratio
Saxby (1987) UK	A sample of 7266 schoolchildren; initial screening by probing assessments around incisors and first molars; LAP cases diagnosed definitively by full-mouth clinical and radiographic examination	Overall prevalence of LAP of 0.1%, 1:1 gender ratio; however, prevalence varied in different ethnic groups (0.02% in Caucasians, 0.2% in Asians, and 0.8% in Afro-Caribbeans)
Neely (1992) USA	1038 schoolchildren 10–12 years old, volunteers in a dentifrice trial; three-stage examination including radiographic and clinical assessments; bite-wing radiographs screened for possible cases; bone loss measurements of the CEJ–bone crest distance of ≥2 mm used to identify probable cases; LAP diagnosed clinically as PD of ≥3 mm at ≥1 first permanent molars in the absence of local irritants	117 possible and 103 probable cases identified in steps 1 and 2, respectively; of 99 probable cases contacted, 43 were examined clinically; 2 cases of LAP confirmed in stage 3, yielding a prevalence rate of 0.46%
Cogen *et al*. (1992) USA	4757 children, aged <15 years, from the pool of a children's hospital; retrospective radiographic examination of two sets of bite-wings; LAP diagnosed in case of arc-shaped alveolar bone loss in molars and/or incisors	Caucasianss: LAP prevalence 0.3%, female:male ratio 4:1 Blacks: LAP prevalence 1.5%, female:male ratio ≈ 1:1 Among Black LAP cases with available radiographs from earlier examinations, 85.7% showed evidence of bone loss in the mixed dentition and 71.4% in the deciduous dentition
Löe & Brown (1991) USA	National Survey of US children, multistage probability sampling representing 45 million schoolchildren; 40 694 subjects, 14–17 years old examined; probing assessments at mesial and buccal sites, all teeth; LAP: ≥1 first molar and ≥1 incisor or second molar and ≤2 cuspids or premolars with ≥3 mm AL; GAP: if LAP criteria not met and ≥4 teeth (of which ≥2 were second molars, cuspids or premolars) with ≥3 mm AL; incidental loss of attachment (ILA): if neither LAP nor GAP criteria met but ≥1 teeth with ≥3 mm AL; bivariate and multivariate analysis	Population estimates: LAP 0.53%; GAP 0.13%; ILA 1.61%; all 2.27% representing almost 300 000 adolescents; Blacks at much higher risk for all forms of early-onset disease than Caucasians Males more likely (4.3:1) to have GAP than females, after adjusting for other variables; Black males 2.9 times as likely to have LAP than Black females; Caucasian females more likely to have LAP than Caucasian males by the same odds
Bhat (1991) USA	A sample of 11 111 schoolchildren, 14–17 years old; probing assessments at mesial and buccal surfaces of all teeth; multistage cluster sampling stratified by age, sex, seven geographic regions, and rural or urban residence; not stratified by race or ethnicity	22% of children with ≥1 site with AL of ≥2 mm, 0.72% of ≥4 mm, and 0.04% of ≥6 mm Supra- and sub-gingival calculus in 34% and 23% of children, respectively
van der Velden *et al*. (1989) The Netherlands	4565 subjects, 14–17 years old examined; randomization among high school students; probing assessments at the mesio- and disto-facial surfaces of first molars and incisors; one bacterial sample from the dorsum of the tongue and one subgingival plaque sample from the site with maximal attachment loss obtained from 103 of the 230 subjects with AL and cultured for identification of *Aggregatibacter actinomycetemcomitans*	Overall, AL occurred in 5% of the sample and was more frequent in males; 16 subjects (0.3%) had ≥1 site with AL of 5–8 mm; female:male ratio in this group 1.3:1 *A. actinomycetemcomitans* identified in 17% of the sampled subjects with AL
Lopez *et al*. (1991) Chile	2500 schoolchildren in Santiago (1318 male, 1182 female), aged 15–19 years; clinical and radiographic assessments; three-stage screening: (1) clinical assessments of PD at incisors and molars, (2) children with ≥2 teeth with PD of ≥5.5 mm subjected to a limited radiographic examination, and (3) children with alveolar bone loss of ≥2 mm invited for a full-mouth clinical and radiographic examination	After screening, 27 subjects had a tentative diagnosis of LAP, of which 8 were confirmed (7 female, 1 male); overall prevalence of LAP 0.32%, 95% CI 0.22– 0.42%; LAP significantly more frequent in the low socioeconomic group

Table 7-3 *Continued.*

Authors/Country	Sample/methodology	Findings
Ben Yehouda *et al*. (1991) Israel	1160 male Israeli army recruits, aged 18–19 years; panoramic radiography; JP diagnosed on the basis of bone loss involving ≥30% of the root length adjacent to first molars or incisors	10 recruits (0.86%, 95% CI 0.84–0.88%) had a bone loss pattern consistent with localized juvenile periodontitis
Melvin *et al*. (1991) USA	5013 military recruits, aged 17–26 years; panoramic radiography followed by full-mouth clinical examination; diagnosis of JP if bone loss and attachment loss was greater at first molars and/or incisors than at other teeth	Overall prevalence of JP 0.76%, female:male ratio 1.1:1 Prevalence in Blacks: 2.1%, female:male ratio 0.52:1 Prevalence in whites: 0.09%, female:male ratio 4.3:1
Tinoco *et al*. (1997) Brazil	7843 schoolchildren, aged 12–19 years; two-stage screening: (1) clinical assessment of PD at first molars, (2) children with ≥1 tooth with PD ≥5 mm examined further; LAP diagnosed if a person with no systemic disease presented with AL >2 mm at ≥1 sites with radiographic evidence of bone loss and ≥1 infrabony defects at molars/incisors	119 subjects identified at initial screening; 25 confirmed cases of LAP; overall prevalence 0.3% Ethnic origins and gender ratios not reported
Lopez *et al*. (2001) Chile	A random sample of 9162 high school students, aged 12–21 years; probing assessments of AL at six sites/tooth at all incisors and molars	Prevalence of AL of ≥1 mm was 69.2%, of ≥2 mm was 16%, and of ≥3 mm was 4.5%. AL was associated with older age, female gender, poor oral hygiene, and lower socioeconomic status
Levin *et al*. (2006) Israel	642 army recruits (87.5% men), aged 18–30 years (mean 19.6 years); radiographic and clinical examination of first molars and incisors	AP prevalence was 5.9% (4.3% LAP, 1.6% GAP); current smoking and north African origin were significantly related to AP
Taylor & Borgnakke (2007) USA	105 young adults aged 18–25 years, living in housing units in Detroit, Michigan; full-mouth examination at four sites/tooth at all teeth present	9% and 2% of sample were found to suffer from "moderate"' or "severe" periodontitis, respectively, according to the CDC/AAP criteria (Page & Eke 2007)
Holtfreter *et al*. (2009) Germany	587 young adults, aged 20–29 years, participants in the Study of Health in Pomerania (SHIP); half-mouth examination of an upper and lower quadrant at four sites/tooth with respect to PD and AL	12% and 1% of sample were found to suffer from "moderate" or "severe" periodontitis, respectively, according to the CDC/AAP criteria, as above 5% of sample exhibited AL ≥4 mm, 2% ≥5 mm and 1% ≥6 mm

Terms used in all but Levin *et al.* (2006): "localized juvenile periodontitis (JP)" instead of "localized aggressive periodontitis (LAP)", and "generalized juvenile periodontitis" instead of "generalized aggressive periodontitis (GAP)".
PD, probing depth; AL, attachment level; CEJ, cemento-enamel junction; AP, aggressive periodontitis; CDC/AAP, Centers for Disease Control/American Academy of Periodontology; CI, confidence interval.

reported to occur in only ten of the examined populations (in four of the nine examined American samples, one of 16 African samples, one of ten Eastern Mediterranean samples, two of 35 European samples, two of 15 South-East Asian samples, and none of 18 Western Pacific samples).

The progression pattern of periodontitis in a sample of 167 adolescents in the UK was studied in a 5-year longitudinal study by Clerehugh *et al*. (1990). In this study, 3% of the initially 14-year olds had attachment loss of ≥1 mm affecting >1% of sites. However, at age 19 years, 77% showed a similar level of attachment loss and 31% of sites were affected. Presence of subgingival calculus at baseline was significantly associated with disease progression. In a study involving a larger sample size in the US, Brown *et al*. (1996) studied a nationally representative sample comprising 14 013 adolescents with respect to the pattern of progression of the disease entity formerly termed *early-onset periodontitis*, that is the type of periodontitis that occurs in individuals of a young age. Subjects were diagnosed at baseline as free from periodontitis, or suffering from LAP, *generalized aggressive periodontitis* (GAP), or incidental attachment loss (IAL). Of the individuals diagnosed with LAP at baseline, 62% continued to display localized periodontitis lesions 6 years later, but 35% developed a generalized disease pattern. Among the group initially diagnosed as suffering from IAL, 28% developed LAP or GAP, while 30% were reclassified in the no attachment loss group. Molars and incisors were the teeth most often affected in all three affected groups. Thus, the study indicated that these three forms of periodontitis may progress in a similar fashion, and that certain cases of LAP may develop into a more generalized form of *aggressive periodontitis*.

The possibility that LAP and *prepubertal periodontitis* are associated conditions, that is the former is a

development of the latter, has also attracted attention. In an early study, Sjödin *et al*. (1989) retrospectively examined radiographs of the primary dentition of 17 subjects with LAP and reported that 16 of these subjects showed a CEJ–bone crest distance of ≥3 mm in at least one tooth site in their deciduous dentition. The same research group (Sjödin & Matsson 1992) examined the CEJ–bone crest distance on radiographs from 128 periodontally healthy children aged 7–9 years, in order to define a threshold value that, if exceeded, would indicate a high probability of periodontal pathology around the deciduous teeth. Having set this threshold value at 2 mm, Sjödin *et al*. (1993) retrospectively examined radiographs of the deciduous dentition from 118 patients with *aggressive periodontitis* and 168 age- and sex-matched periodontally healthy controls. The patients were divided in two groups, one comprising those with only one affected site (45 subjects) and another (73 subjects) including those with 2–15 sites with bone loss in their permanent dentition. It was found that 52% of the patients in the latter group, 20% of those in the former group, and only 5% of the controls exhibited at least one site with bone loss in their primary dentition. The authors concluded that, at least in some young subjects with *aggressive periodontitis*, the onset of the disease may manifest in the primary dentition. Similar results were reported by Cogen *et al*. (1992) from a study in the US. Among systemically healthy young Black subjects with *aggressive periodontitis* and available radiographs of the primary dentition, 71% showed alveolar bone loss adjacent to one or several primary teeth. Finally, an interesting radiographic study of the mixed dentition in Australian children aged 5–12 years by Darby *et al*. (2005) investigated the prevalence of alveolar bone loss around first permanent molars, and first and second deciduous molars. Based on radiographs of 542 children, 13% were found to display definite bone loss, that is bone levels >3.0 mm from the CEJ. Half of all sites with definite bone loss were on the second deciduous molars and, in the vast majority, on distal tooth surfaces. In other words, this study showed that the tooth surface of the deciduous dentition most frequently affected by bone loss was the one in close proximity to the most frequent localization of *aggressive periodontitis* in older children with permanent dentition, that is the mesial surface of the first permanent molar.

Periodontitis and tooth loss

Tooth loss may be the ultimate consequence of destructive periodontal disease. Teeth lost due to the sequelae of the disease are obviously not amenable to registration in epidemiologic surveys and may, hence, lead to an underestimation of the prevalence and the severity of the disease. The well-established epidemiologic concept of *selection bias* (also referred to as the *healthy survivor effect*, indicating that the comparatively healthier subjects will present for an examination while the more severely affected may refuse participation or fail to present because of the morbidity itself) is in this context applicable at the individual tooth level, since the severely affected teeth may have already been extracted/lost. Aspects related to tooth loss on a population basis have been addressed in numerous publications. Important questions that were analyzed included the relative contribution of periodontitis to edentulism (Eklund & Burt 1994; Takala *et al*. 1994) or to tooth extractions in subjects retaining a natural dentition (Reich & Hiller 1993; McCaul *et al*. 2001; Susin *et al*. 2005b; Thorstensson & Johansson 2010; Hirotomi *et al*. 2011).

Typically, surveys addressing the first topic have utilized questionnaire data obtained from general practitioners instructed to document the reasons why teeth were extracted over a certain time period. The results indicate that the reason underlying the vast majority of extractions in ages up to 40–45 years is dental caries. However, in older age cohorts, periodontal disease is about equally responsible for tooth loss. Overall, periodontitis is thought to account for 30–35% of all tooth extractions, while caries and its sequelae for up to 50%. In addition, caries appears to be the principal reason for extractions in cases of total tooth clearance. Finally, identified risk factors for tooth loss include smoking, poor dental health, poverty and other socio-behavioral traits, and poor periodontal status.

Obviously, it is not feasible to "translate" tooth loss data into prevalence figures of periodontal disease. An evaluation, however, of the periodontal status at the population level, and in particular in older age cohorts, must weigh the information provided by tooth loss data; otherwise underestimation of the occurrence and the sequelae of the disease is inevitable (Gilbert *et al*. 2005).

Risk factors for periodontitis

Introduction: Definitions

There is an abundance of both empirical evidence and substantial theoretical justification for accepting the widespread belief that many diseases have more than one cause, in other words they have a *multifactorial etiology* (Kleinbaum *et al*. 1982). Consequently, in any particular instance when a *causal relationship* is investigated, the specificity of the relation between exposure to an etiologic agent and effect (the *necessity* or the *sufficiency* of the condition) may be challenged. In the case of most infectious diseases for example, it is known that the presence of the microbial agent (which is defined as the necessary condition) is not always accompanied by signs or symptoms characteristic of that disorder. Thus, the agent itself is not sufficient to cause any pathologic occurrence; rather, the disease development may be dependent on multiple and diverse additional factors, including specific host responses, toxic exposures, nutritional deficiencies, emotional stress, and the complex

impact of social influences. In non-infectious diseases (except for genetic abnormalities), there is usually no factor known to be present in every single case of the disease. For example, smoking is not necessary for the development of lung cancer, and no degree of coronary atherosclerosis is a necessary condition for myocardial infarction.

The *causal inference*, in other words the process of drawing conclusions related to the cause(s) of a disease, is a particularly complex issue in epidemiologic research. Four decades ago, Hill (1971) formalized the criteria that have to be fulfilled in order to accept a causal relation. These included:

1. *Strength of the association.* The stronger the association between the potential (*putative*) risk factor and disease presence, the more likely it is that the anticipated causal relation is valid.
2. *Dose–response effect.* An observation that the frequency of the disease increases with the dose or level of exposure to a certain factor supports a causal interpretation.
3. *Temporal consistency.* It is important to establish that the exposure to the anticipated causative factor occurred prior to the onset of the disease. This may be difficult in cases of diseases with long latent periods or factors that change over time.
4. *Consistency of the findings.* If several studies investigating a given relationship generate similar results, the causal interpretation is strengthened.
5. *Biologic plausibility.* The anticipated relationship should make sense in the context of current biologic knowledge. However, it must be realized that the less that is known about the etiology of a given disease, the more difficult it becomes to satisfy this particular criterion.
6. *Specificity of the association.* If the factor under investigation is found to be associated with only one disease, or if the disease is found to be associated with only one factor among a multitude of factors tested, the causal relation is strengthened. However, this criterion can by no means be used to reject a causal relation, since many factors have multiple effects and most diseases have multiple causes.

It is important to realize that the criteria described above are meant as guidelines for the establishment of a causal inference. None of them, however, is either necessary or sufficient for a causal interpretation. Strict adherence to any of them without concomitant consideration of the others may result in incorrect conclusions.

A distinction has to be drawn between a *causal* factor, assessed as above, and a *risk* factor. In a broad sense, the term risk factor may indicate an aspect of personal behavior or lifestyle, an environmental exposure, or an inborn or inherited characteristic that is known to be associated with disease-related conditions, based on epidemiologic evidence. Such an attribute or exposure may be associated with an increased probability of occurrence of a particular disease without necessarily being a causal factor. A risk factor may be modified by intervention, thereby reducing the likelihood that the particular disease will occur.

The principles of the *risk assessment process* were discussed by Beck (1994) and consists of the following four steps:

1. The *identification* of one or several individual factors that appear to be associated with the disease.
2. In case of multiple factors, a *multivariate risk assessment model* must be developed that discloses which combination of factors most effectively discriminates between health and disease.
3. The *assessment* step, in which new populations are screened for this particular combination of factors, with a subsequent comparison of the level of the disease assessed with the one predicted by the model.
4. The *targeting* step, in which exposure to the identified factors is reduced by prevention or intervention and the effectiveness of the approach in suppressing the *incidence* of the disease is evaluated.

Thus, according to this process, *potential* or *putative risk factors* (often also referred to as *risk indicators*) are first identified and thereafter tested until their significance as *true risk factors* is proven or rejected.

Finally, distinction must be made between *prognostic* factors (or *disease predictors*), that is characteristics related to the progression of *pre-existing* disease, and *true risk factors*, that is exposures related to the *onset* of the disease. For example, it is established in longitudinal studies of periodontal disease progression (Papapanou *et al*. 1989), that the amount of alveolar bone loss or the number of teeth present at baseline may be used to predict further progression of the disease. These variables are, in fact, alternative measures of the disease itself and express the level of susceptibility of a given subject to periodontal disease. Although they may be excellent predictors for further disease progression, they clearly cannot be considered as risk factors.

There are several ways to study the relation between exposure to a certain factor and the occurrence of a particular disease, as required under step 1. One of these is described in Fig. 7-3, which illustrates a hypothetical situation where exposure to the potential risk factor Z is studied in a cross-sectional study of 1000 subjects, 180 of whom are found to suffer from the disease D (“diseased”), while 820 are disease-free (“healthy”). In this particular setting, it was observed that 155 of the 180 diseased subjects had been exposed to factor Z, but this was also the case for 340 non-diseased subjects. In this example, the association between exposure and disease is expressed by the *odds ratio* (OR), which is the ratio of

	Exposed	Non-exposed	
Diseased	155	25	180
Healthy	340	480	820
	495	505	1000

Fig. 7-3 Contingency table describing the distribution of a group of 1000 subjects according to exposure to a particular factor and disease status.

exposure among the diseased and the healthy. For the data in Fig. 7-3, the OR is calculated as (155/25) over (340/480) = (155 × 480)/(340 × 25) = 8.75. This indicates that diseased individuals were 8.75 times more likely to be exposed to factor Z than healthy individuals. Note that the OR is frequently misinterpreted to describe the risk of an exposed subject developing the disease, something that is only correctly assessed in a prospective cohort rather than a cross-sectional study and is described by the *relative risk*. In the example of Fig. 7-3, if a sample of 495 subjects exposed to factor Z and 505 subjects not exposed to factor Z are prospectively followed over a given time period, and 155 among the exposed and 25 among the non-exposed develop disease D over this period, then the relative risk is calculated as (155/495) over (25/505) = 6.4. In other words, an individual exposed to factor Z is 6.4 times more likely to develop disease D than a non-exposed subject.

In a study of the association between an exposure and the occurrence of a disease, *confounding* can occur when an additional factor is associated with both the exposure and the disease under study. For instance, when examining the association between alcohol consumption and cancer, smoking may act as a confounder, because smokers are frequently alcohol consumers and smoking also has carcinogenic effects.

There are various ways to assess simultaneously the effect of the several putative risk factors identified in step 1 and to generate the *multivariate model* required for step 2. For example, the association between exposure and disease may, for reasons of simplicity, have the form of the following linear equation:

$$y = a - b_1x_1 + b_2x_2 + b_3x_3 + \ldots b_nx_n$$

where y represents occurrence or severity of the disease, a is the intercept (a constant value), x_1, x_2, … x_n describe the different exposures (putative risk factors), and b_1, b_2, … b_n are *estimates* defining the relative importance of each individual exposure as a determinant of disease, after taking all other factors into account. Such an approach will help to identify factors with statistically and biologically significant effects and may minimize the effect of confounders.

In the third step (*assessment step*), a new population sample that is independent of the one used in the construction of the multivariate model is screened for occurrence of disease and presence of the relevant factors included in the multivariate model of step 2. Alternatively, in the case of a prospective cohort study, exposure to the relevant factors is assessed among the subjects of the new sample, and disease incidence, that is the number of new cases of disease, is determined over a time period after a longitudinal follow-up of the subjects. Subsequently, disease occurrence predicted from the model is compared to the actual disease occurrence, and the *external validity* of the model (i.e. the "behavior" or "fitness" of the model in the new population) is evaluated.

Lastly, during the fourth step (*targeting*), aspects of causality or risk are verified if disease occurrence is suppressed when exposure is impeded. Ideally, such studies should be designed as randomized clinical trials, in which treatment is randomly assigned to one of two groups and the effectiveness of the intervention is assessed in direct comparison to outcomes in an untreated, control group. Additionally, an evaluation of the particular preventive/therapeutic strategy from a "cost–benefit" point of view is also facilitated in such studies. Note that successful fulfillment of the targeting step requires that (1) the factor is amenable to intervention and (2) the intervention is delivered at the appropriate time point. Genetic traits are examples of risk factors not amenable to intervention. Likewise, in cases where a single exposure to a factor results in detrimental and/or irreversible biologic damage (e.g. exposure to a high dose of radiation), interventions protecting against subsequent exposure to the factor (radiation) may not lower the incidence of disease (e.g. cancer).

In the context of periodontitis, it should be realized that few of the putative risk factors for disease development have been subjected to the scrutiny of all four steps. In fact, risk assessment studies in dental research in general have been frequently confined to the first two steps. Numerous cross-sectional studies identifying potential risk factors are available, but a relatively limited number of longitudinal studies involve a multivariate approach to the identification of exposures of interest while simultaneously controlling for the effect of possible confounders. Intervention studies in the form of randomized clinical trials are sparse. In the following text, the issue of risk factors is addressed according to the principles described above. Results from cross-sectional studies are considered to provide evidence for putative risk factors that may be further enhanced if corroborated by longitudinal studies involving multivariate techniques, or prospective intervention studies. As reviewed by Borrell and Papapanou (2005), distinction is also made between putative factors that are not amenable to intervention (non-modifiable background factors) and modifiable factors (environmental, acquired, and behavioral).

Non-modifiable background factors

Age

The relationship between age and periodontitis is complex. Although it is clear that both the prevalence and the severity of periodontitis increase with age (Burt 1994; Albandar *et al*. 1999; Dye *et al*. 2007), the concept of periodontitis as an inevitable consequence of aging has been challenged over the years (Papapanou *et al*. 1991; Papapanou & Lindhe 1992) and the alleged "age effect" largely represents the cumulative effect of prolonged exposure to true risk factors. Notably, the association between age and periodontitis appears to be different for pocket depth and amount of clinical attachment loss. While there is a pronounced effect of increasing attachment loss with age, the effect on pocket depth appears to be minimal (Albandar 2002a, b). Interestingly, the effect of age on attachment loss was found to be attenuated after adjustment for co-variates, such as oral hygiene levels or access to dental care services (Albandar, 2002a). In addition, epidemiologic studies have often failed to adjust for important co-variates such as presence of systemic diseases, consumption of multiple medications, and co-morbidities related to nutritional disturbances in the older population, all of which could partly account for the increased prevalence and severity of periodontitis in the elderly. On the other hand, age-associated molecular alterations in key phagocytic cells involved in both the protective and destructive immune responses have been shown to affect their ability to carry out efficient antimicrobial functions and to result in a dysregulation of the inflammatory response (Hajishengallis 2010). Since periodontitis is a microbially-induced inflammatory disorder, these alterations in innate immunity likely contribute to more pronounced periodontal pathology in elderly individuals. An age-related, rather than an age-dependent, increased susceptibility to periodontitis in older people is therefore biologically plausible.

Sex

There is no established, inherent difference between men and women in their susceptibility to periodontal disease, although men have been shown to exhibit worse periodontal conditions than women in multiple studies from different populations (Brown *et al*. 1989; Albandar 2002a; Susin *et al*. 2004a; Dye *et al*. 2007). This difference has been traditionally considered to reflect the documented better oral hygiene practices (Hugoson *et al*. 1998b; Christensen *et al*. 2003) and/or increased utilization of oral health care services among women (Yu *et al*. 2001; Dunlop *et al*. 2002; Roberts-Thomson & Stewart, 2003). On the other hand, there is evidence for sexual dimorphism in elements of both the innate and the acquired immunity that may lead to enhanced pro-inflammatory responses in men (Shiau & Reynolds 2010), which are in line with the epidemiologic evidence of gender-associated disparities in prevalence, extent, and severity of periodontitis.

Race/ethnicity

Differences in the prevalence of periodontitis between countries and across continents have been demonstrated (Baelum *et al*. 1996; Albandar, 2002a; Dye 2012), but no consistent patterns across racial/ethnic groups have been documented when co-variates such as age and oral hygiene were accounted for (Burt & Eklund 1999). National surveys in the US consistently show a racial/ethnic differential pattern in the prevalence of periodontitis, with African–Americans exhibiting the highest prevalence followed by Mexican Americans and non-Hispanic Caucasians; these findings are fairly consistent regardless of the case definition used (Albandar *et al*. 1999; Arbes *et al*. 2001; Borrell *et al*. 2002; Hyman & Reid 2003; Dye *et al*. 2007; Borrell & Crawford 2008). However, race/ethnicity is usually a social construct that determines an array of opportunities related to access, status, and resources (Williams 1997, 1999). As a result, race/ethnicity and socioeconomic status (SES) are strongly intertwined, suggesting that the observed racial/ethnic effect may be partially attributed to confounding by SES due to the unequal meaning of SES indicators across racial/ethnic groups (Williams 1996; Kaufman *et al*. 1997; Krieger *et al*. 1997; Lynch & Kaplan 2000). Corroborating this point, a study reported that African–Americans demonstrated a lower benefit from education and income in terms of periodontal health status than their Mexican American and Caucasian peers (Borrell *et al*. 2004). These findings confirm that socioeconomic

indicators across racial/ethnic groups are not commensurable but, probably, reflect the broad implications of historical unequal opportunities among certain racial groups (Borrell & Crawford 2012).

Gene polymorphisms

Evidence that genetic predispositions are significant determinants of periodontitis phenotype was first documented in a number of classical twin (Michalowicz *et al*. 1991) and family studies (Boughman *et al*. 1992; Marazita *et al*. 1994). The association of *single nucleotide polymorphisms* (SNPs), that is specific variations at defined locations of the genome that occur in at least 1% of the population, with different forms of periodontitis has been studied extensively (Kinane & Hart 2003; Laine *et al*. 2012). Following the report by Kornman *et al*. (1997) of an association between a composite genotype based on specific polymorphisms in the interleukin-1 (*IL-1*) gene cluster and severe periodontitis in non-smokers, there has been an exponential increase in publications examining a plethora of gene polymorphisms as severity markers of periodontitis. These include additional investigations of the particular composite *IL-1* gene polymorphism in cross-sectional and case–control studies (e.g. Diehl *et al*. 1999; Armitage *et al*. 2000; Papapanou *et al*. 2001; Meisel *et al*. 2004; Li *et al*. 2004), longitudinal studies (Ehmke *et al*. 1999; De Sanctis & Zucchelli 2000; Lang *et al*. 2000; Cullinan *et al*. 2001; Christgau *et al*. 2003; Jepsen *et al*. 2003), as well as studies in which polymorphisms in particular loci of the *IL1A* gene (Fiebig *et al*. 2008; Struch *et al*. 2008), the *IL1B* gene (Lopez *et al*. 2005; Ferreira *et al*. 2008), and the IL-1 receptor antagonist (Tai *et al*. 2002; Berdeli *et al*. 2006; Fiebig *et al*. 2008) were studied independently of each other.

Similar work has investigated polymorphisms in additional inflammatory genes, including the tumor necrosis factor (*TNF*) gene (Endo *et al*. 2001; Shapira *et al*. 2001; Craandijk *et al*. 2002; Fassmann *et al*. 2003; Shimada *et al*. 2004); the *IL-6* gene (Anusaksathien *et al*. 2003; Holla *et al*. 2004; Nibali *et al*. 2009); the *IL-4* gene (Kang *et al*. 2003; Holla *et al*. 2008; Kobayashi *et al*. 2009); and the *IL-10* gene (Brett *et al*. 2005; Kobayashi *et al*. 2009). A substantial body of data has accumulated on polymorphisms in genes coding for various receptors, including the leukocyte receptors for the constant part (Fc) of immunoglobulin G (Kobayashi *et al*. 1997; Sugita *et al*. 1999; Kobayashi *et al*, 2000a, b, 2001; Meisel *et al*. 2001; Loos *et al*. 2003; Yamamoto *et al*. 2004; Wolf et al. 2006; Nibali *et al*. 2006); pattern recognition receptors such as CD14 (Holla *et al*. 2002; James *et al*. 2007; Tervonen *et al*. 2007) and Toll-like receptors (TLRs) 2 and 4 (Folwaczny *et al*. 2004, Brett *et al*. 2005; Fukusaki *et al*. 2007; Noack *et al*. 2008); and the vitamin D receptor (Park *et al*. 2006; Nibali *et al*. 2008; Wang *et al*. 2009). Additional polymorphisms studied in single studies or a few cohorts have been discussed in a recent comprehensive review (Laine *et al*. 2012) and a meta-analysis of 53 studies collectively including 4178 cases and 4590 controls (Nikolopoulos *et al*. 2008).

Typically, the majority of these cross-sectional studies report positive associations between the investigated polymorphisms and the extent or the severity of periodontitis. The results, however, are not unequivocal, as the strength of the reported associations is not uniformly consistent across populations, the frequency of occurrence of these polymorphisms appears to vary extensively between ethnic groups, the subject samples involved are generally of limited size, the definitions of the outcome variable (periodontitis) vary considerably, and adequate adjustments for other important co-variates and risk factors have frequently not been carried out. Importantly, there appear to be differences in the impact of these polymorphisms on early-onset versus adult forms of periodontitis. For example, in the case of IL-1 polymorphisms, while it is the rare allele (allele 2) that has been linked with severe disease in adults, it is allele 1 that has been found to be more prevalent in subjects with early-onset periodontitis (Diehl *et al*. 1999; Parkhill *et al*. 2000).

The results of the relatively few longitudinal studies that have studied specific gene polymorphisms as exposures are also conflicting. Ehmke *et al*. (1999) reported no bearing of the *IL-1* gene polymorphism on the prognosis of periodontal disease progression following non-surgical periodontal therapy. Jepsen *et al*. (2003) failed to provide evidence that the *IL-1* risk genotype was associated with higher gingival crevicular fluid (GCF) volume and percentage of bleeding on probing (BoP) sites during the development of experimental gingivitis (Löe *et al*. 1965). In contrast, Lang *et al*. (2000) concluded that *IL-1* genotype-positive subjects have a genetically determined hyper-inflammatory response that is expressed clinically in the periodontal tissues as increased prevalence and incidence of BoP during maintenance. Three treatment studies examined the impact of this particular polymorphism in regenerative therapy: De Sanctis and Zucchelli (2000) reported that the *IL-1*-positive genotype was associated with an inferior long-term outcome for regenerative therapy of intrabony defects. In contrast, Christgau *et al*. (2003) and Weiss *et al*. (2004) failed to document such an association in similar studies. Finally, in a 5-year prospective study of 295 subjects, Cullinan *et al*. (2001) reported an interaction between the positive genotype, age, smoking, and colonization by *Porphyromonas gingivalis*, concluding that the positive genotype is a contributory but non-essential factor for the progression of periodontal disease. A systematic review of longitudinal studies that examined the composite *IL-1* genotype as a predictor of periodontitis progression or of periodontal treatment outcomes failed to establish a significant association (Huynh-Ba *et al*. 2007).

In conclusion, there is insufficient epidemiologic evidence that convincingly establishes any of the above polymorphisms as true risk factors for

periodontitis. Studies employing larger cohorts, strict classification criteria for periodontitis, and refined analytical methods will enhance our understanding of the role of genetic influences in the pathobiology of periodontitis.

Environmental, acquired, and behavioral factors

Specific microbiota

The microbial etiology of experimental gingivitis (Löe *et al*. 1965; Theilade *et al*. 1966) and periodontitis (Lindhe *et al*. 1973) has been established for several decades. Yet, epidemiologic studies that systematically investigated the role of specific microbiota as putative risk factors for periodontitis were undertaken only fairly recently. In a classic paper, Haffajee and Socransky (1994) adapted Koch's postulates for use in the identification of periodontal pathogens and proposed the following criteria:

1. Association, that is elevated ORs in disease
2. Elimination, that is conversion of periodontal disease to health when bacteria are eliminated (or suppressed beyond detection)
3. Development of a host response, typically manifested by a serum antibody titer to the infecting agent
4. Presence of virulence factors that can account for the microbe's ability to inflict tissue damage
5. Evidence from animal studies that corroborate the observations in humans and demonstrate development of periodontal pathology after infection by the microorganism.

Based on these criteria, the consensus report of the 1996 World Workshop in Periodontics identified three species, *Actinobacillus actinomycetemcomitans, P. gingivalis,* and *Bacteroides forsythus*, as causative factors for periodontitis [since then, two of these three causative species have been renamed: *A. actinomycetemcomitans* to *Aggregatibacter actinomycetemcomitans* (Norskov-Lauritsen & Kilian 2006) and *B. forsythus* to *Tannerella forsythia* (Sakamoto *et al*. 2002; Maiden *et al*. 2003)]. However, given that only approximately 50% of the bacteria of the oral cavity are currently recognized (Paster *et al*. 2001), it is clear that these three species cannot be considered to be the only causative pathogens, but are rather the ones for which sufficient data have accumulated.

Over the last decade, interesting data have emerged on the prevalence of these causative bacteria in different populations, including periodontally healthy as well as diseased subjects. Studies performed in children (Yang *et al*. 2002; Tanner *et al*. 2002) analyzed plaque from the gingival crevice, tooth surface, and dorsum of the tongue, and revealed that sizeable proportions of subjects harbored *P. gingivalis*, *T. forsythia*, and *A. actinomycetemcomitans* despite absence of overt gingival inflammation. A comparably high carrier state was documented in studies that sampled infants, children, adolescents, and adults with apparently healthy periodontal conditions (Könönen 1993; McClellan *et al*. 1996; Kamma *et al*. 2000; Lamell *et al*. 2000). Thus, contrary to the conclusions of earlier, culture-based studies suggesting that these bacteria occur infrequently in periodontally healthy oral cavities and behave as exogenous pathogens, use of contemporary molecular techniques for bacterial identification have demonstrated that this is not the case. However, both the prevalence and the level of colonization by these pathogens have been shown to vary significantly between populations of different racial or geographic origin (Ali *et al*. 1994; Sanz *et al*. 2000; Lopez *et al*. 2004; Haffajee *et al*. 2004; Rylev & Kilian 2008).

Several epidemiologic studies have examined the prevalence of the established periodontal pathogens and its relation to clinical periodontal status in population samples from both developed and developing countries. Griffen *et al*. (1998) examined a convenience sample recruited from a university clinic, and reported that 79% of the diseased and 25% of the healthy subjects were positive for *P. gingivalis*. Interestingly, the prevalence of *P. gingivalis* in the periodontally healthy group varied substantially with race/ethnicity, occurring in 22% of Caucasians, 53% of African–Americans, and 60% of Asian–Americans. In a case–control study of periodontitis patients and age- and sex-matched controls with no or only minimal attachment loss in Sweden, Papapanou *et al*. (2000) reported a high prevalence of *P. gingivalis*, *A. actinomycetemcomitans*, *T. forsythia*, and *Treponema denticola* in periodontitis patients (95%, 83%, 97%, and 93%, respectively), but also similarly high prevalence rates among control subjects (82%, 90%, 82%, and 94%, respectively). However, in a quantitative analysis of bacterial load, substantial differences in colonization at high levels (i.e. at an average count of $\geq 10^5$ bacterial cells/plaque sample) were observed between patients and controls for three of the four bacteria: 19% versus 3% for *P. gingivalis*; 54% versus 12% for *T. forsythia*, and 46% versus 19% for *T. denticola*. In contrast, corresponding percentages were similar for *A. actinomycetemcomitans* (1% in both cases and controls). Substantially different prevalence data were reported in a study of blue- and white-collar university employees in Australia (Hamlet *et al*. 2001). These authors detected *A. actinomycetemcomitans* in 23% and *P. gingivalis* in 15% of the subjects.

A number of studies investigated the epidemiology of periodontal pathogens in Asian populations. Timmerman *et al*. (1998) examined a sample of adolescents in rural Indonesia, and detected *P. gingivalis* in 87% and *A. actinomycetemcomitans* in 57%. Mombelli *et al*. (1998) examined young factory workers in China and detected *A. actinomycetemcomitans* in 62% and *P. gingivalis* in 55%. In contrast, an almost ubiquitous presence of *P. gingivalis* and *T. forsythia* was reported

in rural subject samples in China (Papapanou *et al*. 1997) and Thailand (Papapanou *et al*. 2002), while *A. actinomycetemcomitans* was detected in 83% and 93% of the subjects in the Chinese and Thai samples, respectively. Despite this high prevalence, a quantitative analysis of bacterial load correlated well with periodontal status in both studies. For example, a discriminant analysis performed on the data from the Thai study (Papapanou *et al*. 2002) identified threshold levels of average bacterial load which, when exceeded, conferred increased ORs for the presence of three or more sites with a pocket depth of ≥5 mm. For three species [*P. gingivalis*, *T. forsythia*, and *T. denticola;* the "red complex" bacteria (Socransky *et al*. 1998)], colonization above these calculated thresholds resulted in statistically significant, elevated ORs for periodontitis. In addition, an analysis of the association between colonization at high levels by the "red complex" bacteria and specific periodontal conditions, defined in this particular study by the presence of three or more sites with a pocket depth of ≥5 mm and by two different extents of clinical attachment loss (≥10 and ≥30 sites with ≥5 mm attachment loss, respectively), revealed statistically significant ORs ranging between 3.7 and 4.3 for the "red complex" bacteria and all three disease definitions. Similar cross-sectional associations of statistically significant ORs for severe periodontitis conferred by specific bacteria have been also observed in several other studies involving subject samples from the Western world (Grossi *et al*. 1994, 1995; Alpagot *et al*. 1996; Craig *et al*. 2001).

Importantly, the association between high levels of colonization by specific periodontal pathogens and the progression of periodontal disease has been corroborated by longitudinal data in untreated populations. For example, in the study by Papapanou *et al*. (1997), a discriminant analysis based on quantitative assessments of subgingival bacterial load classified correctly the substantial majority of the subjects with progression of periodontitis over a preceding 10-year period. Indeed, bacterial profiles classified correctly 75% of the subjects with ten or more sites with longitudinal attachment loss of ≥3 mm, and 85% of those that remained stable over the observation period. In a 7-year follow-up study of Indonesian adolescents (Timmerman *et al*. 2000, 2001), and in a subsequent 15-year follow-up of the same cohort (van der Velden *et al*. 2006), it was shown that the subgingival presence of *A. actinomycetemcomitans* was associated with disease progression, defined as presence of longitudinal attachment loss of ≥2 mm. In a follow-up of 2–5 years' duration, Machtei *et al*. (1999) reported that subjects colonized by *T. forsythia* at baseline exhibited greater alveolar bone loss, a larger proportion of "loser" sites, that is sites exhibiting progressive attachment loss, and twice as high longitudinal tooth loss than non-colonized subjects. In a 3-year study, Hamlet *et al*. (2004) reported ORs of 8.2 for attachment loss in adolescents with persistent colonization with *T. forsythia*.

An important observation was made in a 2-year prospective study of clinical periodontal status in adolescents in Morocco (Haubek *et al*. 2008). These investigators reported that colonization by a specific clone of *A. actinomycetemcomitans*, namely the highly-leukotoxic JP2 clone, conferred a much higher risk for the onset of aggressive periodontitis in periodontally healthy schoolchildren than concomitant colonization by a variety of clones of the same species, or the total absence of colonization by *A. actinomycetemcomitans*. Indeed, in comparison to schoolchildren who were not colonized by *A. actinomycetemcomitans*, the relative risk for incident disease in those colonized exclusively by JP2 clones was 18.0 (95% CI 7.8–41.2), as compared to 12.4 (95% CI 5.2–29.9) in those colonized by both JP2 and non-JP2 clones, and 3.0 (95% CI 1.3–7.1) in those colonized exclusively by non-JP2 clones of *A. actinomycetemcomitans*. This study underscored the important role of this particular periodontal pathogen in the etiology of aggressive periodontitis, but also demonstrated that within-species variation in virulence is associated with differences in the clinical presentation of the disease.

Collectively, data generated in the past 20 years have enhanced our knowledge of the role of specific periodontal bacteria as risk factors for periodontitis (Table 7-4), and have clarified that (1) the intensity of the exposure to the specific microbiota ("*pathogen burden*") rather than the mere presence of the pathogen is an important determinant of the clinical phenotype; (2) the virulence of the pathogen, and thus its ability to cause periodontal tissue damage and confer risk for disease progression may be entirely different among various clonal types within a single species; and (3) pathogen elimination from the subgingival microbiota (or more correctly, suppression of its levels beyond detection) results in improvements in clinical periodontal status. This last "targeting" criterion of the risk assessment process described earlier has been abundantly fulfilled in the case of microbial risk factors. As demonstrated in systematic reviews, an antimicrobial approach, including removal of subgingival plaque with or without adjunctive antiseptics or antibiotics followed by adequate maintenance care, is the single most successful and consistent strategy in the treatment of periodontitis (Herrera *et al*. 2002; Heitz-Mayfield *et al*. 2002; Tonetti & Chapple 2011).

Cigarette smoking

The biologic plausibility of an association between tobacco smoking and periodontitis was founded on the broad effects of multiple tobacco-related substances on cellular structure and function. Smoking has been shown to affect the vasculature, the humoral and cellular immune responses, cell signaling processes, and tissue homeostasis [for review see Kinane and Chestnutt (2000) and Palmer *et al*. (2005)]. A substantial number of studies, a selection of which is

Table 7-4 Selected studies using bacteria as exposures of significance for periodontitis.

Authors/country[a]	Sample/methodology	Findings
Beck *et al*. (1990) USA	690 community dwelling adults, aged 65+ years; probing assessments at mesio- and mid-buccal surfaces, all teeth; logistic regression for advanced AL and deep pocketing; "advanced disease": ≥4 sites with AL of ≥5 mm and ≥1 of these sites with PD of ≥4 mm	Blacks: 78% of sites with attachment loss, mean AL on these sites 4 mm Caucasians: 65%, 3.1 mm OR in Blacks: tobacco use 2.9; *Porphyromonas gingivalis* >2% 2.4; *Prevotella intermedia* >2% 1.9; last dental visit >3 years 2.3; bleeding gums 3.9 OR in Caucasians: tobacco use 6.2; presence of *P. gingivalis* (+) 2.4; no dental visits for >3 years plus BANA (+) 16.8
Haffajee *et al*. (1991b) USA	38 subjects, aged 14–71 years, with prior evidence of attachment loss; 2-month follow-up; probing assessments at six sites/tooth, all teeth; 28 subgingival samples per subject at baseline, DNA probe analysis with respect to 14 bacterial species; progression threshold: ≥3 mm of longitudinal AL; the mean percentage of the total cultivable microbiota was averaged across active and inactive sites; OR computed at different thresholds for each species	Significant odds ratios for new disease: *P. gingivalis* 5.6, *Campylobacter rectus* 3.8, *Veillonela parvula* 0.16 and *Capnocytophaga ochracea* 0.08 Discriminant analysis using the significantly related species was useful in predicting subjects at risk for new attachment loss
Grossi *et al*. (1994) USA	Random sample of 1426 subjects, aged 25–74 years, in a metropolitan community; full-mouth probing assessments; multivariate analysis of risk indicators for attachment loss. Exposures: (1) clinical – supragingival plaque, gingival bleeding, subgingival calculus, PD, CAL; (2) microbial – *A. actinomycetemcomitans, T. forsythia, C. rectus, Eubacterium saburreum, Fusobacterium nucleatum, P. gingivalis, Capnocytophaga* spp and *P. intermedia*; (3) co-variates – age, gender, race, education, income, smoking and numbers of packs/year, exposure to occupational hazards, systemic diseases	In a multivariable logistic regression model, *P. gingivalis* (OR = 1.59; 95% CI 1.11–2.25) and *T. forsythia* (OR = 2.45; 95% CI 1.87–3.24) were positively associated with severity of AL, while *Capnocytophaga* spp. (OR = 0.60; 95% CI 0.43–0.84) were protective against AL
Grossi *et al*. (1995) USA	Same sample as in Grossi *et al*. (1994); 1361 subjects, aged 25–74 years; assessments of interproximal bone loss from full-mouth radiographs; the degree of association between bone loss and explanatory variables was analyzed by stepwise logistic regression	In a multivariable logistic regression model, *P. gingivalis* (OR = 1.73; 95% CI 1.27–2.37) and *T. forsythia* (OR = 2.52; 95% CI 1.98–3.17) were significantly associated with increasing severity of bone loss
Beck *et al*. (1997) USA (L)	540 dentate adults, aged 65+ years, examined at baseline, 18, 36 and 60 months; incidence of AL was defined as additional AL ≥3 mm; microbial variables included presence of *A. actinomycetemcomitans, P. intermedia*, and *P. gingivalis,* and the BANA test; co-variates included age, gender, missing teeth, education, smoking, dental visits	BANA (+), and presence of *P. gingivalis* were significantly associated with incident disease
Papapanou *et al*. (1997) China (L)	148 subjects, aged 30–39 and 50–59 years in a rural area examined 10 years apart; Full-mouth assessments of PD and AL at six sites/tooth; 14 subgingival plaque samples were obtained from each subject at the follow-up examination (1864 in total) and analyzed with respect to 18 bacterial species	Ubiquitous prevalence for the majority of the investigated species at the subject level. Bacterial colonization at high levels by *P. gingivalis, P. intermedia, Provotella nigrescens, T. forsythia, F. nucleatum, Treponema denticola, Parvimonas micra,* and *C. rectus* conferred statistically significant OR for being classified as "downhill" (≥10 sites with longitudinal AL loss of ≥3 mm)
Machtei *et al*. (1999) USA (L)	A sample of 415 subjects, aged 25–75 years, followed for a period of 2–4 years; full-mouth examination at six sites/tooth at all teeth present; full-mouth intraoral radiographs; bacterial samples obtained from 12 index teeth analyzed with respect to *A. actinomycetemcomitans, T. forsythia, C. rectus, P. intermedia, Capnocytophaga* spp*, P. gingivalis, E. saburreum,* and *F. nucleatum*; co-variates included age, gender, smoking (current smokers 15.4%), education, income	Subjects harboring *T. forsythia* at baseline showed significantly higher longitudinal bone loss, greater proportion of "loser'sites" (sites with additional AL of ≥2 mm) and twice as high tooth mortality

(*Continued*)

Table 7-4 *Continued*

Authors/country[a]	Sample/methodology	Findings
Timmerman *et al*. (2000) Indonesia (L)	A sample of 255 subjects, aged 15–25 years, in a rural area, examined 7 years apart; assessments of PD and AL at vestibular surfaces of all teeth; bacterial samples harvested from a variety of intraoral sites and analyzed with respect to *A. actinomycetemcomitans, P. gingivalis, P. intermedia,* spirochetes and motile microorganisms	Progressive disease (PDS) was defined as ≥1 site with longitudinal AL ≥2 mm Subgingival presence of *A. actinomycetemcomitans* (OR 4.2; 95% CI: 1.4–12.7), *P. gingivalis* (OR 2.3; 95% CI 1.0–5.2), and motile microorganisms (OR 2.2; 95% CI 1.0–5.0) were associated with PDS In a multivariable logistic model, including age and subgingival calculus, subgingival presence of *A. actinomycetemcomitans* (OR = 4.61, *P* = 0.01) was associated with PDS
Papapanou *et al*. (2002) Thailand	Random sample of 356 subjects aged 30–39 and 50–59 years, in a rural area; PD and CAL were assessed at six sites/tooth, at all teeth apart from third molars; subjects were grouped according to different levels of pocketing/attachment loss: subjects with ≥3 sites with PD ≥5 mm (59%, G1); ≥10 sites with CAL ≥5 mm (50%, G2); and ≥30 sites with CAL ≥5 mm (24%, G3) Subgingival plaque samples were obtained maximally at 14 sites/subject; checkerboard hybridizations were used to analyze a total of 4343 samples with respect to 27 bacterial species	OR for heavy colonization by "red complex" species (*P. gingivalis, T. forsythia, T. denticola*) were 3.7 (95% CI 2.3–5.9) for G1; 4.0 (95% CI 2.5–6.6) for G2; and 4.3 (95% CI 2.6–7.1) for G3 OR for heavy colonization by selected "orange complex" species (*F. nucleatum, P. intermedia, P. nigrescens, P. micros, E. nodatum, C. rectus*, and *Campylobacter showae*) were 1.5 (95% CI 0.8–2.9) for G1; 1.5 (95% CI 0.8–2.9) for G2; and 1.5 (95% CI 0.8–3.1) for G3
van der Velden *et al*. (2006) Indonesia (L)	15-year follow-up of 128 subjects from the cohort originally described by Timmerman *et al*. (2000)	In a multivariable logistic model, subgingival presence of *A. actinomycetemcomitans* (OR 4.3; 95% CI 1.2–15.7) was confirmed as a risk factor for the onset of the disease, i.e. longitudinal AL during the first 7-year period, but not for progression of disease during the subsequent 8-year period
Fine *et al*. (2007) USA (L)	1075 primarily African–American and Hispanic children aged 11–17 years were examined periodontally and with respect to oral colonization by *A. actinomycetemcomitans*; 96 children were followed up at 6-month intervals for at least 2.5 years; 38 were *A. actinomycetemcomitans*-positive at baseline (36 periodontally healthy and 2 with pathologic periodontal pockets) and 58 were *A. actinomycetemcomitans*-negative and periodontally healthy at baseline	In the cross-sectional cohort, 4% of the children had signs of periodontal pathology (≥1 pocket with ≥6 mm PD and >2 mm AL; 67% of those were *A. actinomycetemcomitans*-positive, as compared with 14% of the entire cohort In the longitudinal cohort, 21% of the *A. actinomycetemcomitans*-positive and 0% of the *A. actinomycetemcomitans*-negative children developed bone loss over the follow-up period
Haubek *et al*. (2008) Morocco (L)	700 adolescents form public schools in Rabat were examined for clinical periodontal status and presence of *A. actinomycetemcomitans* assessed by PCR; 682 were periodontally healthy; of these, 428 returned for a follow-up exam 2 years later	Individuals who carried the high leukotoxic JP2 clone of *A. actinomycetemcomitans* alone (RR 18.0; 95% CI 7.8–41.2) or together with non-JP2 clones (RR 12.4; 95% CI 5.2–29.9) had a significantly increased risk of developing periodontitis Risk for those carrying non-JP-2 clones alone was less pronounced (RR 3.0; 95% CI 1.3–7.1)

[a] **L** indicates a longitudinal study.
PD, probing depth; AL, attachment level; CAL, clinical attachment level; CEJ, cemento-enamel junction; CPITN, Community Periodontal Index of Treatment Needs; BANA: N-benzoyl-DL-arginine-2-naphthylamide; a substrate hydrolyzed in the presence of *T. denticola, Porphyromonas gingivalis*, and *Tannerella forsythia*;CI, confidenc interval; OR, odds ratio; RR, risk ratio; PCR, polymerase chain reaction.

summarized in Table 7-5, established the association of smoking with poor periodontal status. Importantly, the inferior periodontal status of smokers cannot be attributed to poorer plaque control or more severe gingivitis (Bergström 1989). While earlier reports suggested a rather similar composition of the subgingival microflora in smokers and non-smokers (Stoltenberg *et al*. 1993), recent studies demonstrated that smoking contributes to the formation of a dysbiotic biofilm. It affects bacterial acquisition and colonization (Brook 2011; Kumar *et al*. 2011), bacterial aggregation (Bagaitkar *et al*. 2011), and results in higher levels of colonization by key periodontal pathogens (Haffajee & Socransky 2001; Shchipkova *et al*. 2010; Kubota *et al*. 2011). In an attempt to quantitate the effects of smoking on the periodontal conditions, Haber *et al*. (1993) suggested that the excess prevalence of periodontal disease in the population attributed solely to

Table 7-5 Selected studies using smoking as exposure of significance for periodontitis.

Authors/country[a]	Sample/methodology	Findings
Bergström (1989) Sweden	Patients referred for periodontal therapy (155 subjects, aged 30, 40 and 50 years); a random sample of the Stockholm population served as controls; full-mouth probing assessments; sites with PD ≥4 mm considered diseased; recording of plaque and gingivitis scores	56% of the patients and 34% of the controls were smokers (OR 2.5); significantly higher frequency of periodontally-involved teeth in smokers; no notable difference between smokers and non-smokers with respect to plaque and gingivitis
Haber & Kent (1992) USA	196 patients with periodontitis in a periodontal practice and 209 patients from five general practices; probing assessments at six sites/tooth and full-mouth radiographs; questionnaire on smoking habits; patients with negative history of periodontal therapy from the general practices included as controls; comparison of (1) the prevalence of smoking among the two patient groups and (2) periodontitisdisease severity among current and never smokers	Overall smoking history in the periodontal practice 75%; in the general practice 54% Summary OR for positive smoking history in periodontal versus general practice patients was 2.6; in the periodontal group, frequency of current smoking increased with increasing severity of peridontitis
Locker (1992) Canada	907 adults, aged ≥50 years, living independently in four Ontario communities; partial, probing assessments; half of the participants reported a positive history of smoking and 20% were current smokers	Current smokers had fewer teeth, were more likely to have lost all their natural teeth, and had higher extent and severity of periodontitisthan those who had never smoked
Haber *et al*. (1993) USA	132 diabetics and 95 non-diabetics, aged 19–40 years; probing assessments at six sites/tooth, all teeth; questionnaire on smoking habits; calculation of the population attributable risk percent (PAR%), as an estimate of the excess prevalence of periodontitis in the study population that is associated with smoking	Prevalence of periodontitis was markedly higher among smokers than non-smokers within both the diabetic and non-diabetic groups; PAR% among non-diabetics was 51% in those aged 19–30 years and 32% in those aged 31–40 years
Stoltenberg *et al*. (1993) USA	Of 615 medically healthy adults, aged 28–73 years, attending a health maintenance organization, selection of 63 smokers and 126 non-smokers of similar age, sex, plaque and calculus scores; probing assessments at the proximal surfaces of premolars and molars in a randomly selected posterior sextant; detection of *Porphyromonas gingivalis, Prevotella intermedia, Aggregatibacter actinomycetemcomitans, Eubacterium saburreum*, and *Fusobacterium nucleatum.* by a semiquantitative fluorescence immunoassay, in one buccal and one lingual sample per tooth examined; logistic regression to determine if any of the bacteria or smoking were indicators of mean posterior probing depth of ≥3.5 mm	OR for a smoker having a mean PD of ≥3.5 mm was 5.3 (95% CI 2.0–13.8) No statistically significant difference between smokers and non-smokers with respect to prevalence of the bacteria examined Logistic model revealed that a mean PD of ≥3.5 mm was significantly associated with the presence of *A. actinomycetemcomitans., P. intermedia, E. saburreum.,* and smoking; smoking was a stronger indicator than any of the bacteria examined
Jette *et al*. (1993) USA	1156 community dwellers, aged 70+ years; probing assessments at four sites/tooth, all teeth; evaluation of lifelong tobacco use as a modifiable risk factor for poor dental health; multiple regression analysis	18.1% of men and 7.9% of women were tobacco users (overall 12.3%; including 1% smokeless tobacco users) Years of exposure to tobacco products was a statistically significant factor for tooth loss, coronal root caries, and periodontal disease, regardless of other social and behavioral factors Periodontal disease (number of affected teeth) was predicted by longer duration of tobacco use, male sex, and more infrequent practice of oral hygiene
Martinez Canut *et al*. (1995) Spain	889 periodontitis patients, aged 21–76 years; probing assessments at six sites/tooth, all teeth; analysis of variance to examine the role of smoking on the severity of periodontitis	Smoking was statistically related to increased severity of periodontitis in multivariate analysis; a dose–response effect was demonstrated, with subjects smoking >20 cigarettes/day showing significantly higher attachment loss
Kaldahl *et al*. (1996) USA (L)	74 patients with moderate to advanced periodontitis, including 31 heavy smokers (≥20 cigarettes/day); the effects of cigarette consumption and smoking history on the response to active periodontal treatment and to up to 7 years of supportive periodontal treatment was evaluated Full-mouth examinations performed at baseline, 4 weeks after mechanical plaque control, 10 weeks following periodontal surgery, and yearly during 7 years of supportive periodontal treatment	Past and never smokers consistently exhibited a significantly greater reduction in PD and greater gains in AL than heavy and light smokers All groups experienced a similar decrease in the prevalence of BoP following active therapy

(*Continued*)

Table 7-5 *Continued.*

Authors/country[a]	Sample/methodology	Findings
Grossi *et al*. (1997) USA (L)	143 subjects aged 35–65 years with established periodontitis, including 60 current, 55 former, and 28 non-smokers, examined at baseline and 3 months after non-surgical periodontal therapy	Current smokers showed less reduction in PD and less AL gain than former- and non-smokers Fewer smokers harbored no *P. gingivalis* or *Tannerella forsythia* after treatment, compared to former and non-smokers
Axelsson *et al*. (1998) Sweden	A random sample of 1093 subjects, aged 35, 50, 65, and 75 years; prevalence of smoking in the four age groups was 35%, 35%, 24%, and 12%, respectively; recordings included AL, CPITN scores, DMF surfaces, plaque, and stimulated salivary secretion rate (SSSR)	In the oldest age group, 41% of the smokers and 35% of the non-smokers were edentulous In every age group, mean AL was statistically significantly increased in smokers by 0.37, 0.88, 0.85, and 1.33 mm, respectively Smokers had higher CPITN and DMF scores, increased SSSR, but similar plaque levels
Tomar & Asma (2000) USA	12 329 subjects, aged ≥18 years, participants in the NHANES III study; probing assessments at mesial and buccal sites in one upper and one lower quadrant; mesial assessments performed from the buccal aspect of the teeth; assessments of gingivitis, PD, and location of the gingival margin in relation to the CEJ; "periodontitis" was defined as ≥1 site with AL ≥ 4 mm and PD ≥4 mm	27.9% of participants were current smokers and 9.2% met the definition for periodontitis Current smokers were four times as likely to suffer from periodontitis than never smokers, after adjustments for age, gender, race/ethnicity, education, and income:poverty ratio Among current smokers, there was a dose–response relationship between cigarettes/day and periodontitis 41.9% of periodontitis cases were attributable to current smoking and 10.9% to former smoking
Bergström *et al*. (2000b) Sweden	257 subjects, aged 20–69 years, including 50 current smokers, 61 former smokers, and 133 non-smokers; full-mouth clinical and radiographic assessments of the periodontal tissues; smoking exposure defined in terms of consumption (number of cigarettes/day), duration (number of years of smoking) and lifetime exposure (product of daily consumption and years of duration – cigarettes/year); threshold levels used: heavy versus light consumption: ≥10 cigarettes/day versus <10 cigarettes/day; duration: ≥15 years versus <15 years; lifetime exposure: ≥200 cigarettes/year versus <200 cigarettes/year	Compared to former and non-smokers, current smokers had the highest prevalence of diseased sites (AL ≥4 mm) 40–69-year-old current smokers showed a significantly higher prevalence than 20–39-year-old current smokers (27% versus 4%) The same pattern emerged when comparing heavy versus light smokers according to consumption, duration, and lifetime exposure; in multiple regression, lifetime exposure was highly associated with the frequency of diseased sites and periodontal bone height after adjusting for age, gingival bleeding, and plaque index
Albandar *et al*. (2000) USA	705 subjects, aged 21–92 years, 52% males and 87% Caucasian; full-mouth examination of PD and AL at six sites; periodontitis was classified as advanced, moderate, or mild; cigar, pipe, and cigarette smoking were classified as current, former, and never	In multiple linear regression, current and former smoking, regardless of type, was associated with increased percentage of subjects with moderate/advanced periodontitis after adjusting for age, gender, race, and number of years of cigarette, cigar, and pipe smoking; current smoking was also associated with higher number of missing teeth
Bergström *et al*. (2000a) Sweden (L)	10-year follow-up of a sample of 84 dentally aware musicians, including16 current, 28 former, and 40 non-smokers; full-mouth clinical and radiographic assessments of periodontal status	Prevalence of PD ≥4 mm ("diseased" sites) was 18.7% for current, 11.1% for former, and 8.7% for non-smokers at baseline. At 10 years, these figures were 41.6%, 7.8%, and 6.6%, respectively; a similar pattern was observed for alveolar bone levels After adjusting for age, gingival bleeding, plaque index, and frequency of diseased sites at baseline, current smoking was a significant predictor of the increase in diseased sites at 10 years
Susin *et al*. (2004b) Brazil	974 subjects, aged 30–103 years; full-mouth examination of PD and AL; severe attachment loss was defined as AL ≥5 mm in ≥30% of the teeth; exposure to smoking classified as current/former, heavy/moderate/light/none, and quantified as lifetime consumption	Heavy and moderate smokers had significantly higher prevalence of AL ≥5 mm than non-smokers; in multivariate analysis heavy (OR = 3.6; 95% CI 2.2–6.0) and moderate smoking (OR = 2.0; 95% CI 1.4–2.9) conferred higher OR for AL; the attributable fraction of AL due to smoking was 37.7% and 15.6% among heavy and moderate smokers, respectively

(*Continued*)

Table 7-5 *Continued*

Authors/country[a]	Sample/methodology	Findings
Phipps *et al.* (2009) USA	1210 dentate men aged ≥65 years; random half-mouth assessments of PD and AL at six sites/tooth; "periodontitis" was defined as (1) presence of interproximal attachment loss ≥5 mm in ≥30% of the teeth present (5th European Workshop definition), or (2) according to the CDC/AAP definition; information on smoking habits collected through self-administered questionnaires and converted to pack-years	Prevalence of periodontitis according to the 5th European workshop definition was 30.4% among never smokers, 35.3% among smokers with <20 pack-years, and 50.3% among smokers with ≥20 pack-years (P <0.001); corresponding prevalence figures according to the CDC/AAP definition were 22.0%, 19.2%, and 36.4%, respectively (P <0.001) In multivariate analysis adjusted for age, race, and dental visit attendance, ≥20 pack-years were significantly associated with periodontitis OR 2.11 (95% CI 1.64–2.72) and 2.38 (95% CI 1.79–3.13), according to the two definitions, respectively

[a] **L** indicates a longitudinal study
PD, probing depth; AL, attachment level; BoP, bleeding on probing; CEJ, cemento-enamel junction; CPITN, Community Periodontal Index of Treatment Needs; NHANES, National Health and Nutrition Examination Survey; DMF, decayed, missing, filled; CI, confidence interval, OR, odds ratio.

smoking is much greater than that due to other systemic predispositions, such as diabetes mellitus. Data derived from the NHANES III study (Tomar & Asma 2000) suggested that as many as 42% of periodontitis cases in the US can be attributed to current smoking and another 11% to former smoking. Similarly, a study from Brazil (Susin *et al*. 2004b) reported that the attributable fraction of clinical attachment loss due to cigarette smoking was 37.7% and 15.6% among heavy and moderate smokers, respectively. In longitudinal studies, smoking has been found to confer a statistically significant increased risk for periodontitis progression after adjustment for other co-variates (Beck *et al*. 1995, 1997; Machtei *et al*. 1999; Norderyd *et al*. 1999; Chen *et al*. 2001; Ogawa *et al*. 2002; Paulander *et al*. 2004b).

Figure 7-4 shows an early *meta-analysis* of data from studies reporting on the association between smoking and periodontal conditions. In essence, meta-analysis is a statistical method which combines results from different studies of similar design, in order to achieve increased *power* to detect epidemiologic associations that may be difficult to identify in smaller, individual studies (Oakes 1993; Chalmers 1993; Proskin & Volpe 1994). This analysis, initially published as part of the 1996 World Workshop in Periodontics (Papapanou 1996), incorporated data from six studies, including a total of 2361 subjects with known smoking habits and periodontal status (Bergström & Eliasson 1989; Haber & Kent 1992; Locker 1992; Haber *et al*. 1993; Stoltenberg *et al*. 1993; Grossi *et al*. 1994). It can be observed that smoking was an overall increased, statistically and clinically, significant risk for severe disease (estimated overall OR of 2.82; 95% CI 2.36–3.39).

Studies examining the effects of smoking on the outcome of periodontal treatment have demonstrated that treatment responses are modified by cigarette consumption, with current smokers exhibiting poorer responses than former or never smokers (e.g. Ah *et al*.

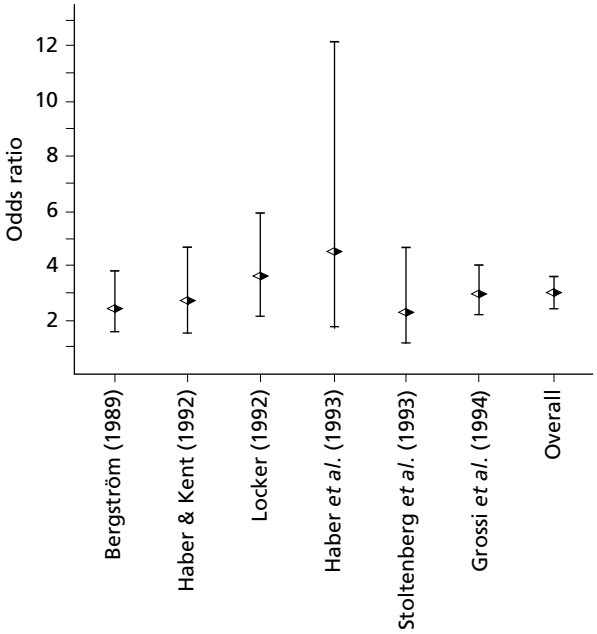

Fig. 7-4 Meta-analysis of smoking as a risk factor for periodontal disease. The studies included are: Bergström (1989), Haber & Kent (1992), Locker (1992), Haber *et al*. (1993), Stoltenberg *et al*. (1993), and Grossi *et al*. (1994). Bars indicate the 95% confidence limits for the depicted odds ratios. (Source: Papapanou 1996. Reproduced from American Academy of Periodontology.)

1994; Kaldahl *et al*. 1996; Grossi *et al*. 1997; Kinane & Radvar 1997; Tonetti *et al*. 1998; Trombelli *et al*. 2003, Stavropoulos *et al*. 2004; Paulander *et al*. 2004a; Rieder *et al*. 2004; Sculean *et al*. 2005; Wan *et al*., 2009). Notably, these studies have confirmed the negative effect of smoking on the outcome of several periodontal treatment modalities, including non-surgical, surgical, and regenerative periodontal therapy. Meta-analyses of the effects of smoking on the outcome of periodontal therapy (Garcia 2005; Labriola *et al*. 2005; Patel *et al*. 2012) support the above conclusions.

In contrast, smoking cessation was shown to have beneficial effects on periodontal status. In a

longitudinal study (Bolin *et al*. 1993), 349 subjects with ≥20 remaining teeth were examined on two occasions 10 years apart (1970 and 1980). Progression of periodontal disease was assessed on radiographs at all approximal tooth surfaces and was shown to be almost twice as rapid in smokers as in non-smokers. It was also observed that subjects who quit smoking at some time point within the observation period had a significantly retarded progression of bone loss compared to that in smokers. Similar observations were made by Krall *et al*. (1997) who reported that, over a mean follow-up period of 6 years, subjects who continued to smoke had a 2.4–3.5-fold risk of tooth loss when compared to individuals who quit smoking. In a 10-year follow-up study, Bergström *et al*. (2000a) observed an increase of periodontally diseased sites concomitant with loss of periodontal bone height in current smokers, as compared to non-smokers whose periodontal health condition remained unaltered throughout the period of investigation. The periodontal health condition in former smokers was similarly stable to that of non-smokers, underscoring the beneficial effects of smoking cessation. In a shorter (12-month) follow-up study evaluating the adjunctive effect of smoking cessation on the outcome of non-surgical periodontal therapy, Rosa *et al*. (2011) showed enhanced gain in clinical attachment in chronic periodontitis patients who quit smoking when compared to their smoking counterparts. Importantly, smoking cessation alone or in conjunction with non-surgical periodontal therapy appears to result in a composition of subgingival microbiota that comprises higher levels of health-associated species and lower levels of periodontal pathogens (Fullmer *et al*. 2009; Delima *et al*. 2010).

In conclusion, cigarette smoking appears to fulfill the majority of the required steps of the risk assessment process stipulated by Beck (1994) and is considered one of the major risk factors for periodontitis.

Diabetes mellitus

The role of diabetes mellitus (DM) as a risk factor for periodontitis has been debated for decades (Genco & Löe 1993), but several biologically plausible mechanisms by which the disease may contribute to impaired periodontal conditions have been identified over the past decade [for reviews see Lalla *et al*. (2000), Mealey & Oates (2006), and Lalla and Papapanou (2011)]. Table 7-6 summarizes the epidemiologic evidence based on a number of case–control and prospective cohort studies that examined the periodontal status of patients with diabetes. A recent meta-analysis including 49 cross-sectional and eight longitudinal studies confirmed a strong association between type 2 DM and periodontitis, but concluded that the evidence for type 1 DM is weaker (Chávarry *et al*. 2009). The adverse effects of DM on periodontal status appear to be particularly pronounced in subjects with a long duration of DM and poor metabolic control (Grossi & Genco 1998; Taylor *et al*. 1996, 1998a; Lalla *et al*. 2004). Indeed, studies have provided evidence of a dose–response relationship between poor metabolic control and the severity as well as the progression of periodontitis (Seppälä *et al*. 1993; Tervonen & Oliver 1993; Taylor *et al*. 1998a; Tervonen & Karjalainen 1997; Guzman *et al*. 2003; Bandyopadhyay *et al*. 2010). Expanding this observed dose–response relationship to the prediabetic state, the level of glucose intolerance in non-diabetic individuals was also correlated with the severity of periodontal disease (Saito *et al*. 2004). In line with the above observations, the outcome of periodontal treatment in well-controlled diabetic patients is similar to that of non-diabetic subjects (Westfelt *et al*. 1996; Christgau *et al*. 1998; Faria-Almeida *et al*. 2006), while patients with poorly controlled DM display an inferior treatment outcome (Tervonen & Karjalainen 1997).

The age of onset of DM manifestations in the periodontal tissues has been addressed in studies examining children and adolescents with type 1 DM (de Pommereau *et al*. 1992; Pinson *et al*. 1995) and both type 1 and type 2 DM (Lalla *et al*. 2006). All three studies documented more pronounced gingival inflammation in subjects with diabetes aged between 6 and 18 years. The case-control study by Lalla *et al*. (2006) further reported that clinical attachment loss was more pronounced in young patients with diabetes after adjustment for age, gender, ethnicity, gingival bleeding, and frequency of dental visits. In a subsequent publication, Lalla *et al*. (2007b) reported data on 350 children with either type 1 or type 2 DM and found a strong positive association between mean HbA1c levels over the 2 years preceding the dental examination and periodontitis. In a report including a total of 700 children, 350 with diabetes and 350 non-diabetic controls, Lalla *et al*. (2007a) documented a statistically increased periodontal destruction in children with diabetes across all disease definitions tested and in both age subgroups of 6–11 and 12–18 years.

Several studies suggest a two-way relationship between DM and periodontitis. Beyond the observed increased severity of periodontal tissue destruction in subjects with DM, studies indicate a higher incidence of DM complications and poorer metabolic control of diabetes in periodontitis patients [for review see Lalla & Papapanou (2011)]. These findings are discussed in more detail in Chapter 14.

Obesity

The biologic plausibility of a potential link between obesity and periodontitis has been suggested to involve a hyper-inflammatory state and an aberrant lipid metabolism prevalent in obesity, as well as the pathway of insulin resistance (Saito *et al*. 1998; Nishimura & Murayama 2001), all of which may collectively result in an accelerated breakdown of the

Table 7-6 Selected studies using diabetes mellitus as exposure of significance for periodontitis.

Authors/country[a]	Sample/methodology	Findings
Hugoson *et al*. (1989) Sweden	82 subjects with long and 72 with short duration IDDM; 77 non-diabetic individuals (aged 20–70 years); full-mouth, probing assessments at four sites/tooth; radiographs of lower molar–premolar regions; subjects assigned into five groups according to increasing severity of periodontal disease; no multivariate analysis	No notable difference in plaque, calculus, and number of teeth between individuals with and without DM Long duration DM patients were more frequently classified in groups 4 and 5 and had significantly more tooth surfaces with PD of ≥6 mm than non-diabetic controls Significantly more extensive alveolar bone loss in individuals with long duration DM aged 40–49 years old
Shlossman *et al*. (1990) USA	3219 Pima Indians, aged ≥5 years; prevalence of NIDDM 23% (20% in men, 25% in women); probing assessments at six sites/tooth for six index teeth; alveolar bone loss from panoramic radiographs; 2878 subjects with available radiographic data, probing assessments or both; comparison between diabetic and non-diabetic individuals with respect to AL and alveolar bone loss	Median attachment loss and alveolar bone loss higher in DM for all age groups and both genders
Emrich *et al*. (1991) USA	Sample and methodology same as above (Shlossman *et al*. 1990); 1342 Pima Indians, aged 15 years and older, with natural teeth; 19% (254) with diabetes and 12% (158) with impaired glucose tolerance; linear logistic models to predict prevalence and severity of periodontal disease; prevalence: ≥1 sites with AL of ≥5 mm or alveolar bone los ≥25% of the root length; severity: square root of average AL or alveolar bone loss	Diabetes, age, and calculus were significant risk markers for periodontitis OR for an individual with DM to have PD was 2.8 (clinically assessed) and 3.4 (radiographically)
de Pommereau *et al.* (1992) France	85 adolescents with IDDM,aged 12–18 years, and 38 healthy ag- matched controls; probing assessments at six sites/tooth, all teeth; bite-wing radiographs at molars and sites with AL >2 mm; patients divided according to disease duration (> or <6 years); sexual maturation according to Tanner's classification; metabolic control expressed through glycosylated hemoglobin (HbA1c); non-parametric pair-wise analysis	None of the subjects had sites with AL ≥3 mm or radiographic signs of periodontitis Despite similar plaque scores, diabetic children had significantly more gingival inflammation No significant relation between gingival condition and age, Tanner's index, HbA1c level or disease duration
Oliver & Tervonen (1993) USA	114 diabetic patients,aged 20–64 years (60% with IDDM and 40% with NIDDM); half-mouth, probing assessments at four sites/tooth; data from the 1985–86 National Survey served as controls	Tooth loss was similar among diabetic and non-diabetic US employed adults 60% of individuals with DM and 16% of controls had ≥1 site with PD ≥4 mm AL data were comparable in both groups
Thorstensson & Hugoson (1993) Sweden	83 IDDM patients and 99 age- and sex-matched non-diabetic controls, aged 40–70 years; full-mouth, probing assessments at four sites/tooth; radiographs of lower molar–premolar regions; subjects assigned to five groups according to increasing severity of periodontal disease; univariate analysis	DM patients aged 40–49 years (mean disease duration 25.6 years) had more periodontal pockets ≥6 mm and more extensive alveolar bone loss than non-diabetic controls, but this was not the case for subjects aged 50–59 or 60–69 years (mean disease duration 20.5 and 18.6 years, respectively) Disease duration appeared to be a significant determinant of development of periodontitis
Pinson *et al*. (1995) USA	26 IDDM children, aged 7–18 years, and 24 controls, 20 of whom were siblings of the diabetic patients; full-mouth, probing assessments at six sites/tooth; metabolic control assessed through HbA1c; analysis of co-variance	Overall, no statistically significant differences between cases and controls No association between levels of HbA1c and clinical variables After correcting for plaque, diabetics showed more severe gingival inflammation in specific tooth regions
Bridges *et al*. (1996) USA	A samples of 233 men, aged 24–78 years, including 118 diabetic (46 type 1 and 72 type 2) and 115 non-diabetic subjects, matched for age and BMI	Plaque and gingivitis, bleeding scores, PD, AL and missing teeth were significantly higher in diabetic than non-diabetic men

(*Continued*)

Table 7-6 *Continued*

Authors/country[a]	Sample/methodology	Findings
Tervonen & Karjalainen (1997) Finland (L)	36 patients with type 1 diabetes and 10 controls, aged 24–36 years, received non-surgical periodontal therapy and were followed at 4 weeks, 6 and 12 months; patient with diabetes were further grouped according to diabetic status as: D1 (n = 13) with no diabetic complications and good long-term metabolic control; D2 (n = 15) moderate metabolic control with/without retinopathy; D3 (n = 8) severe diabetes with poor metabolic control and/or multiple complications; periodontal status was monitored radiographically	The periodontal status of the diabetic patients with good control and no complications (D1) and those with moderate control (D2) was similar to non-diabetic controls Diabetic subjects with poor metabolic control and/or multiple complications (D3) exhibited higher extent of AL ≥2 mm at baseline and higher recurrence of PD ≥4 mm during follow up
Taylor *et al*. (1998a) USA (L)	2-year study of 21 patients with type 2 diabetes, including 14 with poor and 7 with better metabolic control, and 338 controls, aged 15–57 years, Native Americans; progression of bone loss was assessed on radiographs; co-variates included age, calculus, gingival and plaque indices, time to follow-up, alcohol consumption, smoking, obesity (BMI >27), coronary heart disease, and gender	In multiple logistic regression, poorly controlled diabetic subjects were 11 times more likely (95% CI 2.5–53.3) to have more pronounced bone loss progression than non-diabetic subjects; no such differences were found between better controlled and non-diabetic controls Age, time to follow-up, pronounced bone loss at baseline, and calculus index were significant predictors of bone loss progression.
Taylor *et al*. (1998b) USA (L)	2-year study of 24 subjects with NIDDM and 362 subjects without diabetes, aged 15–57 years; degree of bone loss on panoramic radiographs was assessed on a scale of 0–4	A regression model having progression of bone loss as the dependent variable revealed a cumulative OR for NIDDM of 4.23 (95% CI 1.8–9.9); the association was modified by age, with younger adults exhibiting higher risk for alveolar bone loss progression
Lalla *et al*. (2007) USA	Case–control study of 350 children and adolescents, aged 6–18 years, with diabetes (325 with type 1 diabetes; 25 with type 2 diabetes) and 350 non-diabetic controls; half-mouth examination at four sites/tooth in all fully erupted teeth with respect to PD and AL; three different definitions of periodontitis were used	Children with diabetes had significantly more plaque and gingival inflammation than controls and a higher number of teeth with AL Regression analysis controlling for age, gender, ethnicity, gingival bleeding, and frequency of dental visits revealed that diabetes was statistically related to periodontal destruction across all disease definitions (OR 1.84–3.72)

[a] **L** indicates a longitudinal study.
PD, probing depth; AL, attachment level; ; BMI, body mass index; OR, odds ratio; CI, confidence interval.
DM: diabetes mellitus.
IDDM and NIDDM, insulin-dependent and non-insulin dependent diabetes mellitus, respectively; these diagnostic terms are no longer used and have been replaced by type 1 and type 2 diabetes.

periodontal tissues. Indeed, a number of studies have indicated a positive association between obesity, defined as body mass index (BMI) ≥30 kg/m^2, and periodontitis. Four publications have documented such an association in the NHANES III database. Wood *et al*. (2003), using a subset including Caucasian subjects aged 18 years and older, reported that BMI, waist-to-hip ratio, visceral fat, and fat-free mass were associated with periodontitis after adjusting for age, sex, history of diabetes, current smoking, and socio-economic status. Al-Zahrani *et al*. (2003) reported a significant association between both BMI and waist-to-hip ratio and periodontitis in younger adults, but no association in middle-aged or older adults. Genco *et al*. (2005) reported that overweight subjects in the upper quartile of the insulin resistance index were 1.5 times more likely to have periodontitis compared to their counterparts with a high BMI but a low insulin resistance index. Finally, Andriankaja *et al*. (2010) demonstrated an association between *metabolic syndrome* (i.e. a combination of hypertension, impaired fasting glucose, large waist circumference, and dyslipidemia) and periodontitis in women, and between abdominal obesity and periodontitis in both women and men.

In a longitudinal study of 1038 healthy, Caucasian US male veterans, obesity conferred a 41–72% increased risk for progression of periodontitis, after adjustment for several co-variates (Gorman *et al*. 2012).

Corroborating data have been reported also from countries other than the US. In a sample of 643 apparently healthy Japanese adults, Saito *et al*. (2001) reported that waist-to-hip ratio, BMI, and body fat were significant risk indicators for periodontitis after adjustments for known risk factors. In a recent longitudinal study from Japan involving a sample of 3590

individuals, the 5-year incidence of periodontitis was statistically higher for both those with a BMI between 25 and 30 kg/m^2 and those with a BMI of ≥30 kg/m^2, when compared to individuals with a BMI of ≤22 kg/m^2 (Morita *et al*. 2011), establishing a dose–response relationship between overweight/obesity and risk for periodontitis. Finally, in a study involving a nationally representative sample of 7188 subjects in Korea, *metabolic syndrome* was associated with periodontitis (Kwon *et al*. 2011). In contrast, an inverse association between obesity and clinical attachment loss was observed in a study involving 1579 men and women in Denmark (Kongstad *et al*. 2009).

Given that (1) the majority of the above publications are cross-sectional, and thus do not facilitate inferences on temporality or mechanisms, and (2) the available epidemiologic data are limited and not universally consistent, additional research on the role of obesity in periodontitis is warranted.

Osteopenia/osteoporosis

Several early cross-sectional studies, of limited sample size and largely confined to post-menopausal women, have suggested that women with low bone mineral density are more likely to have gingival recession and/or pronounced gingival inflammation and clinical attachment loss (von Wowern *et al*. 1994; Mohammad *et al*. 1996, 1997; Tezal *et al*. 2000). In a radiographic study of 1084 subjects aged 60–75 years, Persson *et al*. (2002) reported a positive association between osteoporosis and periodontitis with an OR of 1.8 (95% CI 1.2–2.5). However, studies that have failed to report such an association have also been published (Weyant *et al*. 1999; Lundström *et al*. 2001).

Based on these observations, it has been hypothesized that the systemic loss of bone density in osteoporosis may, in combination with hormone action, heredity, and other host factors, provide a host system that is increasingly susceptible to inflammation-associated destruction of the periodontal tissues (Wactawski-Wende 2001). In a cross-sectional study of 1329 post-menopausal women in the US, systemic bone density was positively associated with clinical attachment loss in women with subgingival calculus, but negatively associated in women without calculus (Brennan *et al*. 2007). The data from longitudinal studies are apparently conflicting. Payne *et al*. (1999, 2000) reported an enhanced longitudinal alveolar bone loss in osteoporotic women versus women with normal mineral bone density, Yoshihara *et al*. (2004) found, after adjustments, a significant association between bone mineral density and 3-year longitudinal attachment loss in Japanese subjects aged ≥70 years. In contrast, Reinhardt *et al*. (1999) reported no significant impact of serum estradiol levels on longitudinal attachment loss over a 2-year period. Recent systematic reviews of the available studies on osteoporosis and periodontitis (Martinez-Maestre *et al*. 2010; Megson *et al*. 2010) concluded that the relationship between the two conditions remains unclear. Additional prospective studies are warranted to clarify the inter-relationship between the two diseases and its clinical implications.

Human immunodeficiency virus infection

Studies published in the late 1980s seemed to indicate that both the prevalence and the severity of periodontitis were exceptionally high in patients with acquired immunodeficiency syndrome (AIDS) (Winkler & Murray 1987), but a more tempered picture emerged in subsequent publications. While it cannot be ruled out that the initial reports included biased samples, it is also possible that the successful control of immunosuppression in human immunodeficiency virus (HIV)-positive subjects by means of high activity antiretroviral therapy (HAART) and other continuously evolving drugs has influenced the incidence of periodontal disease progression in HIV-seropositive subjects and has resulted in less severe periodontal manifestations of HIV infection (Chapple & Hamburger 2000). For example, a cross-sectional study of 326 HIV-infected adults (McKaig *et al*. 1998) revealed that, after adjustments for CD4 counts, persons taking HIV antiretroviral medication were five times less likely to suffer from periodontitis than those not taking such medication, underscoring the importance of the host's immunologic competency in this context.

Nevertheless, publications continue to generate conflicting results. Thus, although a number of studies (Smith *et al*. 1995a; Robinson *et al*. 1996; Ndiaye *et al*. 1997; McKaig *et al*. 1998; Nittayananta *et al*. 2010; Stojkovic *et al*. 2011) have indicated higher prevalence and severity of periodontitis in HIV-positive subjects when compared to controls, other studies have either not supported this notion or have indicated that the differences in periodontal status between HIV-seropositive and -seronegative subjects are limited (Cross & Smith 1995; Lamster *et al*. 1997; Scheutz *et al*. 1997; Lamster *et al*. 1998; Vastardis *et al*. 2003). Studies investigating the pathobiology of periodontitis in HIV-infected subjects suggested that specific IgG subclass responses to periodontopathic bacteria were similar in HIV-positive and HIV-negative subjects (Yeung *et al*. 2002), while CD4 count levels were not found to correlate with the severity of periodontitis (Martinez Canut *et al*. 1996; Vastardis *et al*. 2003).

The few available longitudinal studies are equally conflicting. Two companion publications, from a short-term follow-up study (Smith *et al*. 1995b; Cross & Smith 1995) involving a group of 29 HIV-seropositive subjects who were examined at baseline and at 3 months, reported a low prevalence and incidence of clinical attachment loss. The subgingival microbial profiles of the seropositive subjects resembled those of non-systemically affected subjects, and did not correlate with their CD4 and CD8 lymphocyte counts. Similarly, in a small follow-up study of 12 months' duration, Robinson *et al*. (2000) found no difference in the

progression of periodontitis between HIV-positive and HIV-negative subjects. Hofer *et al*. (2002) demonstrated that compliant HIV-positive subjects can be successfully maintained in a manner similar to non-infected controls. However, a 20-month follow-up study of 114 homosexual or bisexual men (Barr *et al*. 1992) revealed a clear relationship between incidence of clinical attachment loss and immunosuppression, expressed through CD4 cell counts. The authors suggested that seropositivity in combination with older age confers an increased risk for attachment loss. Similar observations were reported by Lamster *et al*. (1997), who concluded that periodontitis in the presence of HIV infection is dependent upon the immunologic competency of the host as well as the local inflammatory response to the subgingival microbiota.

It appears therefore that there is no consensus in the literature on the association of HIV/AIDS and periodontitis. Variation in the severity of oral pathologic conditions due to ongoing advancements in HIV/AIDS therapy will likely further contribute to the diversity of the findings (Freed *et al*. 2005).

Psychosocial factors

The mechanisms by which psychosocial stress may affect the periodontal status are complex. It has been suggested that one of the plausible pathways may involve behavioral changes leading to smoking and poor oral hygiene that, in turn, may affect periodontal health (Genco *et al*. 1998). In the absence of an unequivocal biologic measure of stress, a limited number of studies have used proxy measures of stress to study its association with periodontitis. In a study of 1426 subjects in Erie County, NY, USA, Genco *et al*. (1999) reported that adults who were under financial strain and exhibited poor coping behaviors were at increased risk of severe periodontitis when compared with subjects who demonstrated good coping behavior patterns under similar financial strain, or with controls under no financial strain. In a sample of 1089 adults in rural Japan, job- and health-related stress was positively associated with clinical attachment loss after adjustments for common risk factors (Akhter *et al*. 2005). War-related stress was found to be associated with poor periodontal conditions in Croatia (Spalj *et al*. 2008). Similar observations were made in a study of an immigrant population from Ethiopia, in which psychological distress was positively associated with deep periodontal pockets (Vered *et al*. 2011). In contrast, a study of 681 subjects carried out in Lithuania (Aleksejuniene *et al*. 2002) could not document an association between psychosocial stress and periodontitis, although it reported that the disease did correlate with lifestyle factors. In a small prospective study based on 23 employed adults, Linden *et al*. (1996) reported that longitudinal attachment loss was significantly predicted by increasing age, lower socioeconomic status, lower job satisfaction, and type A personality, characterized by aggressive, impatient, and irritable behavior.

Clearly, the role of stress in periodontitis has not been fully explored and multiple gaps in our knowledge exist. Nevertheless, given the established role of the sympathetic, parasympathetic, and peptidergic/sensory nervous systems, as well as that of the hypothalamic–pituitary–adrenal axis on brain-to-immune regulatory pathways, such a role is clearly biologically plausible. Experimental animal studies have begun to shed light on basic mechanisms that may explain the link between psychosocial factors and periodontitis. For example, a study by Breivik *et al*. (2006) demonstrated that experimentally-induced depression accelerated tissue breakdown in a ligature-induced periodontitis rat model and that pharmacologic treatment of depression attenuated this breakdown. In a study in humans, salivary cortisol levels (indicative of psychological stress) were positively associated with the extent and severity of periodontitis (Hilgert *et al*. 2006).

Additional basic and epidemiologic research is needed to fully elucidate a possible relationship between psychological factors and periodontal disease.

Concluding remarks

The analytical epidemiologic studies described in this chapter are obviously diverse with respect to important elements of design and methodology, such as definitions of disease, sample size, use of full-mouth or partial-mouth recording protocols, length of follow-up in longitudinal studies, adjustment for potential confounders, etc. Nevertheless, despite these apparent shortcomings, a number of conclusions can be made with reasonable certainty:

1. Specific bacteria, cigarette smoking, and diabetes mellitus are the major established risk factors for periodontitis. A number of biologically plausible, potentially important additional factors are in need of further investigation in future studies.
2. There is a need to introduce uniform definitions of periodontitis to be used in analytical epidemiologic studies. This will facilitate valid comparisons, establish whether seemingly conflicting data reflect true biologic variation or are exclusively owed to methodologic inconsistencies, and contribute to the correct identification of risk factors. The definitions proposed by the Consensus Report of the 5th European Workshop in Periodontology (Tonetti & Claffey 2005), the CDC/APP definition (Page & Eke 2007), and the definition for *aggressive periodontitis* in epidemiologic studies (Demmer & Papapanou 2010) may serve such a purpose. Obviously, no definition is devoid of shortcomings and the above proposals are no exception. In the absence of a universally accepted consensus definition, data presentation using several of the above definitions should be encouraged.

3. Studies need to distinguish clearly between risk factors and disease predictors. Although the use of the latter as explanatory variables in multivariate models may increase the coefficient of determination (i.e. the proportion of the variance explained by means of the models), it may also obscure the significance of true etiologic factors. For example, as shown by Ismail *et al*. (1990), factors with biologically plausible etiologic potential (such as dental plaque) may not retain their significance in multivariate models that include alternative expressions of disease such as tooth mobility. It has been demonstrated that baseline levels of disease and morphologic features such as angular bony defects are powerful predictors of future disease progression (Papapanou *et al*. 1989; Papapanou & Wennström 1991). Haffajee *et al*. (1991a) showed that age, plaque, and bleeding on probing are related to baseline disease levels as well as to incident disease. In the search for true exposures of significance for disease onset or progression, inclusion of a factor in a model may thus erroneously discredit another co-varying, biologically significant factor.

An interesting observation was made in a longitudinal study by Beck *et al*. (1995), in which characteristics of patients experiencing clinical attachment loss at previously non-diseased sites were compared with those of patients suffering progression of already established disease. While low income and medication with drugs associated with soft tissue reactions were features common to both groups of patients, new sites with attachment loss were more frequent in patients who used smokeless tobacco and had a history of oral pain. Risk for progression of established disease was higher in cigarette smokers, subjects with high levels of subgingival *P. gingivalis*, and individuals with worsening financial problems. These data suggest that periodontitis may be like other diseases for which the factors associated with the initiation of the disease may be different from the ones involved in its progression. Such a distinction between factors associated with initiation and with progression may have implications for future assessment strategies and may improve the accuracy of the risk/prediction models.

One of the issues related to the descriptive epidemiology of periodontal infections that is still under debate is whether their worldwide prevalence has been decreasing over the last decades. Unfortunately, the data do not allow a clear answer for a number of reasons. First, no universal conclusion is possible, since the prevalence of periodontal disease appears to vary with race and geographic region. Second, the quality of the data available from developing and developed countries is clearly not comparable. While some well-conducted epidemiologic surveys that provide detailed information have been carried out in a number of countries, the majority of the studies in the developing world have used the CPITN system, which produced data of inadequate detail. Moreover, studies using the exact same methodology to evaluate random samples drawn from the same population over time are sparse. Among the few exceptions, data available from some parts of the world, notably the US, are suggestive of such a trend for decreasing prevalence of periodontitis (Dye *et al*. 2007). A series of studies from Sweden (Hugoson *et al*. 1992, 1998b, 2005) that documented, by clinical and radiographic means, the frequency distribution of various levels of severity of periodontitis in four cross-sectional studies over a 30-year period (in 1973, 1983, 1993, and 2003). In these studies, subjects were grouped according to the severity of their periodontal conditions into five groups: groups 1 and 2 included subjects who were periodontally healthy or only had gingivitis; group 3 included subjects with moderate periodontitis, that is whose loss of periodontal tissues support did not extend beyond one-third of the root length; and groups 4 and 5 included subjects with more severe destructive disease. As shown in Fig. 7-5, a clear increase in the frequency of subjects in groups 1 and 2 was noted over the 30-year period, from 49% in 1973 to 60% in 1993 to almost 62% in 2003. This increase occurred primarily at the expense of group 3, which declined from 38% in 1973 to 27% in 1993 and apparently reached a plateau at 28% in 2003. Nevertheless, the frequency of subjects in groups 4 and 5 was virtually stable over the 30-year period: 13% in 1973, 13% in 1993, and 10.5% in 2003. Based on these data derived from a population with arguably the best access to and utilization of oral health care in the world, it may be concluded that the fraction of the population which is most susceptible to severe periodontitis is apparently not declining in frequency. Instead, the main beneficiaries of the improved oral health awareness, access to care, and increased utilization of therapeutic resources that has occurred over the last decades are likely the individuals with

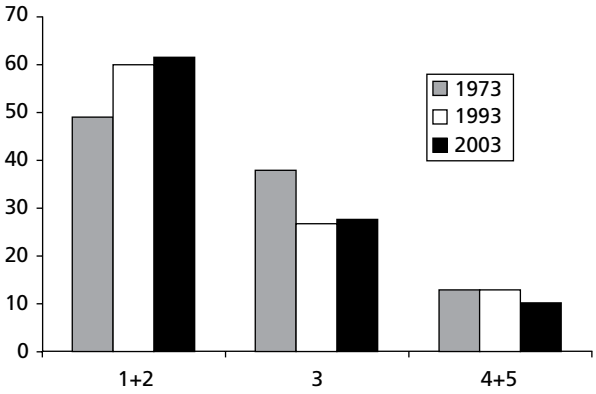

Fig. 7-5 Frequency distribution of subjects with healthy periodontal conditions or gingivitis (groups 1 + 2), moderate periodontitis (group 3), and advanced and severe periodontal disease (groups 4 + 5), in a Swedish cohort in 1973, 1993, and 2003. For definitions see text. (Adapted after personal communication with Anders Hugoson, based on data from Hugoson *et al*. 1992, 1998, 2006).

moderate levels of periodontitis whose prevalence is clearly lower.

It has also been well-documented in these and other studies that the rate of edentulism has decreased substantially over the past 30 years, with elderly groups retaining their natural dentition and higher mean numbers of teeth than their counterparts a generation ago (Kassebaum *et al*. 2014). This fact *per se* should contribute to an increased prevalence of periodontal disease in older age cohorts, since retained teeth in the elderly are more likely to experience substantial cumulative attachment loss which forms the basis of the assessment of prevalence (Douglass & Fox 1993). It has been argued, however, that such a potential increase may not necessarily result in increased need for periodontal therapy (Oliver *et al*. 1989). Additional research is clearly required to further elucidate these issues, and an adequate and consistent epidemiologic methodology is essential for generating valid comparative data. Arguably, the principle task of future epidemiologic research is to elucidate the determinants of susceptibility to severe periodontitis, prior to the development of irreversible tissue damage (Papapanou 2012, 2014). Although several risk factors have been established and a wide array of disease markers has been recognized, the impact of intervention addressing such factors on the state of periodontal health on a population level has yet to be documented. To assess the magnitude of the clinical benefit achieved by such modulation, prospective, long-term epidemiologic surveys have to be conducted.

Part 3: Microbiology

Chapter 8

Dental Biofilms

Philip David Marsh

Department of Oral Biology, School of Dentistry, University of Leeds, Leeds, UK

Introduction

Humans have evolved to have an intimate and dynamic relationship with microorganisms; this includes those that make up the resident microbiota of all environmentally-exposed surfaces of the body as well as those that cause disease. Contemporary studies are demonstrating that the relationship with the resident microbiota is highly interactive, and makes a major contribution to the health of the host. This relationship is dynamic and fragile, and a number of intrinsic and extrinsic factors can perturb this exquisite balance. An understanding of the relationship between host and oral microbiota is critical for the effective clinical management of dental patients both during health and when treating disease.

A remarkable statistic is that the human body is estimated to be composed of $>10^{14}$ cells, of which only 10% are mammalian (Sanders & Sanders 1984; Wilson 2005). The majority are the microorganisms that make up the resident microbiotas that colonize all accessible surfaces of the body and which, as will be discussed later, confer significant benefits to the host. These microbiotas have a diverse composition, and function as interactive microbial communities in which their combined properties are greater than the sum of the activities of the constituent species (see later). The microbiotas of the skin, mouth, digestive and reproductive tracts are distinct from each other despite the frequent transfer of organisms between these sites; their characteristic composition is a consequence of significant differences in the biologic and physical properties of each habitat (Wilson, 2005). These properties determine which microorganisms are able to colonize successfully, and which will predominate or be only a minor component of the established microbial community.

The mouth as a microbial habitat

The mouth is similar to other habitats within the body in having a characteristic microbial community that provides benefits for the host. The mouth is warm and moist, and is able to support the growth of a wide range of microorganisms, including viruses, mycoplasma, bacteria, Archaea, fungi, and protozoa (Wilson 2005; Marsh & Martin 2009). These microorganisms colonize mucosal and dental surfaces in the mouth to form three-dimensional, structurally-organized multispecies communities that are termed biofilms. The biofilms that form on teeth are referred to as dental plaque. In general, desquamation ensures that the microbial load on mucosal surfaces is kept relatively low. In contrast, the mouth is a unique site in the body in that it provides non-shedding surfaces (teeth, dentures) for microbial colonization. This can result in the accumulation of large numbers of microorganisms, particularly at stagnant and hard-to-reach sites, unless patients practice effective oral hygiene. The main focus of this chapter is to describe the properties of biofilms that develop on teeth (dental biofilms).

A number of environmental factors will influence the distribution and metabolic activity of the resident oral microbiota (Fig. 8-1a) (Marsh & Devine 2011).

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

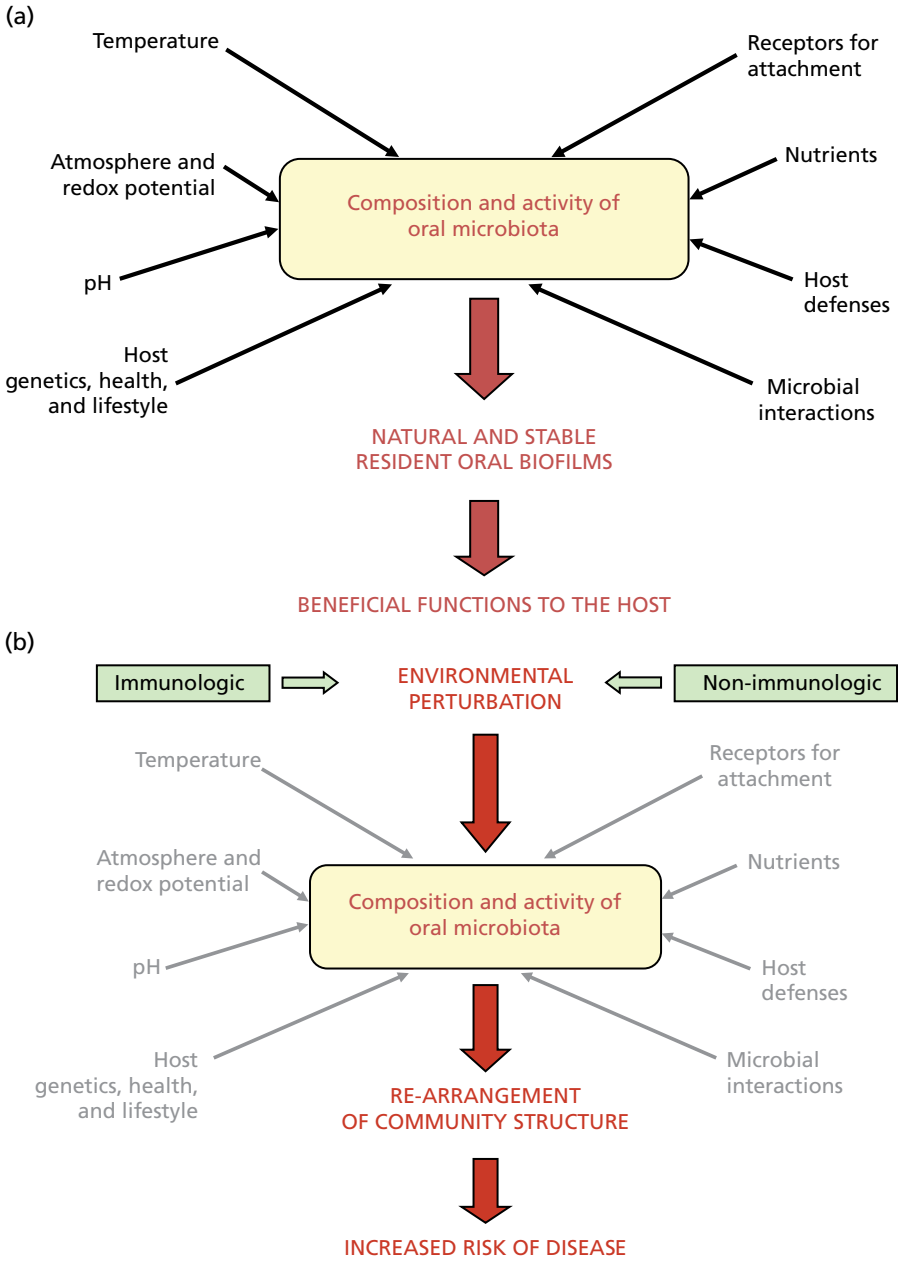

Fig. 8-1 Host factors that influence the microbial composition, activity, and stability of the resident oral microbiota. (a) A number of host factors help to determine the composition and activity of the natural oral microbiota, which provides benefits to the host. (b). Perturbation in a key environmental factor can disrupt the natural stability (microbial homeostasis) of the resident microbiota at a site and result in a rearrangement of the composition and activity of the resident microbial community; such a change might predispose the site to disease. (Source: Adapted from Marsh & Devine 2011, from John Wiley & Sons.)

The mouth is maintained at a temperature of around 35–37 °C, which is suitable for the growth of a broad range of microbes. Temperature does increase at subgingival sites during inflammation, and this can alter bacterial gene expression, which in turn can alter the competitiveness of bacteria within the microbial community, and favor growth and protease activity of some putative periodontal pathogens. Although the mouth is overtly aerobic, the majority of oral bacteria are facultatively or obligately anaerobic. The distribution of these anaerobes in the mouth is generally related to the redox potential (Eh), the measure of the degree of oxidation–reduction at a site. The gingival crevice has the lowest Eh in the healthy mouth, and harbors the largest numbers of obligate anaerobes (Kenney & Ash 1969). As oral bacteria exist as members of microbial communities, some anaerobic species survive in more aerobic habitats by existing in close partnership with oxygen-consuming species. Bacterial metabolism in mature oral biofilms results in sharp gradients of oxygen and Eh, thereby generating a mosaic of microenvironments suitable for the growth of bacteria with a range of oxygen tolerances. Many oral anaerobes also express a range of enzymes whose function is to scavenge low levels of oxygen in the environment to enable them to survive.

In the mouth, pH is a major determinant of bacterial distribution and metabolism. The buffering activity

of saliva plays a major role in maintaining the intraoral pH at around neutrality, which again is suitable for the growth of members of the resident oral microbiota. Changes in environmental pH frequently occur, and when they do they drive major shifts in the proportions of bacteria within dental plaque biofilms. After sugar consumption, the pH in plaque can fall rapidly to below 5.0 by the production of acidic fermentation products (Marsh & Martin 2009). Depending on the frequency of sugar intake, the bacteria in plaque will be exposed to varying challenges of low pH. Many of the predominant plaque bacteria that are associated with healthy sites can tolerate brief conditions of low pH, but are inhibited or killed by more frequent or prolonged exposures to acidic conditions (Svensater *et al*. 1997). This can result in the enrichment of acid-tolerant (aciduric) species, especially mutans streptococci, bifidobacteria, and lactobacilli, which are normally absent or only minor components in dental plaque at healthy sites. Such shifts in the bacterial composition of plaque predispose a surface to dental caries. The pH of the healthy gingival crevice is approximately 6.9, but this rises to between pH7.2 and 7.4 during inflammation, with a few patients having pockets with a mean pH of around 7.8 (Eggert *et al*. 1991). Inflammation results in the increased flow of gingival crevicular fluid (GCF) in the subgingival habitat, and the rise in pH is a consequence of increased bacterial proteolysis of host proteins and glycoproteins in GCF. Even a small change in pH can alter the growth rate and pattern of gene expression in subgingival bacteria, and increase the competitiveness of some of the putative Gram-negative anaerobic pathogens at the expense of species associated with periodontal health (McDermid *et al.* 1988).

Saliva and GCF also have a major influence on bacterial distribution because they provide an array of host molecules that are potential nutrients for microorganisms. Primary nutrients, such as amino acids, proteins, and glycoproteins, are obtained from saliva and GCF; diet has only a minor role on the resident microbiota, mainly via the change in pH from sugar catabolism, as discussed earlier. The metabolism of complex host molecules requires the sequential or concerted action of consortia of bacteria (see later) in order to achieve their complete breakdown (ter Steeg & van der Hoeven 1989; Homer & Beighton 1992a, b; Bradshaw *et al*. 1994; Palmer *et al.* 2006; Periasamy & Kolenbrander 2009).

The mouth is richly endowed with components of both the innate (e.g. lysozyme, lactoferrin, sialoperoxidase, host defense peptides, neutrophils, etc.) and adaptive (secretory IgA, IgG, etc.) immune response (Marsh & Martin 2009). Complement, which bridges both the innate and adaptive immune responses, is also present. An area of considerable research activity at present concerns the relationship between the resident microbiota at any site and the host defenses, and how these microbial communities persist without triggering an undesirable and unwanted detrimental host response, while the host retains the ability to respond to a genuine microbial challenge. Evidence is accumulating that some members of the resident oral microbiota are involved in active cross-talk with the host to down-regulate potential pro-inflammatory responses (Hasegawa *et al*. 2007; Cosseau *et al*. 2008).

The lifestyle of an individual can affect the distribution and metabolism of the oral microbiota (Marsh & Devine 2011). The impact of a diet with a high frequency of intake of fermentable carbohydrates has been discussed already. Smoking may select for potential periodontal pathogens in dental biofilms, and individuals with diabetes have a higher frequency of certain Gram-negative periodontal pathogens in plaque. The composition of the oral microbiota can also change with age as a consequence of a number of host-related events, including tooth eruption in early life or the waning of the immune response in old age. The influence of female hormones in GCF during pregnancy on the prevalence of some periodontal pathogens is controversial (Adriaens *et al*. 2009), although correlations have been found between maternal hormone levels and the increased proportions of black pigmented anaerobes, such as *Porphyromonas gingivalis* and *Prevotella intermedia*, in dental biofilms (Carrillo-de-Albornoz *et al*. 2010).

In general, once established, the microbial composition of the biofilm at a site remains stable over time, unless a major perturbation occurs in a key environmental determinant, such as a major change in diet or an alteration to the immune status of the host. Such perturbations can drive shifts in the balance of the microbiota, which can increase the risk of disease (Fig. 8-1b).

Significance of a biofilm and community lifestyle for microorganisms

The vast majority of microorganisms in nature, including those in the mouth, are found attached to surfaces as biofilms. Biofilms have been defined as matrix-embedded microbial populations, adherent to each other and/or to surfaces or interfaces (Costerton *et al*. 1995). The ability to attach to and be retained at a surface is a fundamental survival strategy for most prokaryotic organisms. Microorganisms would be lost from the mouth if they did not firmly attach to an oral surface and form a biofilm. The microbes found in multispecies biofilms are not randomly distributed but are spatially and functionally organized, and many natural biofilms have a highly diverse microbiota.

There would be little scientific or clinical interest if the properties of biofilms were simply those of planktonic (liquid culture) cells attached to a surface, and if the properties of microbial communities were merely the sum of those of the constituent species. However, studies have established that bacterial gene expression can alter markedly when cells form

a biofilm, resulting in many organisms having a radically different phenotype following attachment to a surface (Marsh 2005). Furthermore, the binding of bacteria to specific host receptors can also trigger significant changes in patterns of host cell gene expression. Most natural biofilms contain multiple species that engage in a wide range of physical, metabolic, and molecular interactions, and are termed microbial communities. This community lifestyle provides several potential benefits to the participating organisms (Caldwell *et al*. 1997; Shapiro 1998; Marsh & Bowden 2000) including:

- *Broader habitat range for growth*. For example, the metabolism of early colonizers alters the local environment, making conditions suitable for attachment and growth of later (and sometimes more fastidious) species.
- *Increased metabolic diversity and efficiency*. Molecules that are normally recalcitrant to catabolism by individual organisms can often be broken down by microbial consortia.
- *Enhanced tolerance of environmental stress, antimicrobial agents, and the host defenses*. Neighboring cells of a different species can produce neutralizing enzymes (β-lactamase, IgA protease, catalase, etc.) that protect inherently susceptible organisms from inhibitors (Brook 1989). Horizontal gene transfer is also more efficient in multispecies biofilms (Molin & Tolker-Nielsen 2003; Wilson & Salyers 2003). Microbial communities can also give physical protection from phagocytosis to cells deep within a spatially-organized consortium (Costerton *et al.* 1987; Fux *et al*. 2005).
- *Enhanced ability to cause disease*. Abscesses are examples of polymicrobial infections whereby organisms that individually cannot cause disease are able to do so when they are present as a consortium (pathogenic synergism) (van Steenbergen *et al.* 1984).

Thus, microbial communities display emergent properties, in other words the properties of the community are more than the sum of its component populations.

An important clinical consequence of both the structural and functional organization of multispecies biofilms is their reduced susceptibility to antimicrobial agents (Gilbert *et al.* 1997; Ceri *et al*. 1999; Stewart & Costerton, 2001; Gilbert *et al*. 2002). Conventionally, the sensitivity of bacteria to antimicrobial agents is determined by growing them in liquid culture and measuring the minimum inhibitory concentration (MIC) or minimum bactericidal concentration (MBC). The MIC of an organism growing on a surface can be from 2- to 1000-fold greater than that of the same cells grown planktonically (Stewart & Costerton 2001), with older biofilms being most recalcitrant.

The mechanisms behind the increased tolerance of biofilms to antimicrobial agents are still the subject of much research (Stewart & Costerton 2001; Gilbert *et al.* 2002). Resistance conventionally develops due to mutations affecting the drug target, to the presence of efflux pumps or to the production of modifying enzymes, etc., but even sensitive bacteria become less susceptible when growing on a surface. The structure of a biofilm may restrict the penetration of the antimicrobial agent; charged inhibitors can bind to oppositely-charged polymers that make up the biofilm matrix (diffusion–reaction theory). The agent may also adsorb to and inhibit the organisms at the surface of the biofilm, leaving cells in the depths of the biofilm relatively unaffected. The matrix in biofilms can also bind and retain neutralizing enzymes (e.g. β-lactamase) at concentrations that could inactivate an antibiotic or inhibitor (Allison 2003). As stated earlier, bacteria growing on a surface display a novel phenotype, and this can result in a reduced sensitivity to inhibitors, because the drug target may be modified or not expressed, or the organism may use alternative metabolic strategies. Bacteria grow only slowly under nutrient-depleted conditions in an established biofilm and, as a consequence, are much less susceptible than faster dividing cells. In addition, it has also been proposed that the environment in the depths of a biofilm may be unfavorable for the optimal action of some drugs (Gilbert *et al.* 2002). One hypothesis suggests that the increased tolerance of some biofilms to antibiotics is due largely to the presence of a subpopulation of "persister" organisms that are specialized survivor cells (Keren *et al*. 2004).

The most diverse collections of oral microorganisms are found in the biofilms on teeth (dental plaque) (Aas *et al*. 2005; Marsh & Martin 2009; Papaioannou *et al*. 2009; Dewhirst *et al*. 2010). It is now very common to see the term "dental biofilm" used instead of the original descriptor "dental plaque". This does not mean that the original work performed on "dental plaque" is now invalid or irrelevant; rather it emphasizes the point that the broader principles derived from work on biofilms from across the spectrum of microbiologic habitats are directly relevant to dental biofilms, and *vice versa*.

Formation of dental biofilms

Dental biofilms form via an ordered sequence of events, resulting in a structurally- and functionally-organized, species-rich microbial biofilm (Socransky & Haffajee 2002; Marsh 2005; Kolenbrander *et al*. 2006; Marsh *et al.* 2011) (Fig. 8-2). The distinct stages in dental biofilm formation include:

1. Adsorption of a conditioning film (acquired pellicle)
2. Reversible adhesion between the microbial cell surface and the conditioning film
3. More permanent attachment involving interactions between specific molecules on the microbial cell surface (adhesins) and complementary molecules (receptors) present in the conditioning film
4. Co-adhesion, in which secondary colonizers adhere to receptors on already attached bacteria

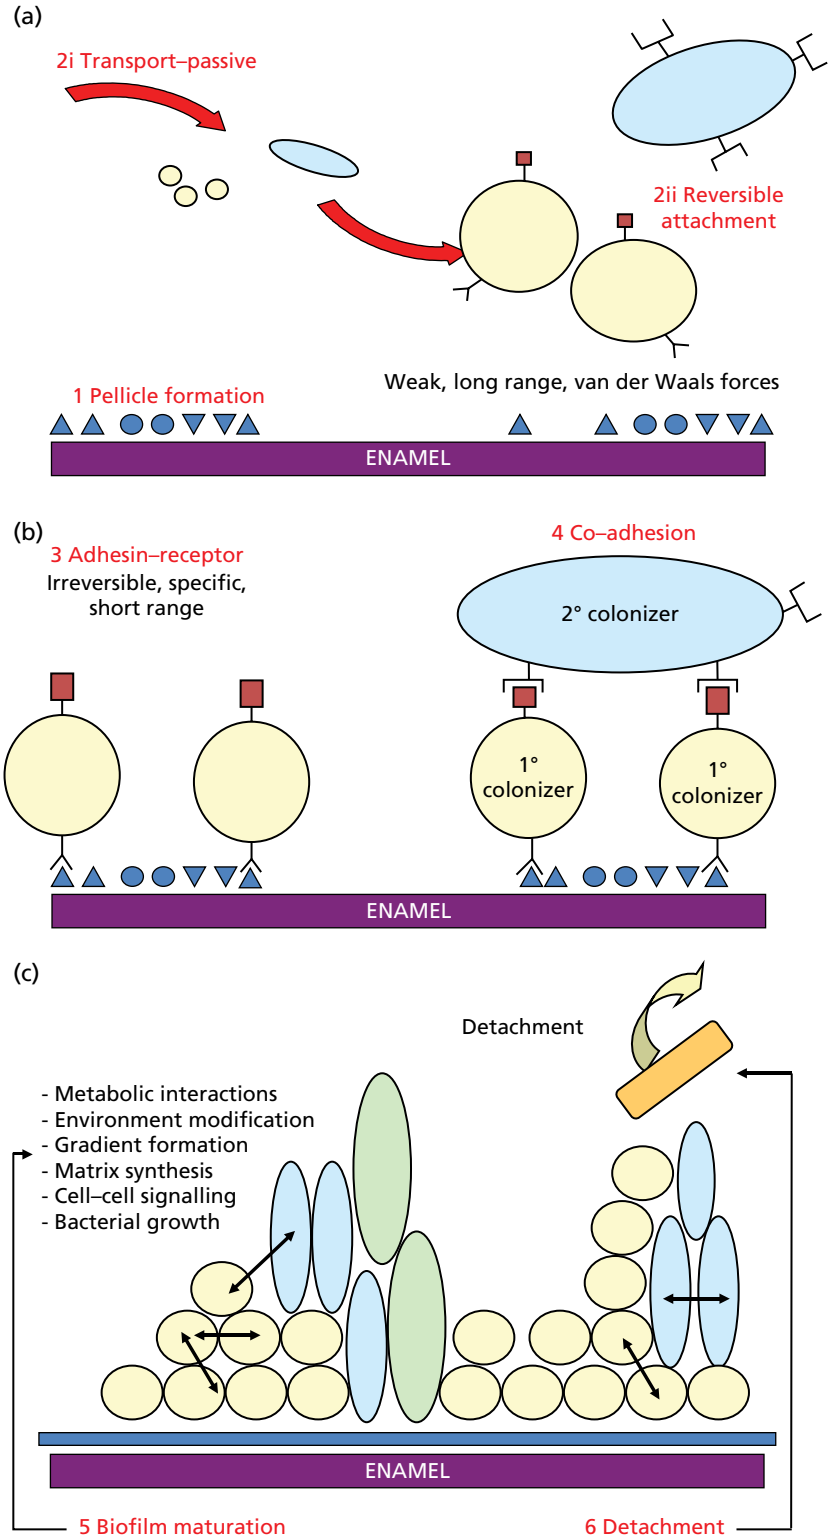

Fig. 8-2 Schematic representation of the different stages in the formation of dental biofilms. (a) Pellicle forms on a clean tooth surface (1). Bacteria are transported passively to the tooth surfaces (2i), where they may be held reversibly by weak, long-range forces of attraction (2ii). (b) Attachment becomes more permanent through specific stereochemical molecular interactions between adhesins on the bacterium and complementary receptors in the pellicle (3), and secondary colonizers attach to the already attached primary colonizers by molecular interactions (co-adhesion) (4). (c) Growth results in biofilm maturation, facilitating a wide range of intermicrobial interactions (synergistic and antagonistic) (5). On occasions, cells can detach to colonize elsewhere (6). (Source: Marsh & Martin 2009. Reproduced with permission from Elsevier.)

(Kolenbrander *et al*. 2010), leading to an increase in microbial diversity

5. Multiplication of the attached cells, leading to an increase in biomass and synthesis of exopolymers to form the biofilm matrix (plaque maturation)
6. Detachment of attached cells to promote colonization elsewhere.

These stages will now be described in more detail.

Conditioning film formation

Bacteria rarely colonize clean enamel. Within seconds of eruption, or following cleaning, tooth surfaces become coated with a conditioning film of molecules (biologically-active proteins, phosphoproteins, and glycoproteins) derived mainly from saliva (but also from GCF and from the bacteria themselves) (Hannig *et al.* 2005). The conditioning film alters the biologic and chemical properties of the surface, and the composition of the pellicle directly influences the pattern of subsequent microbial colonization. Microorganisms interact directly with this conditioning film (Fig. 8-3).

Reversible and more permanent attachment

Initially, only a limited number of bacterial species are able to attach to the conditioning film. Bacteria can be held reversibly near to the surface by weak, long range, physicochemical forces between the electrical charge of the molecules on the pellicle-coated surface and those on the cell surface (Bos *et al.* 1999). This reversible adhesion creates the opportunity for stronger and more permanent attachment to be established. Molecules (adhesins) on these early bacterial colonizers (mainly streptococci, e.g. *Streptococcus mitis*, *Streptococcus oralis*) can bind to complementary receptors in the acquired pellicle to make the attachment stronger (Busscher *et al.* 2008; Nobbs *et al.* 2011). Individual species can deploy multiple adhesins (Nobbs *et al.* 2011); in Gram-positive bacteria, several families of surface proteins can act as adhesins, including serine-rich repeat, antigen I/II, and pilus families. In Gram-negative bacteria, auto-transporters, extracellular matrix-binding proteins, and pili function as adhesins (Nobbs *et al.* 2011).

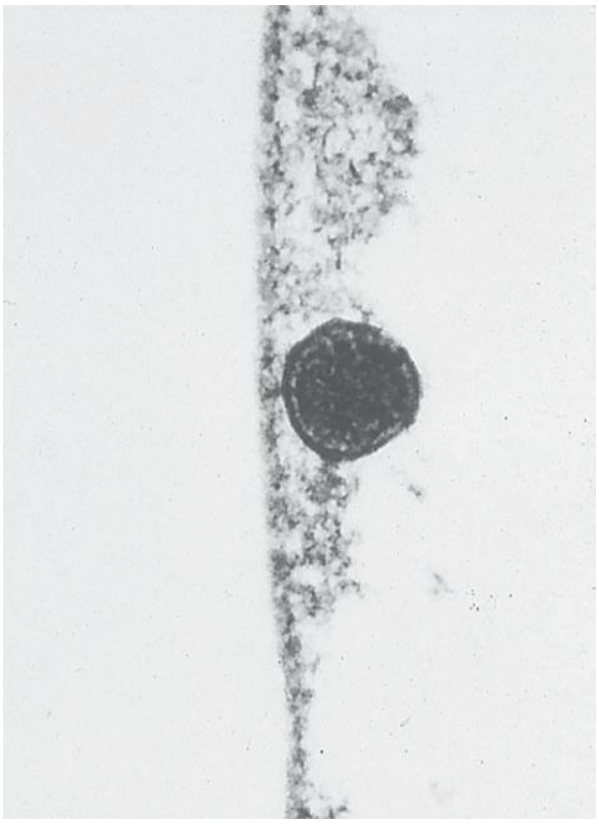

Fig. 8-3 Electron micrograph illustrating a 4-hour pellicle with a single bacterial cell attached. (Source: Brecx *et al.* 1981. Reproduced with permission from John Wiley & Sons.)

Co-adhesion

Once attached, the pioneer colonizers start to multiply. The metabolism of these bacteria that attach early modifies the local environment, for example by making it more anaerobic following their consumption of oxygen and the production of reduced end products of metabolism. As the biofilm develops, adhesins on the cell surface of more fastidious secondary colonizers, such as obligate anaerobes, bind to receptors on bacteria that are already attached by a process termed co-adhesion or co-aggregation, and the composition of the biofilm becomes more diverse (a process termed microbial succession) (Kolenbrander *et al.* 2006) (Figs. 8-4, 8-5). A key organism in plaque biofilm

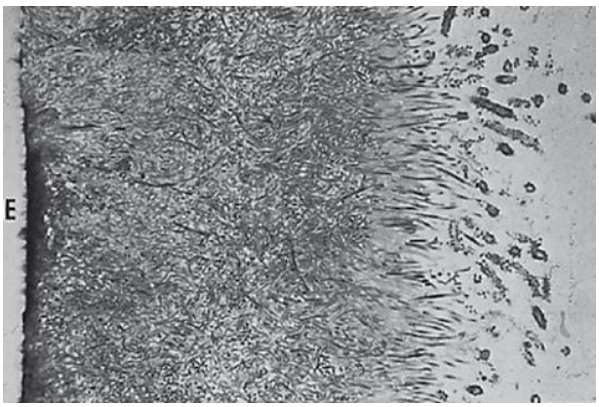

Fig. 8-4 Semi-thin section of a supragingival biofilm on enamel (E) which has been dissolved prior to sectioning. Magnification ×750. (Source: Listgarten 1976. Reproduced with permission from the American Academy of Periodontology.)

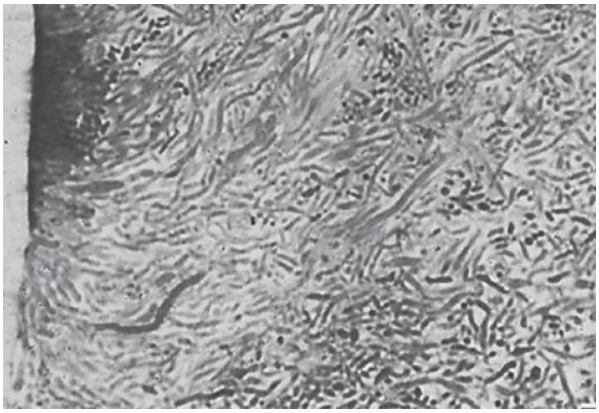

Fig. 8-5 Semi-thin section of supragingival biofilm. Filamentous organisms predominate. At the surface, some of these organisms are surrounded by cocci; the configuration resembles a corn-cob. Magnification ×1400. (Source: Listgarten 1976. Reproduced with permission from the American Academy of Periodontology.)

development is *Fusobacterium nucleatum*. This species can co-adhere to most oral bacteria, and acts as an important bridging organism between early and late colonizing species. Co-adhesion may help ensure that bacteria co-locate with other organisms with complementary metabolic functions.

Plaque maturation

Some of the attached bacteria synthesize extracellular polymers (the plaque matrix) that can consolidate attachment of the biofilm. The matrix is more than a mere scaffold for the biofilm; it can bind and retain molecules, including enzymes, and also retard the penetration of charged molecules into the biofilm (Allison 2003; Vu *et al*. 2009; Marsh *et al.* 2011). Biofilms are spatially- and functionally-organized, and the heterogeneous conditions within the biofilm induce novel patterns of bacterial gene expression, while the close proximity of different species provides the opportunity for interactions (Kuramitsu *et al*. 2007; Hojo *et al*. 2009; Marsh *et al*. 2011). Examples of these interactions include:

- Development of food chains (in which the end product of metabolism of one organism is used as a primary nutrient by secondary feeders) and metabolic cooperation among species to catabolize structurally-complex host macromolecules. These interactions increase the metabolic efficiency of the microbial community (Periasamy & Kolenbrander 2010; Marsh *et al.* 2011).
- Cell–cell signaling. Plaque bacteria have been shown to communicate with one another in a cell density-dependent manner via small diffusible molecules, using strategies similar to those described for other biofilms, for example by the secretion of small peptides by Gram-positive bacteria to coordinate gene expression among cells of a similar species (Suntharalingam & Cvitkovitch 2005). In *Streptococcus mutans*, quorum sensing is mediated by a competence stimulating peptide (CSP) (Li *et al*. 2002). This peptide also induces genetic competence in *S. mutans* so that the transformation frequency of biofilm-grown *S. mutans* was 10–600-fold greater than for planktonic cells. Lysed cells in biofilms could then act as donors of DNA, thereby increasing the opportunity for horizontal gene transfer in dental plaque. This quorum sensing system also functions to regulate acid tolerance in *S. mutans* biofilms. It has been proposed that *S. mutans*, upon exposure to low pH, could release CSP, and initiate a coordinated "protective" response among neighboring cells to this potentially lethal stress.

Other communication systems may function between different oral species (Kolenbrander *et al.* 2002). *LuxS* genes encode for autoinducer-2 (AI-2), and have been detected in several genera of oral Gram-positive and Gram-negative bacteria, implying that AI-2 may signal across a broader species range. Several putative periodontal pathogens (*F. nucleatum*, *P. intermedia*, *P. gingivalis*, *Aggregatibacter actinomycetemcomitans*) secrete a signal related to AI-2 (Fong *et al*. 2001; Frias *et al.* 2001).

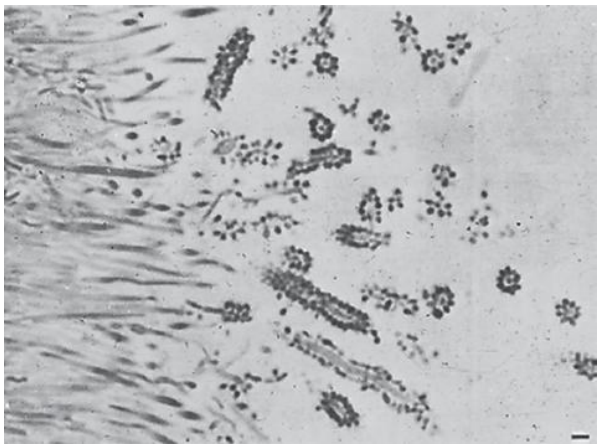

Fig. 8-6 "Corn-cob" formations seen at the biofilm surface shown in Figs. 8-4 and 8-5. Magnification ×1300.Bar 1 μm (Source: Listgarten 1976. Reproduced with permission from the American Academy of Periodontology.)

Characteristic cell associations can be seen in mature dental plaque, such as "corn-cob" (in which coccal-shaped cells attach along the tip of filamentous organisms; Fig. 8-6) and "test-tube brush" (rod-shaped bacteria sticking out perpendicularly from bacterial filaments) formations (Zijnge *et al*. 2010). These will be discussed further in the next section.

The structure of biofilms facilitates the likelihood of successful horizontal gene transfer. As discussed above, signaling molecules such as CSP markedly increase the ability of recipient cells in biofilms to take up DNA. The transfer of conjugative transposons encoding tetracycline resistance between streptococci has been demonstrated in model biofilms. The recovery from the nasopharynx of resident (*S. mitis*, *S. oralis*) and pathogenic (*S. pneumoniae*) bacteria with penicillin resistance genes showing a common mosaic structure confirms that gene transfer can occur *in vivo* (Dowson *et al*. 1990; Hakenbeck *et al*. 1998). Similar evidence suggests sharing of genes responsible for penicillin-binding proteins among commensal and pathogenic *Neisseria* (Bowler *et al*. 1994).

Structure of dental biofilms

Early studies using electron microscopy (EM) gave important insights into the structure of dental plaque from different sites, and demonstrated the presence of biofilms containing a range of morphologic types of microorganism, often as a compacted structure. More recently, confocal laser scanning microscopy has been used, which does not require the type of sample processing as for EM, and so samples can be seen in their natural, hydrated state. In confocal

microscopy, biofilms are optically sectioned and reconstructed as three-dimensional structures using appropriate software. The use of confocal microscopy has confirmed that dental plaque can also have an open architecture similar to that of biofilms from other habitats. Channels have been observed within biofilms, although they may also contain exopolymers (Wood *et al*., 2000; Auschill *et al*. 2001). Various microscopy techniques can also be combined with new staining methods to give more detail about the composition and organization of these biofilms. For example, the use of live/dead stains has indicated that bacterial vitality varies throughout the biofilm, with the most viable bacteria present in the central part of plaque, and lining the voids and channels (Auschill *et al.* 2001). This more open architecture should enable molecules to readily move in and out of plaque, but the presence of a matrix comprised of a diverse range of exopolymers creates a complex environment for accurately predicting the penetration and distribution of molecules within plaque (Robinson *et al*. 1997; Thurnheer *et al*. 2003; Marcotte *et al*. 2004), including the delivery of oral care and therapeutic agents. Fluorescent *in situ* hybridization (FISH), in which a fluorescent probe is combined with an oligonucleotide probe specific for a particular organism, can show the location of these microbes, including unculturable species, within the biofilm (Marsh *et al.* 2011; Zijnge *et al.* 2010) (Fig. 8-7).

Supragingival plaque biofilms appear to be quite heterogeneous in structure when viewed using FISH probes designed against a range of bacterial species (Zijnge *et al.* 2010). Subgingival plaque has an even more complex architecture. Initial studies using conventional light microscopy identified distinct tooth-associated and epithelial cell-associated biofilms, with the possibility of a less dense zone of organisms between the two (Socransky & Haffajee 2002). Co-adhesion is considered to be important in the temporal and spatial development of subgingival biofilms. Many of the putative pathogens that can be found in subgingival dental plaque in health are present in low numbers, and persist by attaching to the early streptococcal and actinomyces colonizers (Kuboniwa & Lamont 2010). These developing complex microbial communities engage in numerous metabolic interactions in order to survive.

Recently, subgingival biofilms were observed directly on extracted teeth, and the identification and location of bacteria was investigated using FISH (Zijnge *et al.* 2010). The architecture of subgingival biofilms was shown to be complex, with four layers being identified. The basal layer was composed of rod-shaped bacteria (*Actinomyces* spp.) attached perpendicularly to the tooth surface, above which was an intermediate layer composed of many spindle-shaped cells, including *F. nucleatum* and *Tannerella forsythia*. In the top layer were many putative periodontal pathogens, such as *P. gingivalis*, *Porphyromonas endodontalis*, *P. intermedia*, and *Parvimonas micra*. A fourth layer of unattached cells mainly consisted of spirochetes. Also, *Synergistetes* spp. formed a palisade-like layer along the outer edge of the biofilm, and were in direct contact with host immune cells. These bacteria are very difficult to grow in pure culture (most are currently "unculturable"), but can make up a sizeable proportion of subgingival plaque, and their location may indicate an important role in modulating host–biofilm interactions (Zijnge *et al.* 2010). The FISH studies allowed the identification of the species involved in the characteristic aggregates seen in subgingival biofilms. Lactobacilli formed the central axis of some of the "test-tube brushes", with organisms such as *Tannerella*, *F. nucleatum*, and

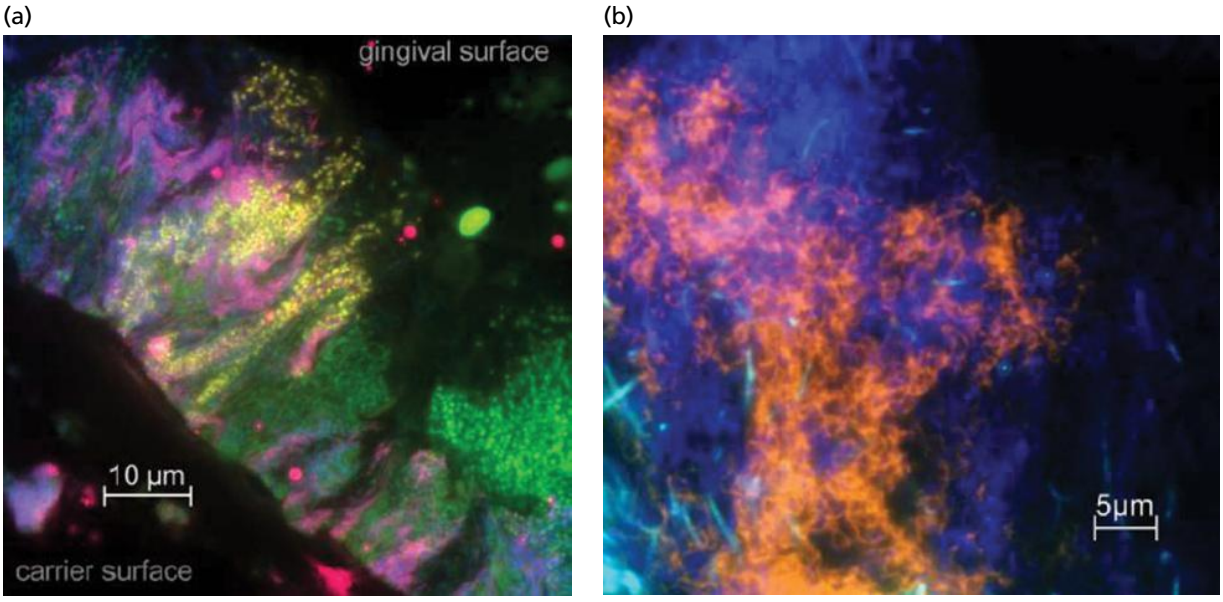

Fig. 8-7 Samples of subgingival biofilms with various oral species detected by fluorescence *in situ* hybridization (FISH). (a) Clusters of *Fusobacterium* spp. (magenta) and *Prevotella intermedia* (yellow). (b) Unculturable spirochetes (orange) and *Fusobacterium* spp. (light blue). (Source: Marsh & Moter 2011a. Reproduced with permission from John Wiley & Sons.)

Synergistetes spp. radiating from this central cell. Corn-cobs consisting of streptococci adhering to a central axis of yeast cells or hyphae were observed by FISH (Zijnge *et al.* 2010). Corn-cobs formed between streptococci and *Corynebacterium matruchotii*, and between *Veillonella* spp. and *Eubacterium* spp. have also been reported.

Bacterial metabolism in plaque results in the development of gradients within dental biofilms in parameters that are critical to microbial growth (nutrients, pH, oxygen, etc.). These gradients are not necessarily linear; the use of two-photon excitation microscopy coupled with fluorescent lifetime imaging demonstrated considerable heterogeneity in pH over relatively short distances in model mixed culture oral biofilms (Vroom *et al*. 1999). Such environmental heterogeneity will allow fastidious bacteria to survive in plaque, and enable microorganisms to coexist that would be incompatible with one another in a more homogeneous environment. This explains how organisms with apparently contradictory metabolic and growth needs (e.g. in terms of atmospheric and nutritional requirements) are able to persist at the same site.

Microbial composition of dental biofilms

As discussed earlier, the mouth supports the growth of a characteristic microbiota which includes viruses, mycoplasma, bacteria, Archaea, fungi, and protozoa (Marsh & Martin 2009). Bacteria are the most numerous group and, initially, they were characterized using traditional cultural approaches. Over time, it became apparent that there was a large discrepancy between the number of bacteria in a sample that could be grown by these conventional approaches and those that were observed directly by microscopy (Choi *et al*. 1994; Paster *et al*. 2001). It is estimated that only about 50% of the resident oral microbiota can currently be cultivated in pure culture in the laboratory (Wade 1999, 2002). This may be due to our ignorance of the growth requirements of some species, but probably also reflects our naïvety in attempting to isolate microbes in pure culture that have evolved over millennia to grow with other species as part of a community (Vartoukian *et al.* 2010a, b).

Our knowledge of the richness and diversity of the resident oral microbiota has been enhanced by the recent application of culture-independent, molecular approaches (Pozhitkov *et al*. 2011; Wade 2011). The accumulated data from numerous studies of different surfaces and sites based around amplification, cloning, and sequencing of the *16S rRNA* gene have identified around 900 species in the mouth. Most sites (mucosal or plaque) yielded 20–30 different predominant species, while the number of species per individual mouth can range from 34 to 72 (Aas *et al.* 2005). However, these figures may still be an underestimate and the use of more powerful, high throughput, next-generation sequencing platforms will better detect low abundance species.

Underway is the "Human Oral Microbiome" project, which aims to identify and characterize all members of the resident oral microbiota found in health and disease (Dewhirst *et al.* 2010). Data are being placed in the publically accessible web-based Human Oral Microbiome Database (http://www.homd.org), which also feeds information into the larger Human Microbiome Project. It is beyond the scope of this chapter to describe the properties of members of the resident oral microbiota, and the reader is recommended to refer to this website or to other specialist texts for more detail (Marsh & Martin 2009).

Biofilms develop on mucosal and dental surfaces, and the microbial composition of the biofilm varies at distinct sites on a tooth (fissures, approximal surfaces, gingival crevices), reflecting the inherent differences in their anatomy and biology (Fig. 8-8) (Aas *et al.* 2005; Sachdeo *et al.* 2008; Marsh & Martin 2009; Papaioannou *et al.* 2009). The properties of each habitat will select for those organisms that are best adapted to the prevailing conditions, and are able to persist. This also means that any changes to the environment will directly impact on the composition and activity of the biofilm. The remainder of this chapter will focus on the properties of dental biofilms.

The normal microbiota of *fissures* is relatively sparse and the organisms present have a saccharolytic metabolism (i.e. their energy is derived from sugar catabolism), and are either aerobic or facultatively anaerobic. The predominant bacteria are streptococci, many of which produce extracellular polysaccharides, and there are few Gram-negative or anaerobic organisms (Theilade *et al*. 1982). The properties of this site are strongly influenced by saliva.

In contrast, the *gingival crevice* has a more diverse microbiota, including many Gram-negative anaerobic and proteolytic species; this is due to the lower Eh at this site and the delivery of a distinct set of proteins and glycoproteins by the GCF (Slots 1977). The black pigmented anaerobes have an absolute requirement for hemin for growth, and these organisms can obtain this co-factor from the degradation of heme-containing host molecules present in GCF. Molecular studies using culture-independent approaches have emphasized the fact that the gingival crevice supports the most diverse microbial communities in the healthy mouth, with 40% of the amplified clones representing novel phylotypes. Many currently unculturable species can be detected at this site (Figs. 8-7b, 8-8).

Approximal surfaces have a microbiota that is intermediate in composition between that of fissures and gingival crevices, and also harbors many anaerobic species. These sites have high proportions of *Actinomyces* spp. (Bowden *et al.* 1975).

As discussed earlier, once established, the composition of the resident microbiota at any site remains relatively stable over time, unless there are marked changes to the habitat. Importantly, this stability,

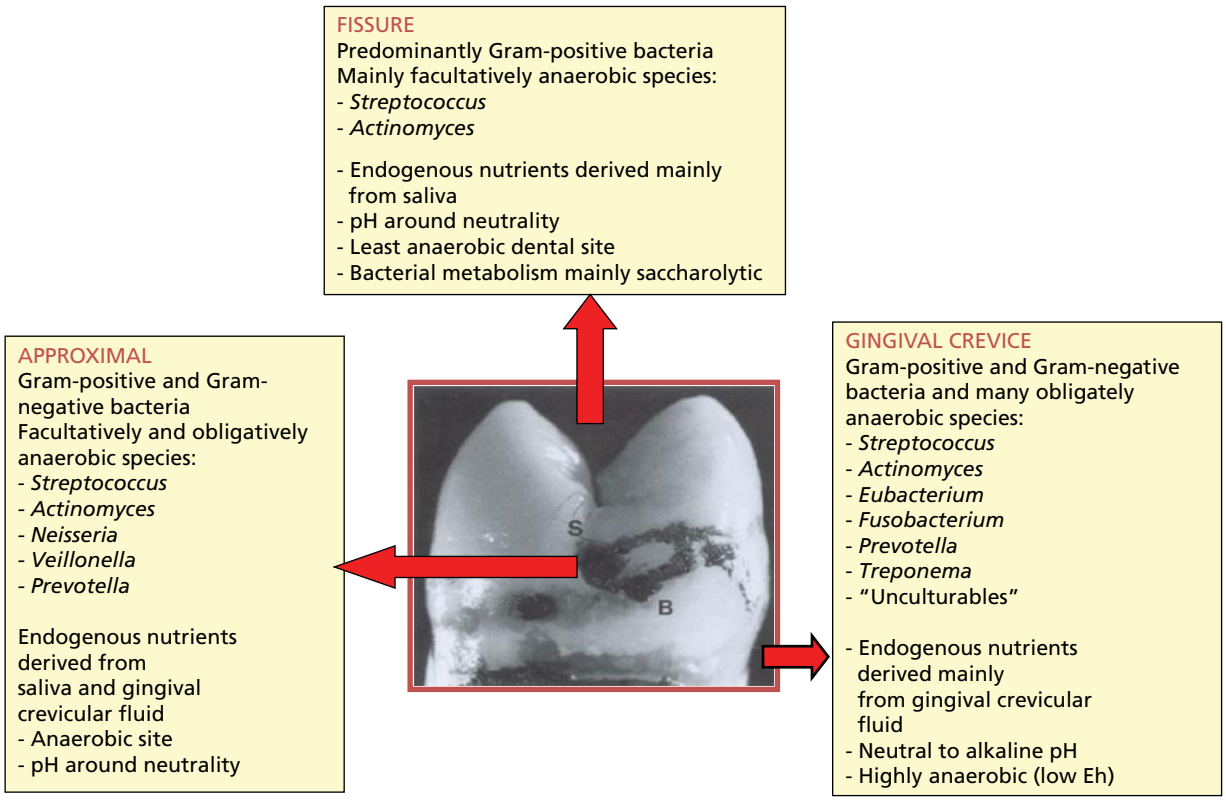

Fig. 8-8 Predominant groups of bacteria found at distinct sites on the tooth surface, and key features of each habitat.

termed microbial homeostasis, stems not from any metabolic indifference by the resident microbiota, but reflects a highly dynamic state in which the relative proportions of individual species are held in balance due to the numerous interactions, both synergistic and antagonistic, described earlier (Marsh 1989). This natural balance is maintained despite continual surveillance by the host defenses and the regular exposure of the mouth to a variety of modest environmental stresses, such as via the diet, changes in saliva flow, and oral hygiene (see Fig. 8-1a). However, microbial homeostasis can break down on occasions if one of the key parameters affecting growth is perturbed and this perturbation is sufficiently robust or regular to result in the reorganization of the composition of the biofilm, with the outgrowth of previously minor components (see Fig. 8-1b). Such perturbations can be due to immunologic (e.g. neutrophil dysfunction, immune suppression, etc.) or non-immunologic (e.g. xerostomia, diet change, etc.) factors, and can predispose a site to disease (Marsh & Martin 2009; Marsh *et al.* 2011b), and forms the basis of the "ecological plaque hypothesis" (Marsh 2003) that describes the dynamic relationship between the oral microbiota and the host in health and disease.

Benefits to the host of a resident oral microbiota

The host has a sophisticated array of host defenses provided by both the innate and adaptive arms of the immune system, the primary function of which is to protect tissues against microbial colonization and invasion. Despite these host defenses, the host has evolved over millennia to support a complex resident microbiota and, at first sight, this might appear paradoxical (the "commensal paradox") (Henderson & Wilson 1998). It is now apparent that the resident microbiota confers considerable benefit to the host, and that these natural microbial residents are essential for the normal development of the physiology, nutrition, and defenses of the host (Marsh 2000; Wilks 2007) (Fig. 8-9).

The biologic mechanisms that permit a constructive coexistence between the host and the resident microbiota, while enabling the host to retain the capacity to respond to exogenous microbial insults, are now being dissected. The host is not indifferent to the presence of the diverse microbial communities that reside on its surfaces. It is actively engaged in cross-talk with its resident microbiota in order to effectively maintain a constructive relationship. The host is able to detect microorganisms, and has evolved systems to enable it to tolerate resident microorganisms without initiating a damaging inflammatory response, while also being able to mount an efficient defense against pathogens. Pathogenic and non-pathogenic bacteria may initiate different intracellular signaling pathways and innate immune responses in epithelial cells (Canny & McCormick 2008; Hooper 2009; Neish 2009). Certain oral streptococci have been shown to suppress epithelial cell cytokine expression (Hasegawa *et al.* 2007; Peyret-Lacombe *et al.* 2009). *Streptococcus salivarius* K12 not only down-regulated epithelial cell inflammatory responses by inhibiting the NF-κB pathway,

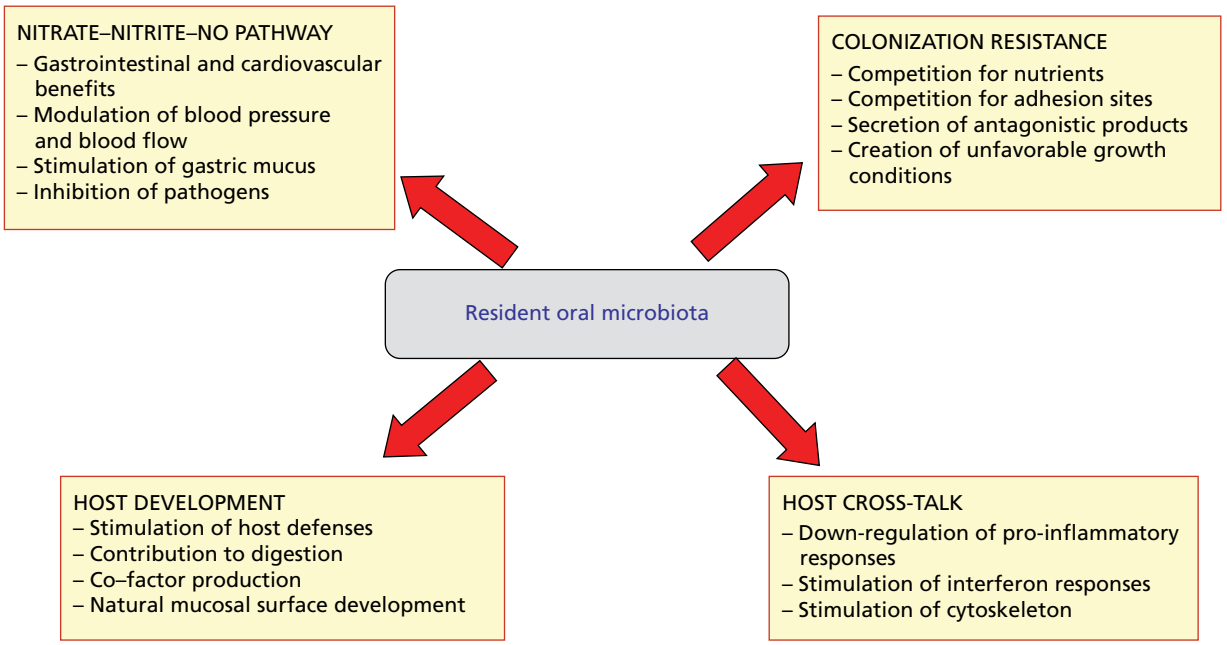

Fig. 8-9 Beneficial functions of the resident oral microbiota.

but also actively stimulated beneficial pathways, including type I and II interferon responses, and exerted significant effects on the cytoskeleton and adhesive properties of the host cell (Cosseau *et al.* 2008). The "commensal communism" paradigm proposes that our oral microbiota and mucosa form a unified "tissue" in which host–microbe "cross-talk" is finely balanced to ensure microbial survival and prevent the induction of damaging inflammation (Henderson & Wilson 1998).

One of the principal benefits emanating from the existence of a resident microbiota at a site is the ability to prevent colonization by exogenous (and often pathogenic) microorganisms. This property, termed "colonization resistance" (Van der Waaij *et al.* 1971), is due to various properties of resident microbes, including more effective (1) attachment to host receptors, (2) competition for endogenous nutrients, (3) creation of unfavorable growth conditions to discourage attachment and multiplication of invading organisms, and (4) production of antagonistic substances (hydrogen peroxide, bacteriocins, etc.). Colonization resistance can be impaired by factors that compromise the integrity of the host defenses or perturb the stability of the resident microbiota, such as the side effects of cytotoxic therapy or the long-term use of broad-spectrum antibiotics (Johnston & Bodley 1972). For example, the latter can suppress the resident bacterial oral microbiota, permitting overgrowth by previously minor populations of oral yeasts. Attempts to boost colonization resistance using replacement therapy (in which resident organisms are deliberately re-implanted), for example after periodontal therapy (Teughels *et al.* 2007) or by the use of probiotics (Devine & Marsh 2009), are being explored, although the evidence for benefits from oral probiotics is still equivocal.

The resident oral bacteria play an important role in maintaining many important aspects of the gastrointestinal and cardiovascular systems, via the metabolism of dietary nitrate. Approximately 25% of ingested nitrate is secreted in saliva where facultatively anaerobic oral resident bacteria reduce nitrate to nitrite. Nitrite affects a number of key physiologic processes, including the regulation of blood flow, blood pressure, gastric integrity, and tissue protection against ischemic injury. Nitrite can be further converted to nitric oxide in the acidified stomach. This has antimicrobial properties and contributes to defense against enteropathogens and in the regulation of gastric mucosal blood flow and mucus formation. Significantly, studies have shown that the use of an antimicrobial mouthwash (Govoni *et al.* 2008; Petersson *et al.* 2009) or a broad-spectrum antibiotic (Dougall *et al.* 1995) reduced the microbial conversion of nitrate to nitrite with a loss of the biologic benefits of nitrite, including reduced gastric mucus thickness and loss of an expected fall in blood pressure.

Concluding remarks

The mouth supports the establishment of diverse communities of microorganisms. These communities, and those present at other habitats in the body, play an active and critical role in the normal development of the host and in the maintenance of health. Clinicians need to be aware of the beneficial functions of the resident oral microbiota, so that treatment strategies are focused on the control rather than the elimination of these natural biofilms. In conclusion, oral care practices should attempt to maintain plaque at levels compatible with health in order to retain the beneficial properties of the resident oral microbiota, while preventing microbial excesses that increase the risk of dental diseases.

Chapter 9

Dental Calculus

Dieter D. Bosshardt[1] and Niklaus P. Lang[1,2]

[1] Department of Periodontology, School of Dental Medicine, University of Berne, Berne, Switzerland
[2] Center of Dental Medicine, University of Zurich, Zurich, Switzerland

Dental calculus or tartar represents mineralized bacterial plaque, although calculus formation can be induced in germ-free animals as a result of precipitation of mineral salts originating from saliva (Theilade 1964). Supragingival calculus is located coronal to the gingival margin (Fig. 9-1a), whereas subgingival calculus is found apical to the gingival margin (Fig. 9-1b). Supra- and sub-gingival calculus has characteristic features. It should be noted that calculus continually harbors viable bacterial plaque (Zander *et al*. 1960; Theilade 1964; Schroeder 1969).

Clinical appearance and distribution

Supragingivally, calculus can be recognized as a creamy-whitish to dark yellow or even brownish mass of moderate hardness (Fig. 9-2). The degree of calculus formation is not only dependent on the amount of bacterial plaque present, but also on the secretion of the salivary glands. Hence, supragingival calculus is predominantly found adjacent to the excretion ducts of the major salivary glands, such as the lingual aspect of the mandibular anterior teeth and the buccal aspect of the maxillary first molars, where the parotid gland ducts open into the oral vestibule. The duct openings of the submandibular glands are located in the former region.

Subgingivally, calculus may be found by tactile exploration only, since its formation occurs apical to the gingival margin and, hence, it is usually not visible to the naked eye. Occasionally, subgingival calculus may be visible on dental radiographs provided that the deposits are of sufficient mass (Fig. 9-3). Small deposits or residual deposits following root instrumentation may barely be visualized radiographically. If the gingival margin is pushed open by a blast of air or retracted by a dental instrument, a brownish-to-black calcified hard mass with a rough surface may become visible (Fig. 9-4). Again, this mineralized mass reflects predominantly bacterial accumulations mixed with products from gingival crevicular fluid (GCF) and blood. Consequently, subgingival calculus is found in most periodontal pockets, usually extending from the cementoenamel junction to close to the bottom of the pocket. However, a band of approximately 0.5 mm is usually found coronal to the apical extension of the periodontal pocket (Fig. 9-5). This zone appears to be free of mineralized deposits owing to the fact that GCF is exuding from the periodontal soft tissues and acting as a gradient against the microbial accumulation. This calculus-free zone can also be seen in histologic sections (see Fig. 9-1a, b). Like supragingival calculus, subgingival calculus also provides an ideal substrate for bacterial adhesion (Zander *et al*. 1960; Schroeder 1969).

Plaque mineralization varies greatly between and within individuals and, as indicated earlier, also within the different regions of the oral cavity. Not only the formation rate for bacterial plaque (amount of bacterial plaque per time and tooth surface), but also the formation rate for dental calculus (time period during which newly deposited supragingival plaque with an ash weight of 5–10% becomes calcified and yields an ash weight of approximately 80%) is subject to great variability. In some subjects, the time required for the formation of supragingival

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

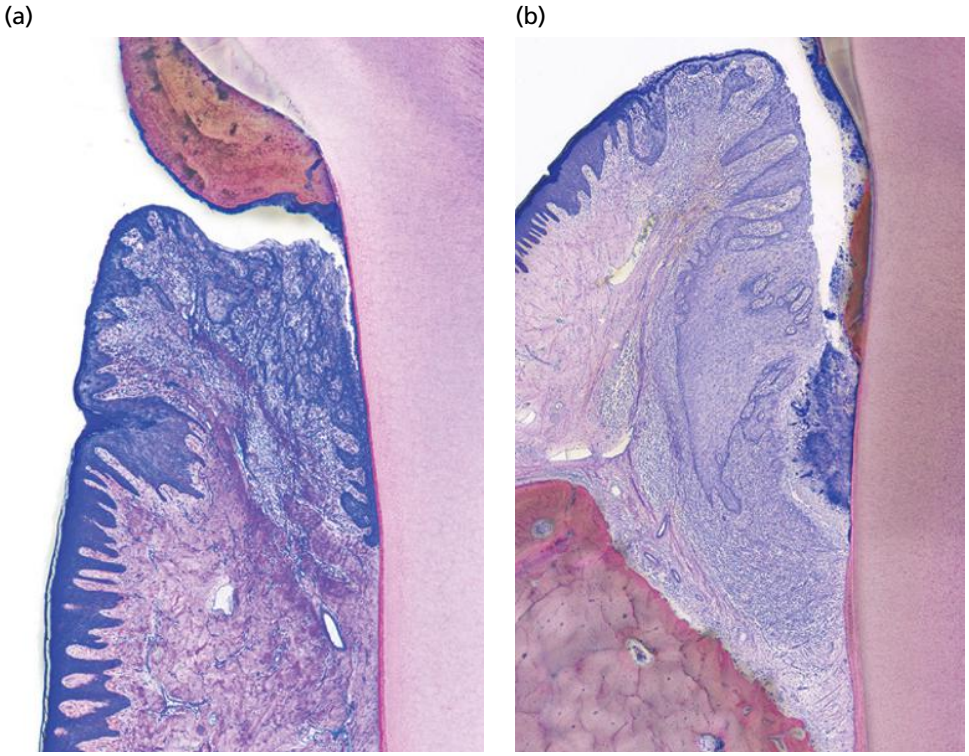

Fig. 9-1 (a) Supragingival calculus adhering to enamel and the root surface of a dog tooth. An initial gingival pocket and a slight gingival inflammation has developed. (b) Subgingival calculus on the root of a dog tooth with a periodontal pocket. Note the inflamed gingival tissue and bone loss. For both supra- and sub-gingival calculus, uncalcified dental plaque extends apically and forms a calculus-free zone between the apical termination of calculus and the apical extension of the pockets. Undecalcified ground sections stained with toluidine blue and basic fuchsin.

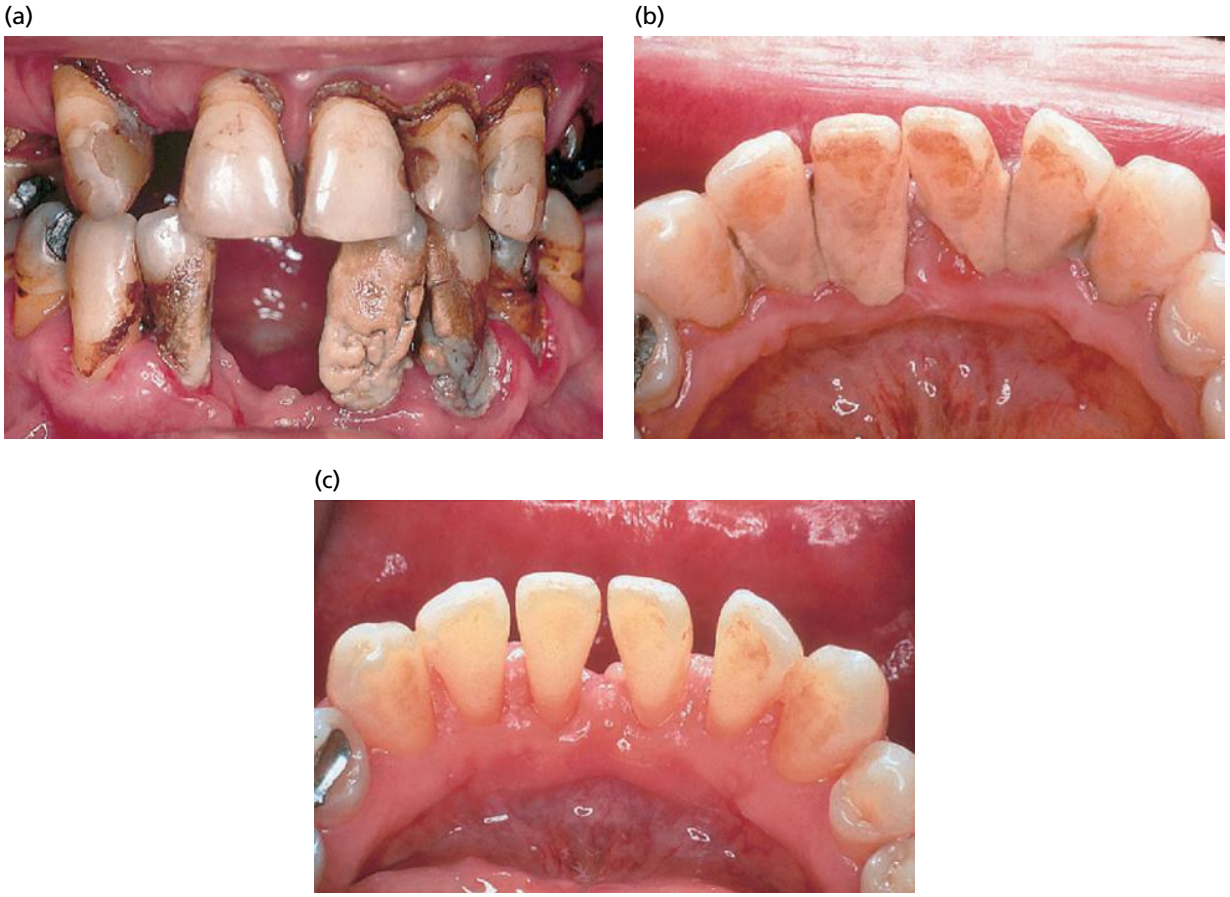

Fig. 9-2 Abundance of supragingival calculus deposits. (a) Gross deposits as a result of long-term neglect of oral hygiene. Two mandibular incisors have been exfoliated. (b) Supragingival plaque usually covering the lingual aspect of mandibular incisors. Note the intense inflammatory reaction adjacent to the deposits. (c) Same patient and region as in (b) following removal of the calculus. The gingival tissues demonstrate healing.

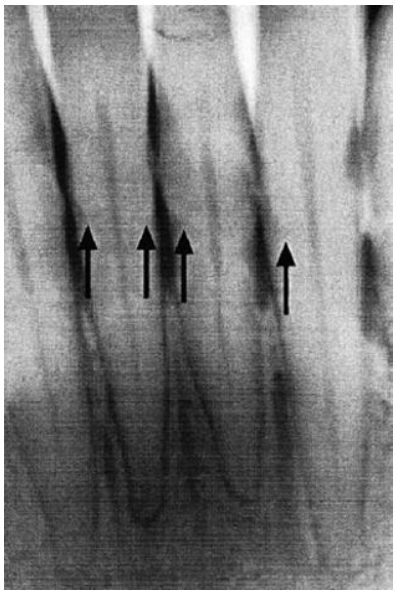

Fig. 9-3 Subgingival calculus may be visible (arrows) on radiographs if abundant deposits are present.

(a)

(b)

Fig. 9-4 (a) Subgingival calculus presents as a black–brownish hard mass if the gingival margin is retracted or reflected during a surgical procedures. (b) Healing of the site following removal of all hard deposits.

calculus is 2 weeks, at which time the deposit may already contain approximately 80% of the inorganic material found in mature calculus (Fig. 9-6) (Mühlemann & Schneider 1959; Mandel 1963; Mühlemann & Schroeder 1964). In fact, evidence of

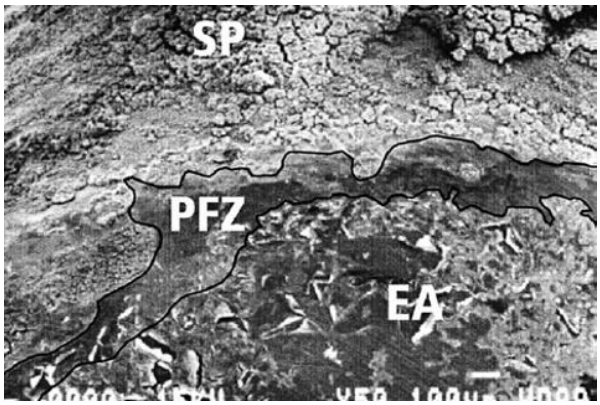

Fig. 9-5 Plaque- and calculus-free zone coronal to the epithelial attachment. (SP, subgingival plaque bacteria; PFZ, plaque-free zone; EA, remnants of junctional epithelium.)

Fig. 9-6 Seven-day-old calcified plaque. Observe the isolated calcification centers indicated by the black areas (van Kossa stain).

mineralization may already be present after a few days (Theilade 1964). Nevertheless, the formation of dental calculus with the mature crystalline composition of old calculus may require months to years (Schroeder & Baumbauer 1966).

Calculus formation and structure

In humans, the formation of calculus is always preceded by the development of a bacterial biofilm (see Chapter 8). The intermicrobial matrix and the bacteria themselves provide the matrix for calcification, which is driven by the precipitation of mineral salts. Supragingival plaque becomes mineralized due to the precipitation of mineral salts present in saliva, whereas subgingival plaque mineralizes due to the presence of mineral salts in the inflammatory exudate passing through the pocket. It is, therefore, evident that subgingival calculus represents a secondary product of infection and not a primary cause of periodontitis.

Mineralization starts at crystallization foci in the intermicrobial (intercellular) matrix and on the bacterial walls (Fig. 9-7), and eventually proceeds inside the bacteria (Fig. 9-8) (Zander *et al*. 1960). The detection of lactate dehydrogenase, alkaline and acid phosphatase activities, and various extracellular matrix proteins in plaque suggests that calculus formation is not merely

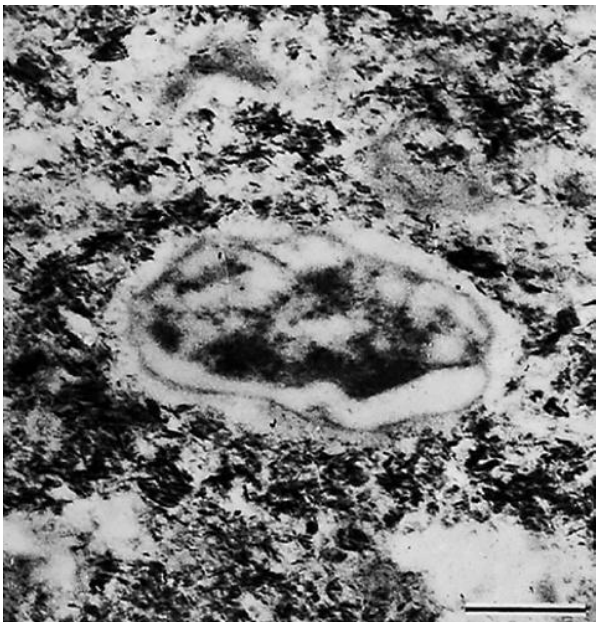

Fig. 9-7 Thin section of old plaque. A degenerating organism is surrounded by intermicrobial matrix in which initial mineralization has begun with the deposition of small needle-shaped electron-dense apatite crystals. ×26 500. Bar: 0.5 μm. (Source: Zander *et al*. 1960. Reproduced with permission from Sage.)

Fig. 9-8 Thin section of old mineralizing plaque. The intermicrobial matrix is totally calcified, and many microorganisms show intracellular crystal deposition. ×9500. Bar: 1 μm. (Source: Theilade 1964.)

a passive mineralization process. Bacterial enzymes (Friskopp & Hammarström 1982), calcium phosphate supersaturation, cell membrane-associated constituents, and inactivation of nucleation inhibitors (Jin & Yip 2002) may all be involved in the initiation and regulation of plaque calcification. Osteopontin and bone sialoprotein (Fig. 9-9), two non-collagenous extracellular matrix proteins involved in the mineralization of bone and cementum, have indeed been immunodetected in human calculus, but not in the unmineralized dental plaque. Osteopontin and bone sialoprotein are present in blood plasma and osteopontin has been identified in GCF and calculus. Their presence in the intermicrobial matrix and at the surface of bacteria suggests an involvement in the regulation of mineralization.

The progression of mineralization in an incremental pattern from the inner zones of the bacterial plaque outward may produce concentric rings, called Liesegang rings, that reflect successive phases of mineralization. Furthermore, the presence of numerous mineralization foci, from which mineralization spreads and which partially coalesce, may leave some unmineralized areas and thus account for the porous nature of calculus whose cavities and channels are filled with uncalcified plaque (see Fig. 9-6).

Attachment to tooth surfaces and implants

Dental calculus generally adheres tenaciously to tooth surfaces. Hence, the removal of subgingival calculus may be expected to be rather difficult. The reason for this firm attachment to the tooth surface is the fact that the pellicle beneath the bacterial plaque also calcifies. This, in turn, results in an intimate contact with enamel (Fig. 9-10), cementum (Fig. 9-11) or dentin crystals (Fig. 9-12) (Kopczyk & Conroy 1968; Selvig 1970). In addition, the surface irregularities are also penetrated by calculus crystals and, hence, calculus is virtually locked onto the tooth. This is particularly the case on exposed root cementum, where small pits and irregularities occur at the sites of the previous insertion of Sharpey's fibers (Bercy & Frank 1980). Uneven root surfaces may be the result of carious lesions and small areas of cementum may have been lost due to resorption, when the periodontal ligament was still invested into the root surface (Moskow 1969). Under such conditions it may become extremely difficult to remove all calculus deposits without sacrificing some hard tissues of the root.

Although some irregularities may also be encountered on oral implant surfaces, the attachment to commercially pure titanium generally is less intimate than to root surface structures. This in turn means that calculus may be chipped from oral implants (Fig. 9-13) without detriment to the implant surface (Matarasso *et al*. 1996). Excess cement at the crown–abutment interface has been associated with peri-implant disease (Pauletto *et al*. 1999; Gabski *et al*. 2008; Wilson 2009). The rough surface of the cement may provide a plaque/calculus retention site, which can lead to peri-implant disease (Lang *et al*. 2004). Overhang at such sites (Fig. 9-14) may impede calculus removal. It has been shown that clinical and endoscopic signs of peri-implant disease were absent in the majority of cases after removal of excess cement (Wilson 2009).

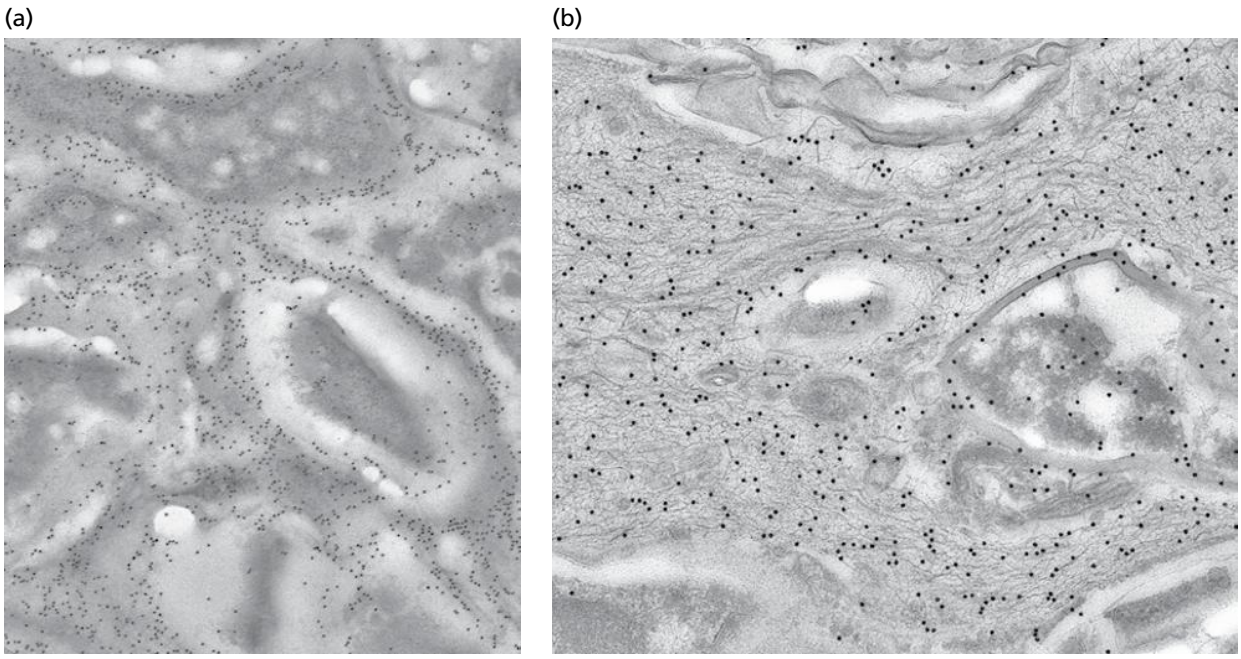

Fig. 9-9 Immunolabeling of calculus on a human tooth root with an antibody against bone sialoprotein. (a) Predominant gold particle labeling of the bacterial cell walls in the inner portion of calculus. (b) Labeling over extensive intermicrobial filamentous matrix. Ultrathin sections viewed under the transmission electron microscope.

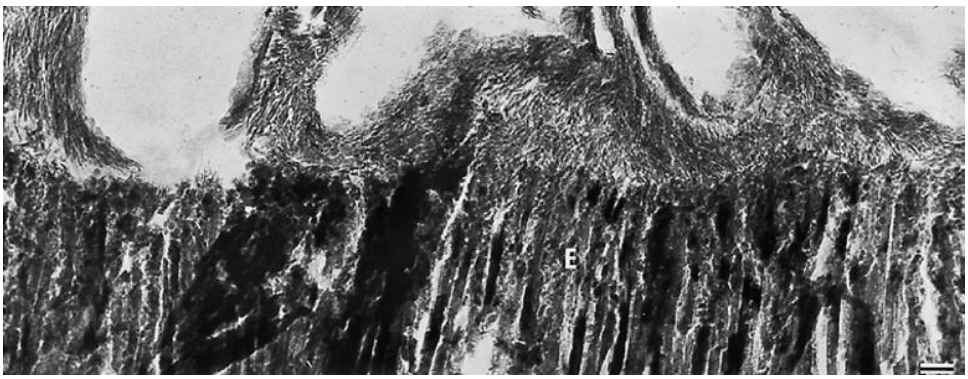

Fig. 9-10 Thin section of enamel surface (E) with overlying calculus. The enamel and calculus crystals are in intimate contact, and the latter extends into the minute irregularities of the enamel. ×37 500. Bar: 0.1 µm. (Source: Selvig 1970. Reproduced with permission from John Wiley & Sons.)

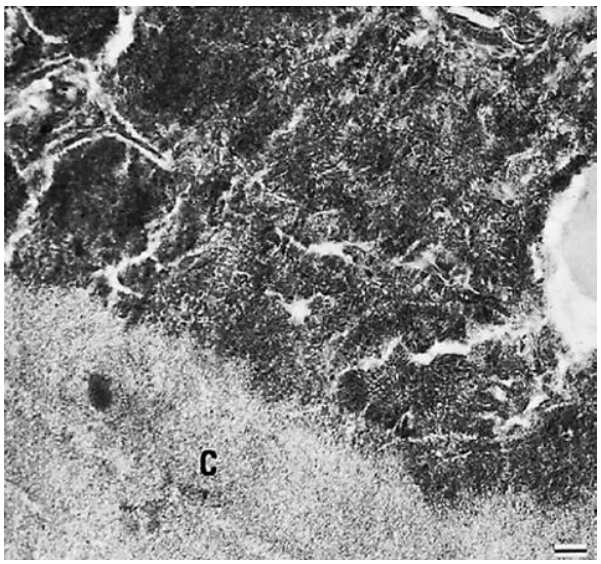

Fig. 9-11 Thin section of cementum surface (C) with overlying calculus. The calculus is closely adapted to the irregular cementum and is more electron dense and therefore harder than the adjacent cementum. To the right, part of an uncalcified microorganism. ×32 000. Bar: 0.1 µm. (Source: Selvig 1970. Reproduced with permission from John Wiley & Sons.)

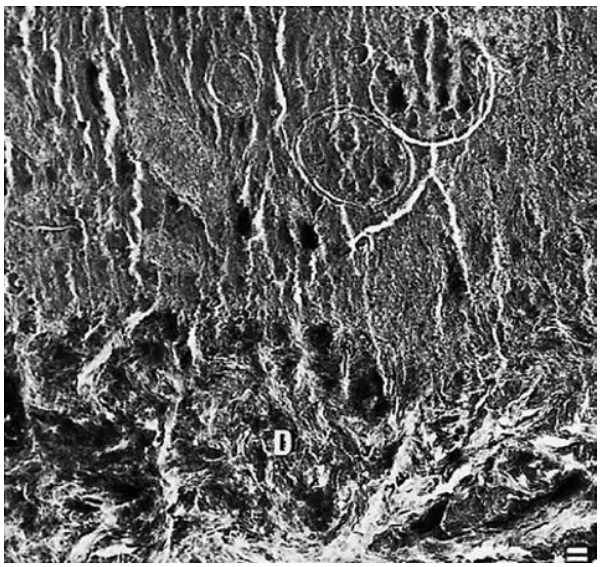

Fig. 9-12 Thin section of dentin (D) surface with overlying calculus. The interface between the calculus and dentin cannot be precisely determined because the calculus crystals fill the irregularities of the dentin surface, which is devoid of cementum as a result of a previous scaling of the root surface. The circular profiles in the calculus completely surround calcified bacteria. ×19 000. Bar: 1 µm. (Source: Selvig 1970. Reproduced with permission from John Wiley & Sons.)

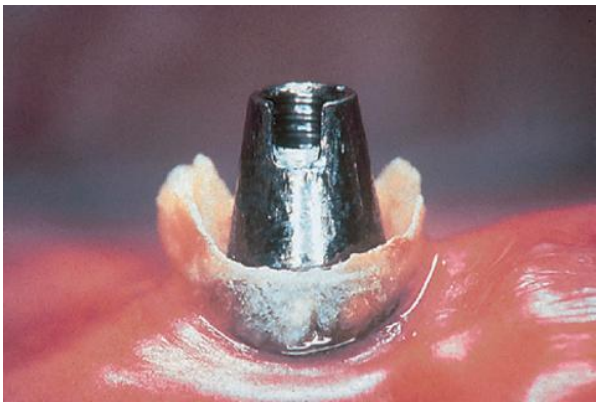

Fig. 9-13 Calculus deposit on an oral implant in a patient without regular maintenance care.

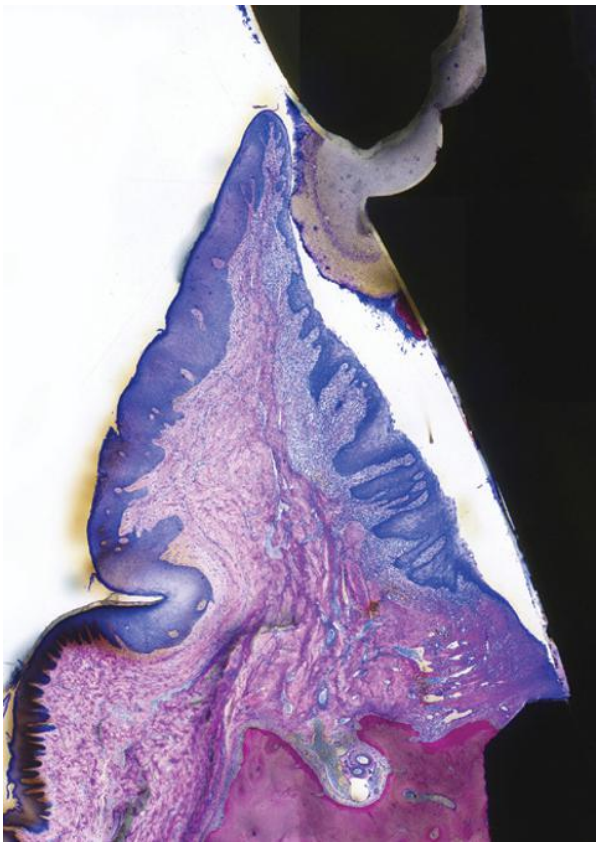

Fig. 9-14 Excess cement at the abutment–crown interface provides an ideal substrate for plaque and calculus deposition and retention. Bacterial plaque covers the entire surface of the cement, whereas calculus is present apical to the cement overhang. Detachment of the epithelium indicates pocket formation. The detachment of the apical-most portion of the epithelium, however, may represent an artifact due to histologic processing. Undecalcified ground section stained with toluidine blue and basic fuchsin.

Calculus composition

Recent and old calculus consists of four different crystals of calcium phosphate [for review see Schroeder (1969) and Jepsen *et al*. (2011)]:

1. $CaH(PO_4) \times 2H_2O$ = brushite (B)
2. $Ca_4H(PO_4)_3 \times 2H_2O$ = octa calcium phosphate (OCP)
3. $Ca_5(PO_4)_3 \times OH$ = hydroxyapatite (HA)
4. $\beta\text{-}Ca_3(PO_4)_2$ = whitlockite (W).

X-ray diffraction studies suggest that mineralization begins with the deposition of OCP and dicalcium phosphate dehydrate (DCPD), followed by less soluble HA and W (Rowles 1964; White 1997).

Supragingival calculus is clearly built up in layers and shows a great heterogeneity from one layer to another with regard to mineral content. On average, the mineral content is 37%, but ranges from 16% to 51%, with some exceptional layers having a maximal density of minerals of up to 80% (Kani *et al*. 1983; Friskopp & Isacsson 1984). The predominant mineral in exterior layers is OCP, while HA is dominant in the inner layers of old calculus. W is only found in small proportions (Sundberg & Friskopp 1985). B is identified in recent calculus, not older than 2 weeks, and appears to form the basis for supragingival calculus formation. Each type of crystal has a characteristic appearance: OCP forming platelet-like crystals for OCP; HA forming sandgrain or rod-like crystals, and W forming hexagonal (cuboidal, rhomboidal) crystals for W (Kodaka *et al*. 1988).

Subgingival calculus appears somewhat more homogeneous since it is built up in layers of equally high mineral density. On average, the density is 58% and ranges from 32% to 78%. Maximal values of 60–80% have been found (Kani *et al*. 1983; Friskopp & Isacsson 1984). The predominant mineral is always W, although HA has been found (Sundberg & Friskopp 1985). W contains small proportions (3%) of magnesia (McDougall 1985).

In the presence of a relatively low plaque pH and a concomitant high Ca/P ratio in saliva, B is formed and this may later develop into HA and W. When supragingival plaque mineralizes, OCP forms and is gradually changed into HA. In the presence of alkaline and anaerobic conditions and concomitant presence of magnesia (or Zn and CO_3), large amounts of W are formed in a stable form of mineralization.

Clinical implications

Although strong associations between calculus deposits and periodontitis have been demonstrated in experimental (Wærhaug 1952, 1955) and epidemiologic studies (Lövdal *et al*. 1958), it has to be realized that calculus is always covered by an unmineralized layer of viable bacterial plaque. It has been debated whether or not calculus may exert a detrimental effect on the soft tissues owing to its rough surface. However, it has clearly been established that surface roughness alone does not initiate gingivitis (Wærhaug 1956). In monkeys a normal epithelial attachment with the junctional epithelial cells forming hemidesmosomes and a basement membrane on calculus could be observed if the calculus surface was disinfected using chlorhexidine (Fig. 9-15) (Listgarten & Ellegaard 1973). Furthermore, it has been demonstrated that autoclaved calculus may be encapsulated in connective tissue without inducing marked inflammation or abscess formation (Allen & Kerr 1965).

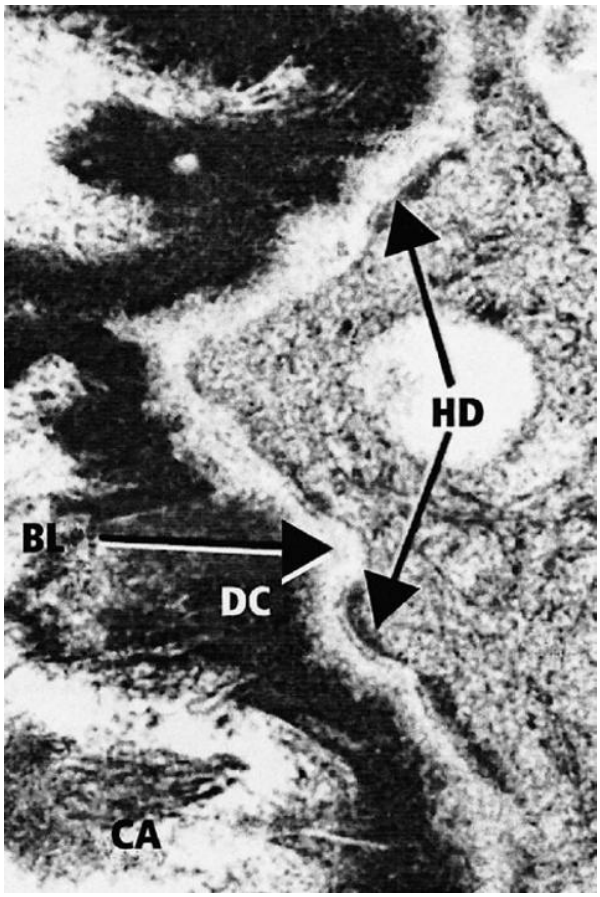

Fig. 9-15 Hemidesmosomal attachment of junctional epithelium on dental calculus in the absence of bacteria following application of chlorhexidine. (CA, calculus; HD, hemidesmosomes; BL, basement lamina; DC, dental cuticle.) ×32 000. (Data from Listgarten & Ellegaard 1973).

These studies clearly exclude the possibility of dental calculus being a primary cause of periodontal diseases. Calculus seems to have a secondary effect by providing a surface configuration conducive to further plaque accumulation and subsequent mineralization.

Nevertheless, calculus deposits may develop in areas that are difficult to access for oral hygiene or may, depending on their size, jeopardize proper oral hygiene practices. Calculus may also amplify the effects of bacterial plaque by keeping the bacterial deposits in close contact with the tissue surface, thereby influencing both bacterial ecology and tissue response (Friskopp & Hammarström 1980).

Well-controlled animal (Nyman *et al*. 1986) and clinical (Nyman *et al*. 1988; Mombelli *et al*. 1995) studies have shown that the removal of subgingival plaque on top of subgingival calculus results in healing of periodontal lesions and the maintenance of healthy gingival and periodontal tissues, provided that the removal is meticulous and done on a regular basis. One of these studies (Mombelli *et al*. 1995) clearly demonstrated that microbiota composition and clinical parameters following the diligent and complete removal of subgingival plaque on top of mineralized deposits after chipping off gross amounts of calculus were almost identical to those obtained with routine removal of subgingival calculus by root surface instrumentation. Again, it has to be realized that meticulous supragingival plaque control guarantees the depletion of the supragingival bacterial reservoir for subgingival recolonization. These studies have clearly elucidated the role of subgingival calculus as a plaque-retaining factor.

The presently available techniques used to remove deposits on the root surface cannot completely eliminate all calculus from diseased root surfaces. Factors such as anatomy, probing depth, instruments, and operator experience influence the efficacy of subgingival calculus removal (Jepsen *et al*. 2011). Some agents have been proven to reduce calculus formation (Jepsen *et al*. 2011). However, their effects appear to be limited to supragingival calculus and complete prevention cannot be achieved with them.

Conclusion

Dental calculus represents mineralized bacterial plaque. It is always covered by unmineralized viable bacterial plaque, and hence, does not directly come into contact with the gingival tissues. Calculus, therefore, is a secondary etiologic factor for periodontitis. Its presence, however, makes adequate plaque removal impossible and prevents patients from performing proper plaque control. It is the most prominent plaque-retentive factor that has to be removed as a basis for adequate periodontal therapy and prophylactic activities.

Chapter 10

Periodontal Infections

Mike Curtis

Institute of Dentistry, Barts and The London School of Medicine and Dentistry,
Queen Mary University of London, London, UK

Introduction

Our mucosal surfaces are colonized by complex communities of microorganisms, or microbiotas, which are uniquely adapted to the different environmental niches in the human body. These microbiotas are composed of distinct and specialized microorganisms which are characteristic of the respective niche, for example the mouth, the gastrointestinal or the genitourinary tract (Fig. 10-1). Collectively the microbiotas on our mucosal surfaces and other anatomic locations in the body comprise the human microbiome, which has become an area of intensive investigation in recent years because of the recognition that the balance between these organisms and the human host plays a fundamental role in our biology, the maintenance of our health, and the development of disease.

The intestinal microbiota, for example, has a profound impact on human physiology, metabolism, local tissue organization, and the development of the immune system. Its composition is heavily influenced by the host genotype and is also dynamic and subject to variation due to environmental factors, including diet, antibiotic usage, and the introduction of pathogenic microorganisms. In some instances, changes in the ecologic balance of the microbiota lead to changes in the bacterial diversity, outgrowth of potentially pathogenic bacteria, and loss of bacterial species normally beneficial to the host (Round & Mazmanian 2009). An unfavorable alteration of the microbiota composition is called *dysbiosis* (Hill & Artis 2010). It has become increasingly evident that alterations to the normally balanced microbial populations at different sites of the human body may have a profound effect on human health (Frank *et al.* 2011). Diseases and conditions which have been linked to dysbiosis of the commensal microbiota include antibiotic-associated diarrhea (Young & Schmidt 2004; Chang *et al.* 2008), bacterial vaginosis (Fredricks *et al.* 2005; Oakley *et al.* 2008), celiac disease (De Palma *et al.* 2011), esophageal disease (Pei *et al.*, 2005), Crohn's disease and ulcerative colitis (Frank *et al.* 2007; Packey & Sartor 2009; Willing *et al.*, 2009, 2010), irritable bowel syndrome (Mättö *et al.* 2005; Kassinen *et al.* 2007; Codling *et al.* 2010), necrotizing enterocolitis (Wang *et al.* 2009), and psoriasis (Paulino *et al.* 2006). More surprisingly however, dysbiosis of the commensal microbiota has also been linked to obesity (Ley *et al.* 2005, 2006; Zhang *et al.* 2009), colorectal cancer (Scanlan *et al.* 2008; Sobhani *et al.* 2011), and metabolic syndrome. Moreover, the *functional* importance of dysbiosis of a mucosal microbiota is now becoming clearer through studies which have demonstrated that several diseases, including obesity, metabolic disorders, and inflammatory bowel conditions, can be transmitted via the transfer of dysbiotic microbiota in animal model systems (Garrett *et al.* 2010).

(Source: Spor *et al*. 2011. Reproduced with permission from Macmillan Publishers Ltd.)

Of all the environmental niches in the human body, the oral cavity provides an optimal habitat for the growth of bacteria: a stable temperature, constant moisture, an abundant supply of nutrients, and, uniquely, the hard surfaces of the teeth. The evolutionary forces which shaped the development of a calcified dentition of animals, including humans, have introduced a developmental weak spot from the perspective of infectious disease: nowhere else in the human body is the normally contiguous epithelial barrier of the mucosal surfaces breached by a solid, non-shedding structure which permits the development of a microbial biofilm in direct contact with the adjacent soft tissues. The defense against this challenge, which has co-evolved with the development of calcified tissues protruding through the mucosal barrier, is a sophisticated set of specialized anatomic features, innate immune and inflammatory responses. Furthermore, this site in the human body actively promotes the selection of a unique microbiota which normally is both tolerated by the adjacent tissues and provides protection from microorganisms deleterious to the healthy status of the tooth-supporting apparatus. Disease of the periodontal tissues can therefore be viewed as a breakdown of this balanced homeostasis between the host tissues and the resident microbiota.

Analysis of the human oral microbiome extends back through history to the very first microscopic observations of bacteria by Antonie van Leeuwenhoek in 1665 and continues apace to this day through the application of high throughput DNA sequencing techniques which are beginning to yield a description of this microbiota in extraordinary detail. This centuries-old tradition of oral microbiologic analysis has placed our knowledge of the bacterial communities of the mouth at the very leading edge of our understanding of the human microbiome. From these investigations, it is clear that the phenomenon of dysbiosis, or a deleterious alteration to the microbiota, is a fundamental characteristic of periodontal disease.

In addition to dysbiosis, several other characteristics of this microbiota need to be considered to properly appreciate the role of bacteria in periodontal disease. First, the growth of these organisms in a subgingival biofilm leads to a number of characteristics which define the biology of these organisms and can present a unique challenge to the adjacent tissues. These include: inter-bacterial nutritional dependencies and communication; the development of specific consortia of different bacterial species which may act cooperatively in the presentation of a microbial challenge; an optimal environment for genetic exchange between different species; and resistance to the immune and inflammatory clearance mechanisms of the host and to chemical antimicrobial agents. A more detailed description of the consequences of the biofilm lifestyle adopted by dental plaque bacteria is given in Chapter 8.

Second, analysis of the population structure of some of the bacterial species associated with periodontal disease reveals significant genetic differences which, in some instances, have a defining role in the pathogenic variation within an individual species. Third, analysis of the properties of bacterial species frequently present in a dysbiotic periodontal microbiota has demonstrated that the ability to successfully manipulate elements of the innate and inflammatory response is a common characteristic of these microorganisms and may indeed represent an overriding principle of periodontal virulence.

Analysis of the microbiology of periodontal disease has been undertaken by very many investigators, beginning with the very first microscopic identification of bacteria as unicellular organisms over 300 years ago. Examination of the medical publication databases reveals that over 10 000 research papers have been written on the subject of periodontal infections over the last 50 years and hence the current chapter can only be a highly selective representation of this literature. The aim is to present an overview of our current understanding of the composition and properties of the periodontal microbiota, and to provide a conceptual framework to understand the mechanisms and consequences of dysbiosis of this microbial community and the influence that this process has on the development of periodontal disease.

Dysbiosis of the oral microbiota in periodontal disease

The underlying principles of infectious disease, first enunciated by Louis Pasteur and subsequently proven by Robert Koch, provided the essential framework for the identification of microorganisms responsible for diseases of a monospecific etiology. Koch's postulates provide four criteria which should be met in order to identify an infectious agent as a disease causing agent: (1) found in abundance in all organisms suffering from the disease, but not found in healthy organisms; (2) isolated from a diseased organism and grown in pure culture; (3) causes disease when the cultured microorganism is introduced into a healthy organism; and (4) re-isolated from the inoculated, diseased experimental host and identified as being identical to the original specific causative agent. Whilst these principles have undergone significant revisions since their introduction and have been updated into a molecular interpretation by Falkow (1988), they underpinned the discovery of the causative agents of very many medically important infections throughout the mid-19th and early 20th centuries. Koch himself applied these criteria to the discovery of *Mycobacterium tuberculosis* and *Bacillus anthracis* – the causative agents of tuberculosis and anthrax, respectively.

However, in the case of diseases involving a complex microbial etiology, where the fundamental basis is one of dysbiosis, or perturbation of a normal commensal microbiota, the description of the infectious challenge is more demanding. Here, the accuracy of the description is intimately linked to the effectiveness of the technology available to quantitatively and qualitatively determine the composition of a complex microbial mixture. In that sense, our understanding of the periodontal microbiota has undergone sequential stepwise changes over time following the introduction and application of increasingly more sophisticated and higher throughput methods for bacterial characterization and identification (Fig. 10-2).

These studies extend back over three centuries to the very first description of bacterial cells by Antonie van Leeuwenhoek, who in 1676 using the newly invented microscope described the "animacules" in the biofilms from human teeth. In the intervening period, our understanding of the complexity, site specificity, and environmentally driven nature of these microbial communities has expanded with each technological advance in microbial identification and classification. Advances have accompanied the introduction of standardized cultural techniques on solid media, the development of anaerobic culture systems, the introduction of non-cultural techniques for bacterial identification, and the use of molecular phylogeny through nucleic acid analyses using DNA–DNA hybridization, the polymerase chain reaction (PCR), Sanger DNA sequencing, and the more recent developments in high throughput pyro-sequencing and metagenomics (Wade 2011). These cultural and non-cultural investigations have now culminated in the development of the Human Oral Microbiome Database (http://www.homd.org), which lists all bacterial species found in the human mouth (Dewhirst *et al.*, 2010), and more recently CORE (http://microbiome.osu.edu) (Griffen *et al.*, 2011), a phylogenetically curated 16S rDNA database of the core oral microbiome representative of the bacteria which regularly reside in the human oral cavity.

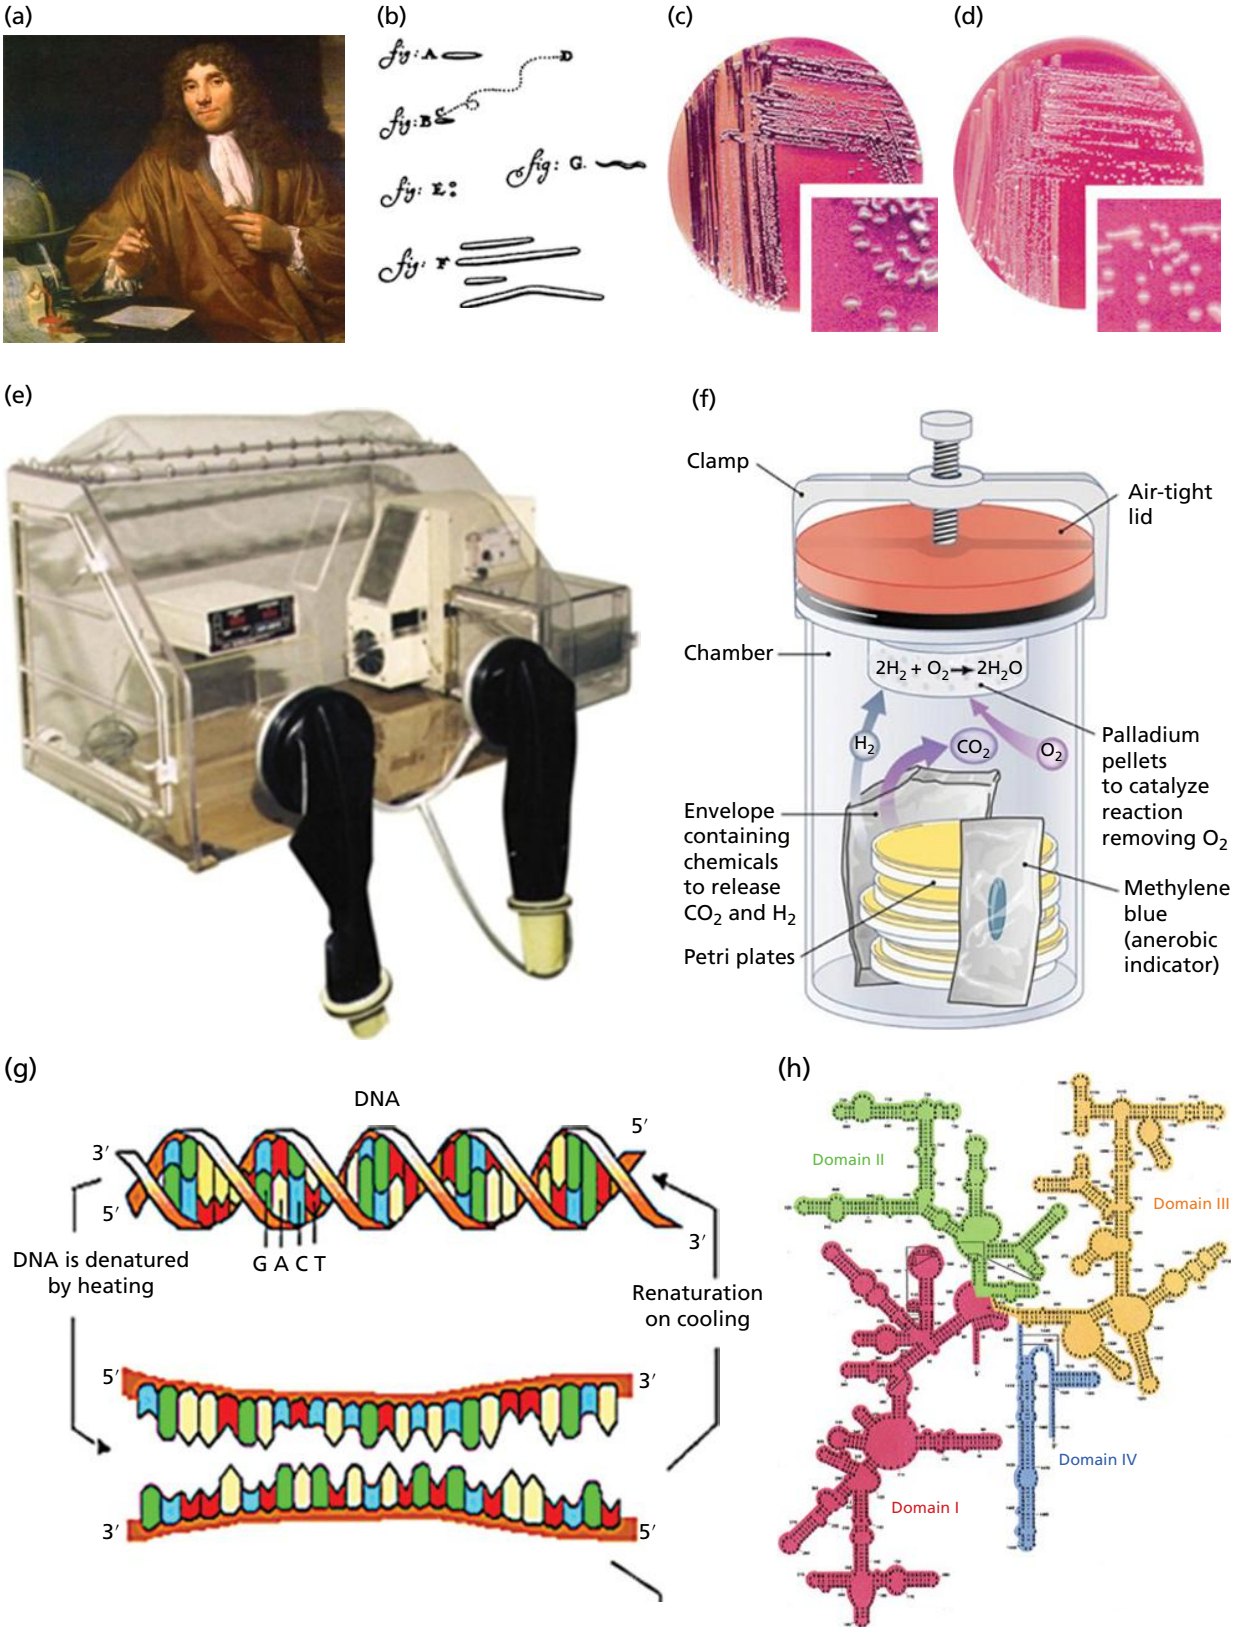

Fig. 10-2 Technological advances linked to increased understanding of the oral microbiota. Appreciation of the complexity of the oral microbiota has increased with the development of technology. Microscopy: (a) Antonie van Leeuwenhoek who used the first microscopes to characterize dental plaque bacteria (b). Bacterial culture on solid media: (c) *Porphyromonas gingivalis* grown on blood agar and (d) a non-pigmenting mutant of *P. gingvalis*. *Anaerobic microbiology:* (e) Anaerobic chambers and (f) anaerobic jars enabled the culture of bacteria whose growth is inhibited by oxygen. *Molecular techniques for bacterial identification*: (g) DNA–DNA hybridization and (h) sequence analysis of the variable regions of the *16S rRNA* gene allow for the identification and quantitation of bacteria in the absence of culture.

Early microscopic and cultural microbiology investigations

The progress made in describing the etiologic agents of infectious diseases in the late 19th and early 20th century naturally led to a search for the causative organisms involved in periodontal infections. These investigations were restricted by the techniques available for visual inspection of subgingival samples or by the relatively primitive cultural techniques that had been developed at this early stage of the discipline of microbiology. Socransky and Haffajee (1994) summarized the findings of these early investigations into the description of four potential groups of etiologic agents.

First, on the basis of cultural microbiologic studies, the streptococci were proposed to be important microorganisms in the disease process. This was perhaps an inevitable conclusion given that the cultural techniques in common use during this period were limited in terms of the diversity of organisms capable of being detected and the streptococci were most probably the only group which was reliably grown. As an indication of the relatively primitive status of bacterial taxonomy at the time, it is worth noting that in the early part of the 20th century there was still significant debate about whether or not "the streptococci" represented just a single bacterial species. Only upon the development of more discriminatory techniques did the heterogeneity within the streptococci, which is now a hallmark of this genus, become apparent. For example, Gordon (1905) stated that "the differential tests which I have recommended in previous reports and applied in recent years to the careful study of "strepto-biology" of milk, saliva, water, excremental matters, and morbid and other materials afford in my opinion a definite basis (hitherto lacking) upon which to classify streptococci. Briefly, the doctrine of the unity of streptococci has arisen chiefly from inability of the use of older laboratory tests to discriminate between species."

The other three groups of organisms which were considered to be potential agents of periodontal disease were all described on the basis of microscopy. Stained smears of dental plaque revealed the presence of ameba, and it was reported that there were higher levels of these organisms in samples taken from periodontal lesions compared to those taken from healthy mouths or those with gingivitis. Wet mount preparations or specific staining techniques enabled the visualization of spirochetes and it was suggested that the levels of these bacteria were positively associated with periodontal disease. Finally, fusiform bacteria, readily detectable because of their characteristic large, spindle-like cellular morphology by light microscopy, were also implicated in the disease process, in particular in acute necrotizing ulcerative gingivitis, which appeared to be a relatively common disease in the early part of the 20th century, particularly among troops in World War I, referred to as "trench mouth".

For each of these agent types however, further investigations – based on comparable studies in other patient groups or the use of treatment regimens designed to specifically target these organisms – failed to reliably support the contention that these organisms explained the microbiologic basis of the disease. This may have reflected the fact that the microbial etiology of periodontal disease varies between individuals and is multifactorial within an individual, as well as the problem that these early investigations were so highly dependent on the analytical tools available at that time. Probably as a result of the inability to accurately define the etiologic agent(s) of the disease, in contrast to the great strides being made elsewhere in describing the causative organisms in the major, monospecific infectious diseases, there was a loss of impetus in microbiologic research into periodontal infections in the early decades of the 20th century.

Nonetheless, it was apparent to the clinicians treating the disease that control of dental plaque was of critical importance both to treatment and to prevention. As a consequence, the notion of a non-specific etiology came to the forefront. The "non-specific" plaque hypothesis suggested that accumulations of microorganisms at or below the gingival margin would produce irritants leading to inflammation, which in turn would lead to periodontal tissue destruction. In this scenario, although bacteria were recognized to be important in the etiology of the disease, the critical factor was their total number, and the resultant magnitude of the challenge they presented to the host tissues, rather than the precise species of bacteria that were present. Alternative hypotheses which describe a more specific etiology will be described in the final section of this chapter.

Advent of anaerobic microbiologic techniques

A major breakthrough in our understanding of the complexity of the periodontal microbiota was achieved through the introduction of methods which allowed the laboratory culture of anaerobic microorganisms. The low oxygen levels in the subgingival biofilm are highly permissive for the growth of obligately anaerobic bacteria and hence a significant fraction of the total periodontal microbiota would have been largely undetected in previous microbiologic investigations conducted under aerobic conditions. This technological advance included the use of anaerobic roll tubes and anaerobic jars which could be flushed with oxygen-free gases and then sealed to prevent the access of air. More latterly, anaerobic chambers were developed which enabled the culture of anaerobic bacteria on both solid and liquid media in a relatively spacious, low oxygen environment periodically flushed with a mixture of nitrogen, carbon dioxide, and hydrogen.

These studies were pioneered by several oral microbiology laboratories throughout the 1970s and 1980s (Socransky *et al.* 1963; Socransky 1970; Slots 1976, 1977; Tanner *et al.* 1979; Slots & Rosling 1983; Haffajee *et al.* 1984; Christersson *et al.* 1985; Dzink *et al.* 1985; Loesche *et al.* 1985; Dzink *et al.* 1988; Haffajee *et al.* 1988; van Winkelhoff *et al.* 1988; Zambon *et al.* 1988; Tanner & Bouldin 1989; Zambon *et al.* 1990; Slots *et al.* 1991; Socransky & Haffajee 1994).The highly labor intensive nature of the methodology meant these studies were usually limited to the analysis of relatively few periodontal subjects. Importantly, however, these investigations began to put clear definition to the very significant qualitative differences in the overall microbiota present at periodontally diseased sites compared to control healthy sites and to identify some of the key, characteristic organisms which were frequently associated with disease. The exhaustive investigations conducted in the Virginia Polytechnic Institute laboratories of Holdeman and Moore (Moore *et al.* 1983, 1985; Moore 1987) were typical of these investigations and are among the most influential studies of the total, cultivatable, anaerobic microbiota. These authors brought the techniques developed in their investigations of the anaerobic microbiota of the intestine to the study of the periodontal microbiota. In a series of publications, throughout the 1980s in particular, they described the bacteriology of chronic and severe periodontal disease in adults, the bacteriology of experimental gingivitis and juvenile periodontitis in young adults, and the stability of the periodontal microbiota over time. Typically these investigations involved sampling the subgingival microbiota at one or more diseased sites in an individual as well as at adjacent control supragingival sites, followed by culture on selective and non-selective media in anerobic roll tubes or jars and, later, in anerobic chambers. Discrete colonies were then isolated and the identity of the resultant pure isolate was established on the basis of a variety of morphologic, serologic, and biochemical techniques. A single study would frequently involve the isolation and characterization of literally thousands of isolates in order to build a complete picture of the total cultivatable microbiota. These were heroic investigations involving laborious and time-consuming methodologies. For example, in their investigation of the bacteriology of severe generalized periodontitis in 21 individuals, they described the isolation and characterization using biochemical techniques of 2723 individual isolates representing 190 bacterial species, subspecies, or serotypes (Moore *et al.* 1982). Of these, 11 species exceeded 1% of the subgingival flora and were most closely associated with the diseased sulci and 11 others were also sufficiently frequently isolated to be suspected as agents of tissue destruction.

An example of the outcome of these investigations can be seen in Table 10-1, which shows the types of cultivatable bacteria that were more numerous in subgingival compared to supragingival plaque samples in young adults with advanced periodontal disease, and conversely those which were more numerous in supragingival samples. This study highlights the marked difference between the overall microbiota in periodontally diseased, subgingival sites compared to the adjacent supragingival microbiota. Whilst the supragingival microbiota is dominated by the actinomyces, streptococci, and veillonella, which comprise some 40% of the total cultivatable bacteria, the same genera represent only approximately 10% of the subgingival organisms. Conversely, members of the bacteroides and fusobacteria represent approximately 20% of the subgingival microbiota, but only approximately 5% of the supragingival microbiota.

Studies of this kind began to convincingly reveal the sheer complexity of the microbiota in periodontal disease to a level that had hitherto been unseen. A reference catalog of bacterial taxa began to develop and this would prove invaluable for later investigations. Furthermore, there were some important additional messages. First, as is evident in Table 10-1, frequently those bacteria which are significant components of the subgingival plaque from diseased sites are also present, albeit at reduced levels, in supragingival samples, and *vice versa*. Indeed, other studies demonstrated that many of the bacteria positively associated with the microbiota at a diseased subgingival site were also present in healthy subgingival sites.

These investigations indicated that a specific etiology for the periodontal disease process could only be explained on the basis of a quantitative rather than solely qualitative perspective. To gain sufficient power to address the nature of the etiology it would be necessary to perform studies involving significantly more samples/subjects than was feasible by this total microbiologic analysis approach, which was typically restricted to investigations on relatively small numbers of individuals. However, these large-scale anaerobic microbiologic analyses on a relatively few samples had provided several valuable, potential "specific periodontal pathogens" for future studies in which it would be possible to increase the sample size through a more targeted analytical approach (Table 10-2). In addition, it is also evident from the data in Table 10-1 that there was a very significant shortfall in the understanding of the taxonomic classification of many of these newly described bacterial taxa, not least in the case of the *Bacteroides*. Clarification of the taxonomy of the periodontal microbiota was therefore a priority.

Significant effort was therefore placed on a systematic analysis of a number of these organisms using biochemical, physiologic, and immunologic approaches. As a result, gradually the underlying diversity within some of the organisms previously characterized as a single bacterial species became apparent (Fig. 10-3). This reclassification was accelerated to a new level by the application of molecular

Table 10-1 Selected taxa as a % of microbiota that were more numerous in (A) the supragingival microbiota and (B) the subgingival microbiota of young adults with severe generalized periodontitis.[a]

Table 10-2 Some of the bacteria which emerged as putative periodontal pathogens from cultural investigations of the subgingival microbiota.

Initial description	Reclassification
Bacteriodes melaninogenica	*Porphyromonas gingivalis, Prevotella intermedia*
Actinobacillus actinomycetemcomitans	*Aggregatibacter actinomycetemcomitans*
Tannerella forsythia	
Fusobacterium nucleatum	
Treponema denticola	
Peptostreptococcus micros	
Eikenella corrodens	
Selenomonas spp.	
Eubacteria spp.	

DNA analysis of these bacteria, in particular through comparative analysis of the *16S rRNA* gene (see later), which facilitated the differentiation of individual species. This process was essential in order to guide the identification of those bacterial species most closely associated with the periodontal disease process. A case in point is the evolution of the taxonomy of the black-pigmented bacteroides and the taxonomic changes to the classification of *Bacteroides melaninogenica* shown in Fig. 10-4. Through the application of successively higher definition identification schemes, what was previously a single entity is now appreciated to contain two different genera (*Porphyromonas* and *Prevotella*) and multiple species within each of these genera. Importantly, whilst the relevance of the black-pigmented organisms to periodontal infection had been evident through cultural investigations for several decades, the taxonomic definition of this group of organisms made it possible to determine which species were most closely associated with disease. Hence, it has become apparent that whereas *Porphyromonas gingivalis* is a critically important bacterium in disease, and is indeed now classified as one the red complex group of bacteria most closely associated with periodontal disease, this group of organisms also contains species which are frequently associated with periodontal health.

Targeted microbiologic analyses: Rise of specificity

Cultural and immunochemical studies

Having developed a candidate list of putative periodontal pathogens, it became possible to perform rather more targeted investigations that aimed to

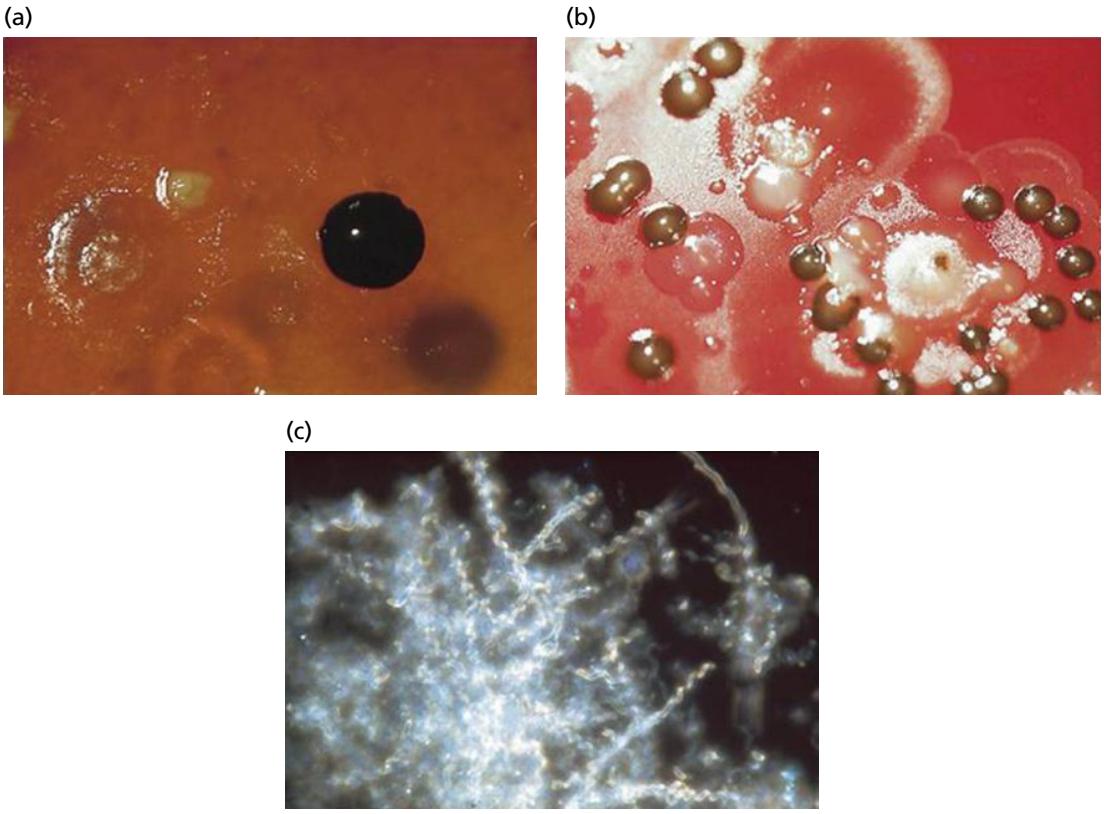

Fig. 10-3 Culture and microscopy analysis of dental plaque. Primary isolation plates of (a) a subgingival plaque sample from a subject with chronic periodontitis – the black-pigmented colony was an isolate of *Porphyromonas gingivalis*; (b) a subject with chronic periodontitis. In the latter case the dark-pigmented colonies were isolates of *Prevotella intermedia*. (c) Photomicrograph of a sample of subgingival plaque from a subject with advanced chronic periodontitis viewed by darkfield microscopy. The sample was dominated by large spirochetes with the typical corkscrew appearance. (Source: Socransky & Haffajee 2008. Reproduced with permission from John Wiley & Sons.)

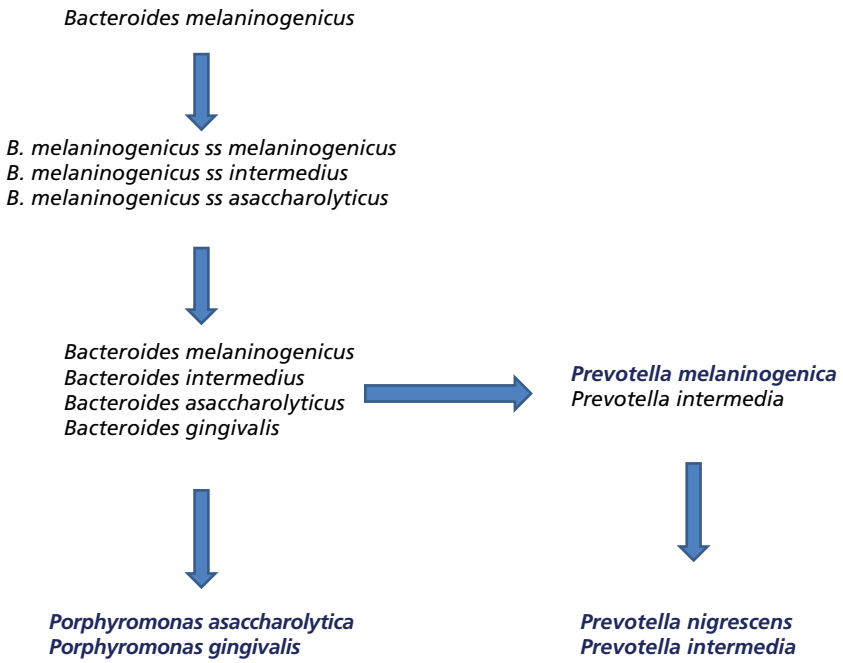

Fig. 10-4 Evolution of the taxonomy of the black-pigmented bacteroides. Organisms in bold are the current designations whilst those not in bold represent intermediate classifications during the reclassification of the taxonomy of this group of bacteria.

focus on detection of this group of bacteria in larger numbers of clinical samples than it was feasible to process when the entire cultivatable microbiota was examined. These investigations relied upon the application of a combination of identification approaches: novel selective media for the enrichment or selective culture of specific bacteria; immunologic techniques using newly developed monoclonal antibodies or polyvalent sera to individual species; or microscopy for the identification of spirochetes. For example, Bragd *et al.* (1987) used a selective media approach to evaluate the association of *Actinobacillus* (now *Aggregatibacter*) *actinomycetemcomitans*, *Bacteroides* (now *Porphyromonas*) *gingivalis*, and *Bacteroides (Prevotella) intermedia* in over 200 samples from progressing and non-progressing periodontal sites. Similarly, Slots *et al.* (1990) employed a cultural approach to examine the influence of subject age on the prevalence and recovery of *A. actinomycetemcomitans* and *B. intermedius* in 1624 patients aged between 15 and 89 years. Grossi *et al.* (1995) used an immunochemical approach to assess the presence of eight candidate periodontal pathogens in a study involving 1361 subjects to identify risk markers for periodontal bone loss. Suda *et al.* (2002) used an indirect immunofluorescence approach to enumerate the levels of *Eikenella corrodens* in samples from over 250 periodontal and control samples, and Riviere *et al.* (1997) a similar antibody- and microscopy-based investigation to determine the levels of different spirochetes in an analysis of the development of periodontal disease using over 1000 samples from 65 subjects.

By focusing on a small group of candidate organisms using relatively high throughput approachesm, it became possible to design appropriately statistically powered investigations to address a number of key issues relevant to the etiology and treatment of periodontal disease. These included studies of the presence of these candidate periodontal pathogens in different global populations (van Winkelhoff *et al.* 1999); of the association between different organisms such as *Bacteroides forsythus* and *Bacteroides gingivalis* (Gmur *et al.* 1989), and their spatial distribution in plaque (Kigure *et al.* 1995); the association with disease of different morphotypes of the same species, such as the smooth and rough colony types of *Peptostreptococcus micros* (van Dalen *et al.* 1998; Kremer *et al.* 2000); and the effect of treatment on persistence/eradication of these key organisms (Mandell *et al.* 1986; Rodenburg *et al.*, 1990; Mombelli *et al.* 2000). Furthermore, when isolation and identification of a specific organism was coupled to more detailed characterization of the individual strain (e.g. by restriction digestion of the isolates' DNA followed by separation by agarose electrophoresis), it became feasible to perform transmission studies. Notably, Petit *et al.* (1993a, b) and Van Steenbergen *et al.* (1993) used this approach to demonstrate that *P. gingivalis* was transmitted between spouses and that intrafamilial transmission of individual strains of *P. intermedia* and *Prevotella nigrescens* also occurred.

Other investigations utilized these selective methodologies to examine the association of alternative bacterial species with periodontal disease in addition to the, by now, well- established, periodontal bacteria mentioned earlier. In so doing the list of bacterial species positively associated with periodontal disease, in particular adult disease, was extended to include, for example, *Wolinella* (now *Campylobacter*) *recta* (Lai *et al.* 1992; Rams *et al.* 1993), *Enterococci* (Rams *et al.* 1992), *Peptostreptococcus micros* (van Dalen *et al.* 1998), eubacterial species (Grossi *et al.* 1995), *E. corrodens* (Suda *et al.* 2002), and *Fusobacterium*

nucleatum (van Winkelhoff *et al.* 2002). Hence, whilst a specific microbial etiology for periodontal disease was still considered by many to be the most reasonable interpretation of the accumulated data, there was an acceptance that the nature of the microbial challenge, particularly in the case of chronic adult periodontitis, was highly complex and likely to vary significantly between individuals and potentially within an individual at different sites and at different times (Maiden *et al.* 1990).

In contrast to adult-type chronic periodontitis, in one particular instance of aggressive periodontitis affecting adolescents of African descent, there is evidence to suggest that a single specific microbial etiology may be responsible for the development of disease. *A. actinomycetemcomitans* is a Gram-negative rod that produces a leukotoxin that specifically lyses human neutrophils. The organism displays significant genetic diversity, but one particular clone, referred to as JP2, has a number of genetic variations that distinguish it from other clonal types, including a 530-base pair deletion in the promoter region of the leukotoxin gene *operon*. As a result, the JP2 clone produces significantly enhanced levels of leukotoxin compared to the other lineages of this bacterium: this could theoretically lead to an enhanced potential to disrupt the immune defenses of the periodontium. Population genetic analysis by multilocus sequencing of *A. actinomycetemcomitans* strains from geographically dispersed individuals suggest that the JP2 clone originally emerged as a distinct genotype in the Mediterranean part of Africa over 2000 years ago and subsequently spread to West Africa, from where it was transferred to North and South America by the trans-Atlantic slave trade in the 16th–18th centuries. Remarkably, despite its now global dissemination, the JP2 clone remains exclusively associated with individuals of West African descent, indicating a strong host tropism effect (Haubek *et al.* 2008). While the prevalence of aggressive periodontitis in adolescents is normally <1%, it is far higher in individuals of North and West African descent. In a longitudinal study of the disease in Moroccan adolescents, 61 of 428 (14.3%) individuals who were periodontally healthy at baseline had developed disease after 2 years. Moreover, in this population, individuals who carried the JP2 clone at baseline were far more at risk of developing disease than those who carried non-JP2 clones of this bacterium (relative risk 18.0 versus 3.0) (Haubek *et al*. 2008). Hence, the JP2 clone of *A. actinomycetemcomitans* has the characteristics of a traditional bacterial pathogen, albeit in a host-restricted background.

Nucleic acid-based techniques for bacterial identification

With the development of a catalog of the major cultivatable species in the periodontal microbiota through these cultural microbiologic analyses came the need to develop more rapid, less time-consuming and laborious methods for larger sale epidemiologic analyses of the association of these organisms with health and disease. This was accomplished through the introduction of techniques that were not reliant on culture immediately following sample collection. The most commonly used of these were analyses based on nucleic acid approaches – PCR amplification of specific regions of the chromosome of the target organism, usually the *16S rRNA* gene, followed by quantitation of the product and DNA–DNA hybridization techniques.

Use of the DNA–DNA checkerboard methodology

A step change in the potential throughput of microbiologic analyses of periodontal plaque samples arrived with the introduction and application of DNA–DNA hybridization technology. The development of the checkerboard assay allowed the simultaneous hybridization of 45 individual DNA samples extracted from periodontal plaque against 30 different DNA probes on a single membrane. The DNA probes can either be prepared from whole genomic DNA extracted from the relevant target bacterium or alternatively from PCR amplicons of bacterial species-specific regions of the *16S ribosomal RNA (rRNA)* gene. Hybridization of the sample DNA with the probe DNA is then visualized via a chemifluorescent signal, the intensity of which is proportionate to the amount of the target organism DNA present in each sample (Fig. 10-5).

Whilst there are some limitations to the accuracy of identification of individual bacterial species due to potential cross-hybridization of DNA from closely related bacterial species in the same clinical samples, this technology has revolutionized the analysis of clinical samples and the ability to make definitive bacterial associations with periodontal health and disease. Now it was possible to perform qualitative and quantitative analysis of the bacterial composition of far, far greater numbers of clinical samples than with the previous culture-based methodologies. For example, in a landmark investigation, Socransky *et al*. (1998) analyzed approximately 13000 plaque samples from 185 subjects using whole genomic DNA probes to 40 bacterial species. Associations were sought among species using cluster analysis and community ordination techniques. One of the key and fundamental findings of this study, which has shaped our understanding of periodontal infections, was the definition of bacterial complexes, as opposed to individual bacterial species, that were associated with either periodontal health or periodontal disease (Fig. 10-6).

This finding led to the concept that there may be a co-dependency or synergy between different bacterial species acting in concert as a specific complex. The complex most strongly associated with periodontal disease became the focus of intense investigation. The "red complex" is composed

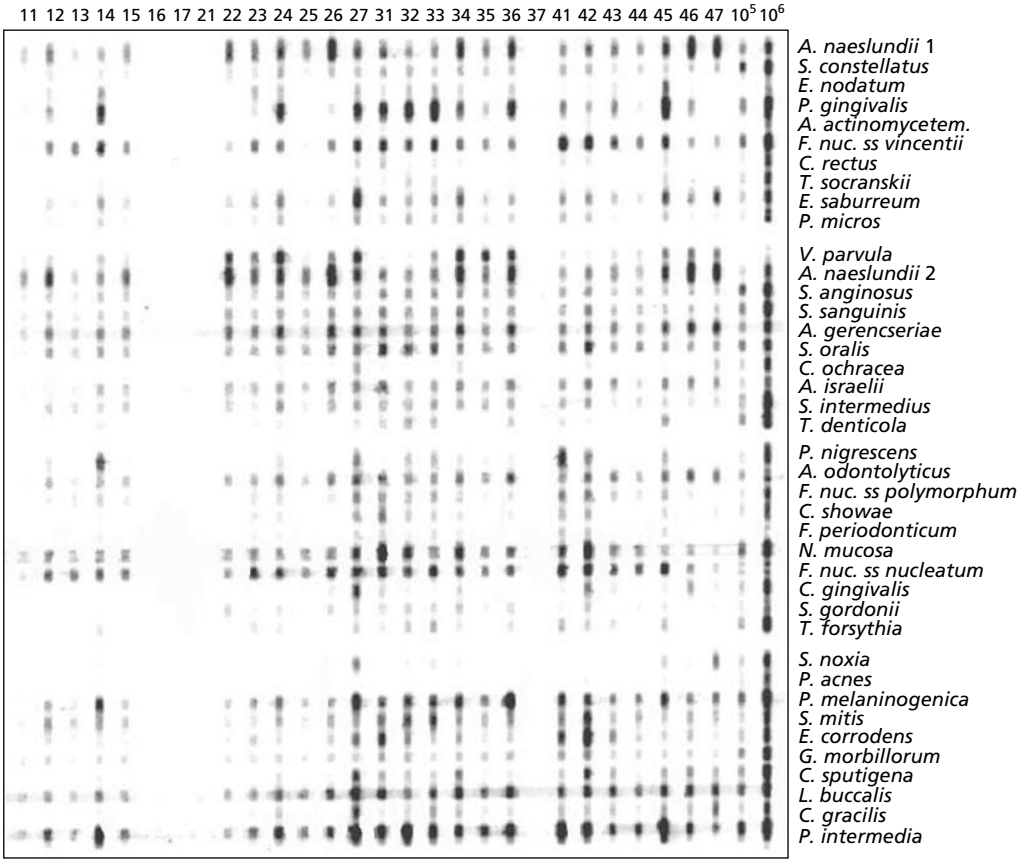

Fig. 10-5 DNA–DNA checkerboard analysis. The vertical lanes are the plaque samples numbered 11–47 and the two lanes of standards on the far right contain either 10^5 or 10^6 cells of each test bacterial species. The horizontal lanes contain whole genomic DNA probes labeled with digoxygenin to each represented bacterium. A signal at the intersection of the vertical and horizontal lanes indicates the presence of a bacterial species and the intensity of the signal is related to the number of bacterial cells present. The methodology enables the simultaneous and rapid analysis of 40 different bacterial species in 28 different plaque samples. (Source: Socransky & Haffajee 2008. Reproduced with permission from John Wiley & Sons.)

of three bacterial species: *P. gingivalis*, *Treponema denticola*, and *Tannerella forsythia.* Other complexes, for example the *yellow complex* which comprises predominantly different *Streptococcus* species, and the green complex which comprises a preponderance of *Capnocytophaga* species, represent early colonizers of dental plaque which were more closely associated with health. The orange complex contains those organisms generally considered to colonize dental plaque later: *Fusobacteria*, *Prevotella*, and *Campylobacter* species. The presence of these organisms is now thought to facilitate colonization of mature dental plaque by the red complex organisms either through the presentation of appropriate binding sites or by the creation of a suitable environment for the growth of these more fastidious species.

It is noteworthy that *A. actinomycetemcomitans*, the bacterium associated with rapidly progressive disease in individuals of West African descent, does not cluster with the most disease-associated red complex organisms. This probably reflects the very large effect of the host genetic background on the disease associated with this bacterium, as described previously.

Use of the checkerboard technology enabled a range of questions to be addressed concerning, for example, the sequential changes that occur in the composition of supragingival and subgingival plaque during development, and the qualitative and quantitative influence of tooth cleaning on the microbiology of supragingival and subgingival plaque. An example of this kind of study is shown in Fig. 10-6b, which demonstrates the significant qualitative and quantitative differences associated with disease not only in subgingival but also supragingival plaque.

Furthermore, the sensitivity of the checkerboard assay meant it was possible to examine site-to-site variations both between and within individuals and to correlate the differences with periodontal disease experience. For example, Fig. 10-7 demonstrates the changes in 40 bacterial species before and 12 months following therapy at sites which showed improvement in attachment level of >2 mm, sites that showed loss of attachment of >2 mm, and sites where the change in attachment level was intermediate between the two extremes. The data are an excellent representation of the community-wide compositional changes that occur in periodontal samples at sites of different disease outcome. Whilst a major reduction is observed in the red complex group of organisms in those periodontal sites where a gain in attachment level is observed, it is also evident that significant changes also occur in many of

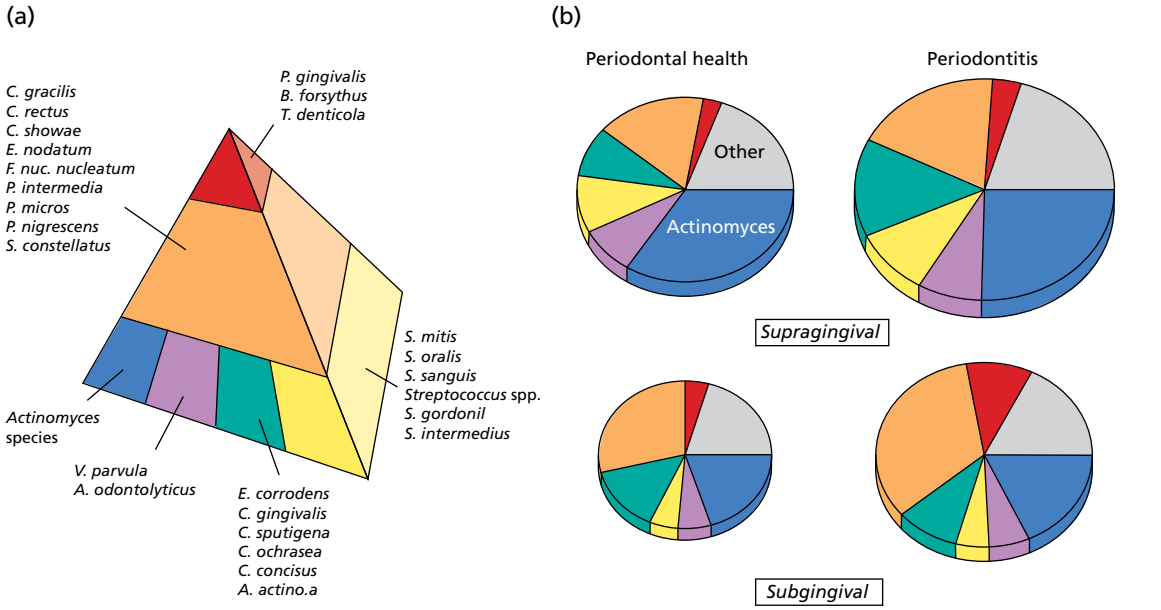

Fig. 10-6 (a) Association among subgingival species. The different colors in the pyramid represent different bacterial complexes which are frequently detected in association with one another. The base of the pyramid represents the early stage of plaque development, whereas the apex contains those organisms thought to be the last species to become established in the microbiota. The red complex of bacteria includes those organisms frequently associated with sites of periodontal disease. (Source: Socransky & Haffajee 2002. Reproduced with permission from John Wiley & Sons.) (b) Pie charts of the mean percentage DNA probe count of microbial groups in supragingival plaque. Plaque samples from periodontally healthy (58) and periodontitis (136) subjects and subgingival plaque samples from periodontally healthy (189) and periodontitis subjects (635). The species were grouped into seven microbial groups based on the description of Socransky *et al.* (1998) and described in more detail in (a). The "other" category represents probes to species that did fall into a complex as well as probes to new species whose relationships with other species has not yet been ascertained. The areas of the pie charts were adjusted to reflect the mean total DNA probe counts at each of the sample locations. The significance of differences in mean percentages of the supra- and sub-gingival complexes in health and disease was tested using the Kruskal Wallis test. All complexes differed significantly among groups (P <0.001 after adjusting for seven comparisons. (Source: Socransky & Haffajee 2008. Reproduced with permission from John Wiley & Sons.)

the other species. Thus, even in this snap shot of 40 microorganisms, it is evident that the overall population structure of the bacteria in a periodontal site may strongly influence disease outcome.

PCR amplification of the *16S rRNA* gene of periodontal bacteria

16S rRNA is a component of the 30S small subunit of all bacterial ribosomes. The genes coding for it are referred to as *16S rDNA*. Although the sequences of *16S rDNA* are highly conserved between different bacteria, they also contain hypervariable regions that can provide species-specific signature sequences useful for bacterial identification. Therefore, once the sequence of a *16S rDNA* gene from a bacterium has been determined, it is possible to design a PCR, using primers which will anneal to sequences within the hypervariable regions, which will specifically amplify only the *16S rDNA* from the target bacterium. The great advantages of the application of this methodology in the detection of periodontal bacteria in clinical samples is the high sensitivity of detection, the high throughput, the assay speed, and the multiple bacterial species that can be detected in the same reaction – multiplex PCR. As a result, this technology has been used extensively for the detection of putative periodontal pathogens. Typically, these studies have focused on the detection of only a few bacterial species, including the well-established periodontal bacteria *P. gingivalis, T. forsythia, T. denticola*, and *A. actinomycetemcomitans* (Leys *et al.* 2002; de Lillo *et al.* 2004; Sanz *et al.* 2004; Tanner *et al.* 2006). However, studies involving PCR amplification of the *16S rDNA* gene have also been used to confirm the presence of novel bacterial species whose presence was originally identified by cloning and sequence analysis of the *16S rDNA* gene in periodontal samples. These investigations confirmed that several additional species, including those that have not yet been grown *in vitro*, were associated with oral health or periodontitis.

The initial studies in this area were largely qualitative in nature in that they only determined whether an organism was present or absent (or more correctly below the limits of detection of the assay – typically 100 bacterial cells). More recently, real-time PCR, also referred to as qPCR or qRT-PCR, has been introduced: it quantifies the numbers of copies of the gene of interest in a given sample. Real-time PCR has been used to detect and quantify several periodontal pathogens, including *A. actinomycetemcomitans*, *P. gingivalis*, and *Prevotella intermedia*, and total bacteria in clinical samples (Lyons *et al.* 2000; Maeda *et al.* 2003; Boutaga *et al.* 2007; Atieh 2008).

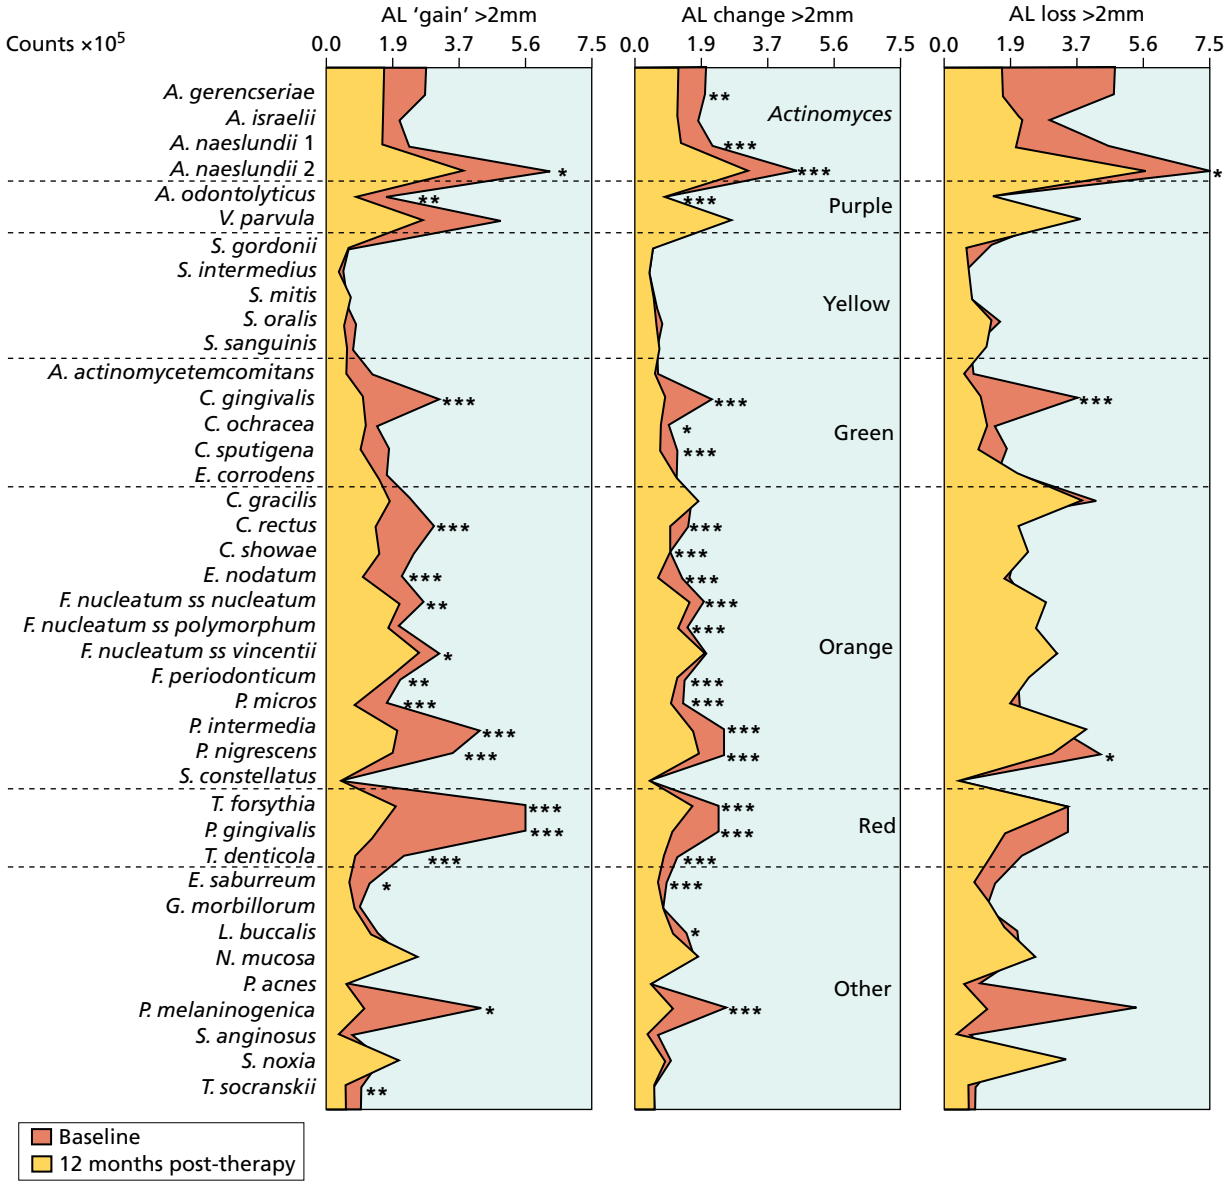

Fig. 10-7 Plots of mean counts (×10[5]) of 40 taxa in subgingival plaque samples at baseline and 12 months following therapy from sites that exhibited attachment level (AL) "gain" of >2 mm, (left panel), change of ≤2 mm (middle panel) or loss of >2 mm (right panel). Counts of each species at sites in each of the three attachment level change categories were determined, averaged within a subject, and then averaged across subjects in the three site categories separately at baseline and 12 months post therapy. Significance of differences between counts at baseline and 12 months was determined using the Wilcoxon signed ranks test and adjusted for multiple comparisons (*P <0.05; **P <0.01; ***P <0.001). Species were ordered according to microbial complexes. (Source: Haffajee *et al*. 2006. Reproduced with permission from John Wiley & Sons.)

Serologic analyses

The largely culture-based investigations which identified a relatively small group of bacteria as potentially key agents in periodontal disease were reinforced by serologic analyses of the antibody response of periodontal patients. These studies have tended to rely upon analysis of the serum IgG antibody response to whole cells of the candidate bacterium in periodontal patients compared to that in healthy age-matched control individuals. They have demonstrated unequivocally that patients with a history of periodontal disease quite frequently display elevated serum IgG antibody titers to several of the candidate periodontal pathogens (Ebersole *et al*. 1982, 1987; Taubman *et al*. 1992; Colombo *et al*. 1998). Hence, it is reasonable to assume that these bacteria, as well as being associated with the disease, also interact with the immune system of periodontitis patients.

The majority of these studies have focused upon a limited number of periodontal organisms, most notably *P. gingivalis* and *A. actinomycetemcomitans*. In the case of the former bacterium, the overwhelming evidence from these investigations indicates a very significant positive association between elevated levels of serum IgG antibodies to this organism and various forms of periodontal disease. In the case of *A. actinomycetemcomitans*, a similar relationship exists, although in this instance the association is most pronounced in the case of localized aggressive

periodontal disease – the form of the periodontitis most closely associated with colonization by this bacterium. Furthermore, multiple investigations indicate that titers to important periodontal pathogens are substantially reduced after successful periodontal therapy (Aukhil *et al.* 1988; Johnson *et al.* 1993; Darby *et al.* 2001). One can therefore conclude that many, although not all, patients experiencing periodontal attachment loss exhibit elevated levels of antibodies to antigens of candidate periodontal pathogen organisms, suggesting that these species gain access to underlying tissues, directly interact with the immune system of the colonized host, and may therefore initiate or at least contribute to the observed pathology.

However, it is also clear that diseased subjects exhibit elevated serum antibody to numerous other oral microorganisms. For example, Ebersole *et al.* (1992) examined the serum antibody response to a panel of organisms including *P. intermedia*, *E. corrodens*, *W. recta*, *F. nucleatum*, and *Capnocytophaga* species, and demonstrated elevated levels of antibody to this panel of organisms in adult periodontitis patients, primarily to *P. gingivalis, E. corrodens,* and *W. recta*. Similarly, elevated serum antibodies to multiple periodontal species have been reported in individuals with chronic periodontitis (Haffajee *et al.* 1995), early-onset periodontitis (Albandar *et al.* 2001), and refractory periodontitis (Hernichel-Gorbach *et al.* 1994; Colombo *et al.* 1998). In a longitudinal study, Papapanou *et al.* (2004) determined the serum IgG antibody reactivity to a range of oral bacteria in 89 patients with chronic periodontitis and 42 control subjects with no deep periodontal pockets and no or minimal attachment loss. In addition to the anticipated elevated antibody responses in the patients compared to the controls to the established periodontal organisms, *A. actinomycetemcomitans*, *P. gingivalis*, *T. forsythensis*, and *T. denticola*, there was clear evidence for elevated immune recognition of multiple other species. These included *P. intermedia*, *P. nigrescens*, *Micromonas micros*, *Campylobacter rectus, F. nucleatum*, *Streptococcus intermedius*, *Eubacterium nodatum*, *Streptococcus oralis*, *Capnocytophaga ochracea*, and *E. corrodens.* Conversely, the controls displayed statistically significantly higher titers against *Prevotella melaninogenica* and *Actinomyces naeslundii*, while no statistically significant differences could be detected in titers to *Porphyromonas endodontalis* and *Veillonella parvula.* Hence, similar to the cultural microbiologic findings, the patterns of the serologic response in periodontal disease are consistent with global shifts in the microbial composition of the microbiota in disease, wherein some species become more predominant whilst others are reduced as a proportion of the total population.

In a variation of these studies, rather than using whole bacterial cells in these assays, which could present a potentially wide range of different surface antigens, preparations of individual cellular constituents, such as the outer membranes in the case of Gram-negative bacteria or selected surface or extracellular antigens, were used as the target antigens. These studies enabled some definition of the specificity of the immune response to periodontal organisms and a start to the identification of the cellular location of the immunodominant antigens. In turn, this led to the characterization of these dominant antigens by more detailed immunochemical analysis, such as Western blotting, as a means to identify putative virulence factors produced by these organisms. For example, in one study of the serum IgG antibody response to outer membrane proteins of *P. gingivalis* (Curtis *et al.* 1991), immunodominant antigens with molecular weights of approximately 105 kDa, 55 kDa, and 47 kDa were identified that were strongly recognized by periodontal patient serum samples, but poorly reactive with sera from age-matched control individuals. Subsequent characterization of the identity and functions of these outer membrane constituents of *P. gingivalis* revealed that the 47-kDa protein represented a component of one of the potent proteolytic enzymes of this bacterium, Arg gingipain (Curtis *et al.* 1999), whilst the other two antigens, RagA and RagB, were components of a cell surface complex involved in outer membrane transport (Hanley *et al.* 1999). These antigens, initially revealed by serologic analysis of the outer membranes, have become recognized as important colonization and virulence determinants of *P. gingivalis*.

Hence, serologic investigations have played an important role both in confirming the association of different bacteria with the disease process, consistent with dysbiosis of the resident microbiota, and in facilitating the discovery of some of the important bacterial factors which are likely to be involved in the interaction of the bacterium with the host. It should be remembered however, that there are some limitations to the methodology: the approach can only be readily applied to those bacteria which can be cultured; growth of a bacterium *in vitro* will not necessarily lead to the expression of the proteins and other cell surface components which the bacterium produces when growing *in vivo*; there may be cross-reacting antibodies present in the serum of periodontal patients which were originally produced by another organism, for example in the gut, unrelated to the periodontal bacterium under study.

Challenge of the unculturable bacteria

As in other environments, a significant proportion of the total oral microbiota remains as yet unculturable and hence non-cultural methods are required to describe the overall species richness of the oral microbiome. Sequence analysis of *16S rRNA* has been the method of choice because of its universal presence in all organisms and because, through PCR primer design, it is possible to describe either all the species present in a given sample or target-specific genera. Application of this approach led to the description of 13 phyla in the domain Bacteria in the human oral microbiome: Actinobacteria, Bacteroidetes,

Chlamydiae, Chloroflexi, Euryarchaeota, Firmicutes, Fusobacteria, Proteobacteria, Spirochetes, SR1, Synergistetes, Tenericutes, and TM7, in addition to methanogenic species of the Methanobrevibacter genus from the domain Archaea. Several hundred distinct species are contained within these divisions, representing the highly diverse microbial communities of the mouth. The periodontal microbiota is particularly heterogeneous and in excess of 400 species have been described in this habitat alone using a *16S rRNA* amplification, cloning, and Sanger sequencing approach (Dewhirst *et al.* 2010). These molecular studies have significantly extended the number of potential periodontal pathogens. For example, based on their *16S rDNA* analysis of subgingival plaque samples from healthy subjects and subjects with refractory periodontitis, adult periodontitis, human immunodeficiency virus periodontitis, and acute necrotizing ulcerative gingivitis, Paster *et al.* (2001) described several new candidates. Species or phylotypes commonly detected in disease but rarely in health included *Eubacterium saphenum, Filifactor alocis* (formerly *Fusobacterium alocis*), *Catonella morbi, Megasphaera* spp., *Dialister* spp., and *Selenomonas sputigena*, and several of these organisms, in particular *F. alocis*, have subsequently been confirmed in other studies to be positively associated with disease.

The Human Oral Microbe Identification Microarray

Recognition of this increased and substantial microbial diversity through the identification of lower abundance species and organisms not amenable to routine laboratory culture has led to the development of a new diagnostic methodology capable of the rapid identification of greater numbers of bacterial phylotypes in periodontal infections (Paster & Dewhirst 2009). The Human Oral Microbe Identification Microarray (HOMIM) was developed in order to examine the complex oral microbial diversity in a single hybridization on glass slides (Paster *et al.* 2006; Preza *et al.* 2008, 2009b). This high sample-throughput, *16S rRNA*-based technology allows the simultaneous detection of approximately 300 key and predominant bacterial species, including species that have not yet been cultivated. *16S rRNA*-based, oligonucleotide probes are printed onto glass slides. The *16S rRNA* genes in clinical samples are PCR amplified using *16S rRNA* universal forward and reverse primers, fluorescently labeled and then hybridized to the probes on the slides. In order to analyze the large datasets from HOMIM arrays, individual signals are translated into a "bar code" format in which the bands correspond to the presence or absence of a particular organism and band intensities reflect the organism's abundance. Figure 10-8 illustrates the bar code format of HOMIMs comparing the microbial profiles of approximately 300 bacterial species from subjects with periodontal health and periodontitis. These data can be analyzed further to determine specific bacterial associations (Colombo *et al.* 2009; Preza *et al.* 2009a, b) or the relationships of *entire* microbial populations with respect to health and disease using correspondence analysis, as shown in Fig. 10-9. The dramatic difference in the overall bacterial population structure of these two sets of data vividly reinforces the findings of the total cultural microbiology studies performed some 30 years ago and is consistent with dysbiosis of the microbiota as a defining characteristic of periodontal disease.

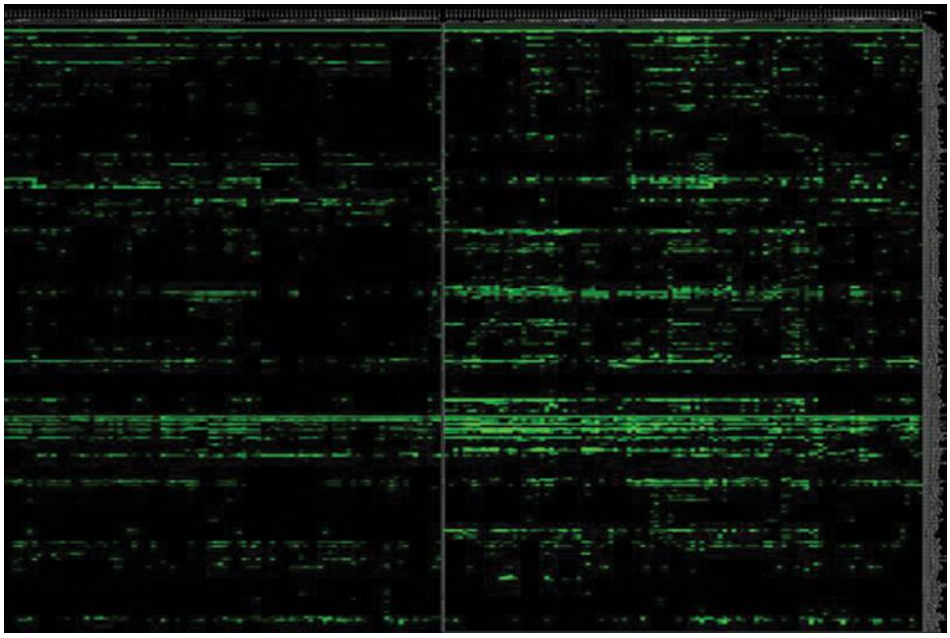

Fig. 10-8 Bacterial profiles of 461 bacterial taxa (representing approximately 300 species) comparing subgingival plaque from 105 healthy sites in periodontally healthy subjects (n = 20) (left panel) to 154 diseased sites from periodontally diseased subjects (n = 47) (right panel). Fig 10-9 Correspondence analysis (CA) of subgingival plaque bacterial communities in health and disease. Each symbol represents one community from one site. Communities that are closer together have more similar HOMIM profiles. In this plot, the healthy sites from healthy subjects (green circles) are distinct from healthy and diseased sites in diseased subjects (red symbols). (Courtesy of Dr Vanja Klepac-Ceraj, Forsyth Dental.)

Whilst these findings have significantly enhanced our understanding of the oral microbiome, they have also highlighted the likelihood that there may be an additional large number of low abundance species which have remained undetected using this standard methodologic approach, largely because of the relatively time-consuming and laborious nature of the techniques. This issue is now being addressed through the application of deep sequencing methods, in particular pyro-sequencing technologies which enable a more comprehensive coverage of the *16S rRNA* sequences in large numbers of samples.

High throughput sequencing revolution

Application of next-generation DNA sequencing to the oral and periodontal microbiota in health and disease is the newest technological advance in our study of these consortia. Although relatively few large-scale studies have been undertaken, there are indications that it may be necessary to revise our estimates of the species richness of the oral microbiome, perhaps by a factor of 10. For example, in a study of the microbiota of saliva and supragingival plaque from 71 and 98 healthy adults, respectively, amplicons from the V6 hypervariable region of the small-subunit *rRNA* gene were generated by PCR and sequenced by means of 454 technology. The 197 600 sequences analyzed were suggested to represent 22 phyla comprising 3621 and 6888 species-level phylotypes in saliva and plaque, respectively (Keijser *et al.* 2008). However, these early data need to be viewed with some caution as it is well recognized that the errors inherent in pyrosequencing, particularly of homopolymeric tracts, may lead to over estimation of the total number of unique sequences in a given sample. The development of increasingly sophisticated software to minimize these problems should lead to increasingly accurate estimates of the species diversity of the oral microbiome and indeed more recent investigations have tended to suggest more conservative phylotype numbers (Zaura *et al.* 2009). Nonetheless, the application of high throughout sequencing approaches, particularly to comparative analyses of health and disease, are likely to lead to increasing insights into the range of bacterial species associated with the development of pathology. For example, this technology has been applied to compare the total oral, gut, and atherosclerotic plaque microbiota in patients with atherosclerosis (Koren *et al.* 2011). This comprehensive analysis indicated that bacteria from the oral cavity, and perhaps even the gut, may correlate with disease markers of atherosclerosis (Fig. 10-10). A significant challenge in this area will be the analysis and interpretation of these high volumes of data: whilst the frequent condensation of high granularity phylotype information to the phylum or genus level, which is evident in much of the published literature on human microbiomes, enables ready comparison of different datasets, this practice does not maximize the value of these high throughput approaches.

Genetic variation

A further layer of complexity to the microbial diversity of the periodontal microbiota derives from the genetic variation between different isolates of the same bacterial species caused by changes to the bacterial chromosome over time. These changes can result from random point mutations during chromosomal replication, and internal genome rearrangement and duplications during recombination events. Furthermore, it is clear that genetic exchange between different bacterial species may be a very significant force in bacterial genome evolution. For example, it is well established that bacterial pathogenicity factors may be encoded by transmissible genetic elements, including plasmids, bacteriophages or transposons, which have the capacity to spread between different bacterial populations. Furthermore, the study of bacterial genomes in the last decade has revealed that bacterial virulence determinants are frequently encoded in regions of the genome which appear to have arisen via horizontal gene transfer from a separate organism. These pathogenicity islands are specific chromosomal elements which can occupy quite large regions often flanked by mobility genes such as insertion sequences. Mutations during replication and acquisition of additional genetic loci through horizontal gene transfer both increase the flexibility of a bacterial species and can contribute to the spread and evolution of virulence.

These intraspecies chromosomal variations result in the generation of a population structure for each species. In some instances, this variation leads to

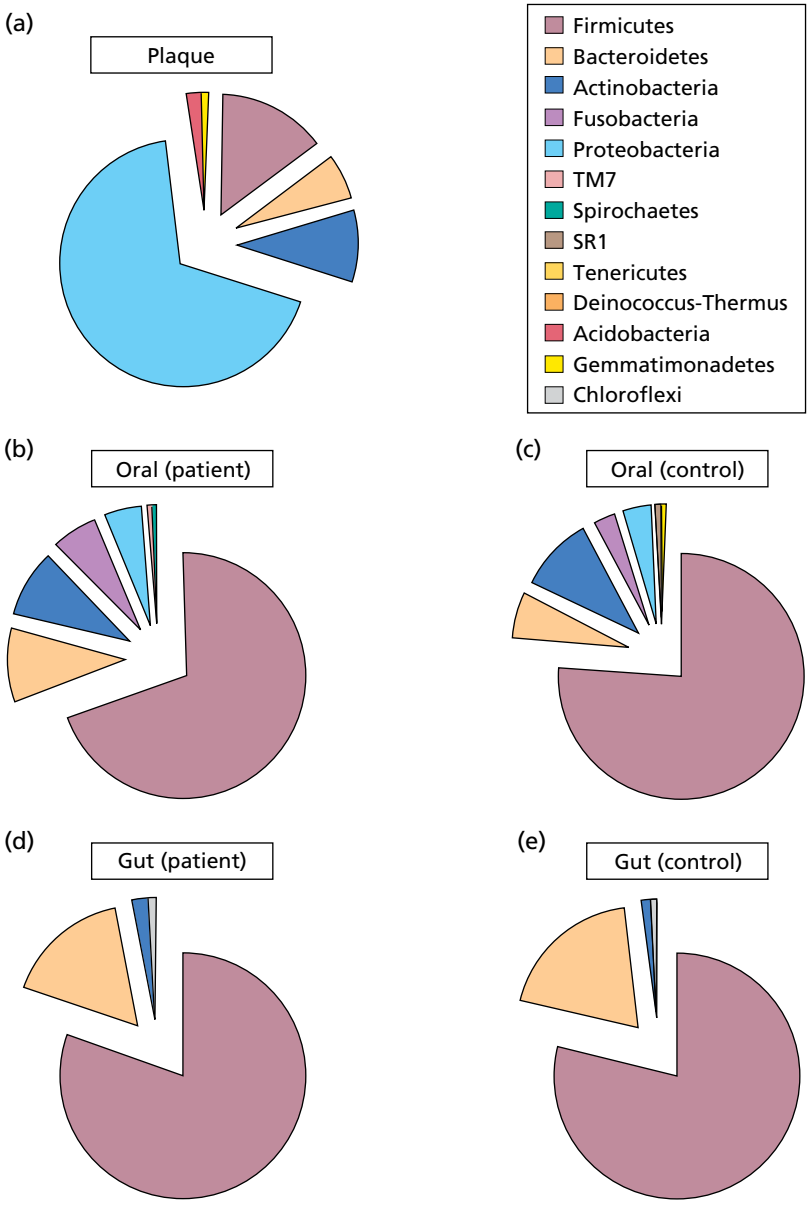

Fig. 10-10 Composition of the microbiota at different body sites in patients with atherosclerosis and controls determined by pyrosequencing. Plotted values are mean sequence abundances in each phylum for 1700 randomly selected sequences per sample. (a) Atherosclerotic plaque; (b) oral cavity, patient; (c) oral cavity, control; (d) gut, patient; (e) gut, control. (Source: Koren *et al*. 2011. Reproduced with permission from PNAS and R.E. Ley and F. Bäckhed.)

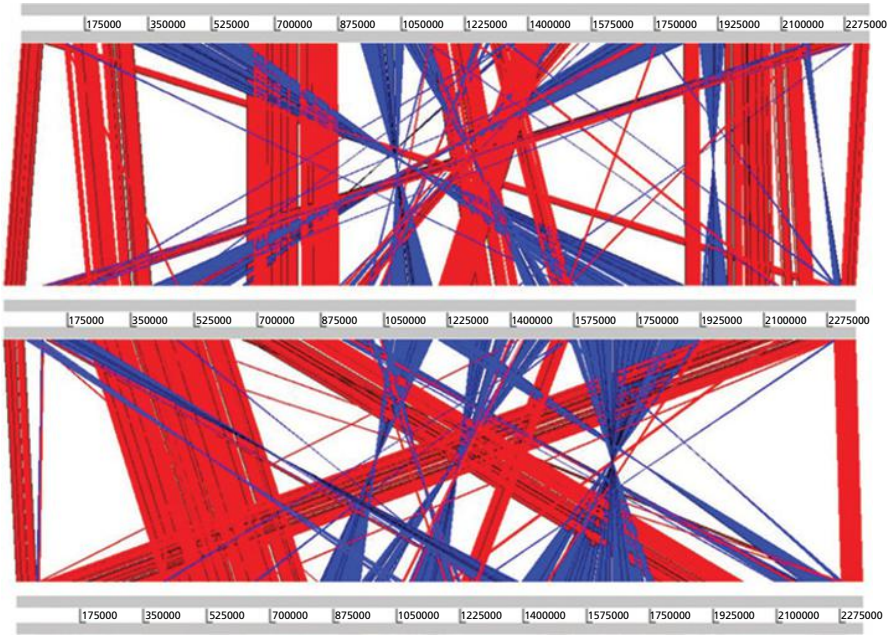
the generation of distinct clonal types, some of which may have properties which cause them to be responsible for the majority of the disease caused by that particular bacterial species. A good example of this in the periodontal microbial field *A. actinomycetemcomitans*, an organism which is strongly implicated in periodontal disease in individuals of West African descent, most especially through a specific clonal type, referred to as JP2. In this instance, as previously described, the chromosomal change which has resulted in a more clinically deleterious phenotype involves a small genetic deletion upstream of the leukotoxin gene of this organism. This has placed the transcription at this locus under a stronger promoter than in the original locus, leading to elevated synthesis of this virulence determinant.

At present, the JP2 clone of *A. actinomycetemcomitans* remains the most persuasive example of how genetic variation within a periodontal bacterial species can lead to the generation of a more virulent clonal type and consequent variation in the disease potential within the species. However, good evidence from the *in vitro* assessment of other periodontal organisms suggests that intraspecies genetic variation will also play a role in the disease potential of these bacteria. For example, the virulence potential of different isolates of *P. gingivalis* has been examined using a number of *in vivo* animal models and *in vitro* systems. It is clear from these experiments that there is highly significant variation within this species, for example in its capacity to cause disease in murine infection models, suggesting that genetic variation between different strains may have a significant



P. gingivalis strain	Genome size (bp)	% Guanosine-cytosine	Genes encoded	Strain specific genes	Reference
W83	2 343 476	48.30	1,990	415	(Nelson *et al.* 2003)
ATCC33277	2 354 886	48.40	2,090	461	(Naito *et al.* 2008)

Fig. 10-11 Comparison of the genome organization of three strains of *P. gingivalis:* W83, ATCC33277, and TDC60. Each genome is shown as a numbered gray bar representing the forward and reverse strands. Top: *P. gingivalis* W83; middle: *P. gingivalis* ATCC 33277; bottom *P. gingivalis* TDC60. The red lines between the genomes represent DNA–DNA homologies between the two forward sequences. The blue lines represent homologies between the forward strand of the upper sequence and the reverse complement of the lower sequence. The analysis demonstrates very extensive rearrangements of the genetic material in these three strains which will contribute to the interstrain variation in their biologic properties.

influence on their role in periodontal disease in human populations.

An example of the genetic diversity within *P. gingivalis* is shown in Fig. 10-11, which compares the genomes of three isolates of this species which have been sequenced in recent years. Figure 10-11 demonstrates that while the total genome size of all three isolates is approximately the same (2.3 Mb), each strain contains several hundred strain-specific genes (i.e. genes which are not present in the other two strains) and there has been extensive rearrangements of the bacterial chromosomes over time; these could also have an influence on gene expression in the different isolates and consequent properties in an infection. Hence, whilst routine diagnostic microbiology may indicate that a clinical sample contains a given bacterial species such as *P. gingivalis*, the genetic variation within that species suggests that different isolates may present quite different challenges to the periodontal tissues.

Influence of a biofilm lifestyle

Microbial biofilms consist of one or more communities of microorganisms, embedded in a largely carbohydrate matrix, that are attached to a solid surface. The biofilm allows microorganisms to adhere to and multiply on surfaces. Thus, attached sessile bacteria growing in a biofilm display a wide range of characteristics that provide a number of advantages over single-cell, planktonic bacteria. The interactions among bacterial species living in biofilms take place at several levels, including physical contact, metabolic exchange, small signal molecule-mediated communication, otherwise known as quorum sensing, and exchange of genetic information (Kolenbrander *et al.* 2006; Newman & Wilson 1999; Socransky & Haffajee 2002; Marsh 2005). A more detailed description of dental plaque as a biofilm is given in Chapter 8.

The key characteristic of a biofilm is that the microcolonies within the biofilm attach to a solid surface. Thus, adhesion to a surface is the essential first step in the development of a biofilm. In the mouth, there is a wide variety of surfaces to which bacteria can attach, including the oral soft tissues, the salivary pellicle-coated teeth, other bacteria, as well as prosthetic replacements such dentures and implants. Many bacterial species possess surface structures such as fimbriae and fibrils that aid in their attachment to different surfaces. Fimbriae have been detected on a number of oral species, including *A. naeslundii, P. gingivalis, A. actinomycetemcomitans*, and some strains of streptococci, such as *Streptococcus salivarius, Streptococcus parasanguinis*, and members of the *Streptococcus mitis* group.

Fibrils can be found on a number of oral bacterial species. They are morphologically different and shorter than fimbriae, and may be densely or sparsely distributed on the cell surface. Oral species that possess fibrils include *S. salivarius*, the *S. mitis group*, *P. intermedia*, *P. nigrescens*, and *Streptococcus mutans*.

In the case of dental plaque, it is clear from the extensive microscopic analysis undertaken over the last 50 years on *ex vivo* samples, that there is a very ordered structure to the biofilms adherent to the tooth surface. A section of human supragingival dental plaque grown on an epon crown in a human volunteer is shown in Fig. 10-12a (Listgarten *et al.* 1975; Listgarten 1976, 1999). The section demonstrates many of the characteristic features of biofilms outlined earlier. Bacterial cells have adhered to the solid surface, multiplied, and, in this section, formed columnar microcolonies. The heterogeneity of colonizing species is evident even at a morphologic level and yet there is a clear pattern of organizational structure to these bacterial masses. The surface layers of the biofilm exhibit morphotypes that are not evident in deeper layers, perhaps indicative of the role of bacterial succession in the development of the complex microbiota and potentially of the role that co-aggregation plays in the development of biofilms. Not evident in this section are the water channels in biofilms which are thought to be features common to most biofilms in nature. This might be due to preparation or fixation artifacts (Costerton *et al.* 1999). Water channels have been observed in plaque grown in the human oral cavity by confocal microscopy (Wood *et al.* 2000). This dental biofilm has all of the properties of biofilms in other habitats in nature. It has a solid substratum, in this case an epon crown but more typically a tooth, mixed microcolonies growing in a glycocalyx, and the bulk–fluid interface provided by saliva.

A second biofilm ecosystem, this time of human subgingival plaque is shown in Fig. 10-12b. The section is at lower magnification than that shown in Fig. 10-12a to permit visualization of regions within the biofilm. The plaque attached to the tooth surface is evident in the upper left portion of the section. This tooth-associated biofilm is an extension of the biofilm found above the gingival margin and may be quite similar in microbial composition. A second, possibly epithelial cell-associated biofilm may be observed lining the epithelial surface of the pocket. This biofilm contains primarily spirochetes and Gram-negative bacterial species (Listgarten *et al.* 1975; Listgarten 1976, 1999). *P. gingivalis* and *T. denticola* have been detected, by immunocytochemistry, in large numbers in the epithelial cell-associated biofilms within the periodontal pocket (Kigure *et al*. 1995). *T. forsythia* might also be numerous in this zone, since high levels of this species have been detected, using DNA probes, in association with the epithelial cells lining the periodontal pocket (Dibart *et al*. 1998). Between the tooth-associated and epithelial cell-associated biofilms, a less dense zone of organisms may be observed. These organisms may be "loosely attached" or they may be in a planktonic state. The critical feature of Fig. 10-12b is that there appear to be tooth-associated and epithelial cell-associated regions in subgingival plaque as well as a possible third weakly attached or

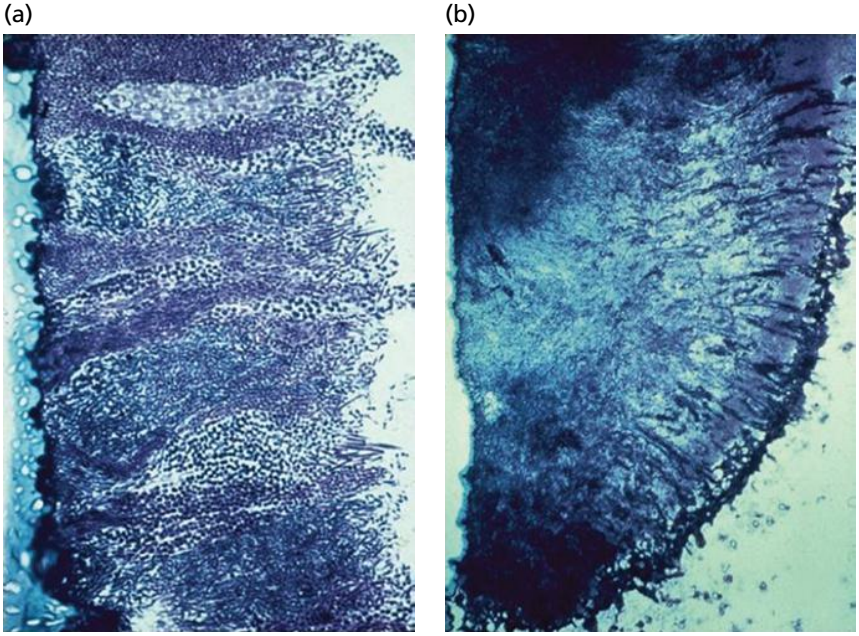

Fig. 10-12 (a) Histologic section of human supragingival plaque stained with toluidine blue–methylene blue. The supragingival plaque was allowed to develop for 3 days on an epon crown in a human volunteer. The crown surface is on the left and the saliva interface is towards the right. (b) Histologic section of human subgingival dental plaque stained with toluidine blue–methylene blue. The tooth surface is on the left and the epithelial lining of the periodontal pocket is on the right. Bacterial plaque attached to the tooth surface is evident towards the upper left of the section, while a second zone of organisms can be observed lining the periodontal pocket wall. (Courtesy of M. Listgarten, University of Pennsylvania.)

unattached zone of microorganisms. It is highly likely that these regions differ markedly in microbial composition, physiologic state, and their response to different therapies.

The markedly different environmental conditions prevailing within a biofilm compared to a free-living planktonic state have a significant influence on the properties of the resident organisms. Changes to, for example, the availability of nutrients, local conditions of pH and redox potential (Eh), and the presence of bacteria producing bacteriocidal agents to other species and signaling molecules from the same and different species are all considered to be pivotal to alterations in gene expression of bacteria in sessile versus planktonic conditions. Such altered patterns of gene expression and the resultant influence on the phenotype of periodontal bacteria growing in biofilms have been demonstrated in several studies. For example, Lo *et al.* (2009) compared the overall transcription of genes of *P. gingivalis* in either the planktonic or biofilm state grown in continuous culture. Approximately 18% of the *P. gingivalis* genome was differentially expressed when the bacterium was grown as a biofilm. This included genes involved in the formation of the cell envelope, DNA replication, energy production, and biosynthesis of co-factors, prosthetic groups which were all down-regulated in biofilm cells. Conversely, genes encoding transport and binding proteins were up-regulated. The study also demonstrated that several genes predicted to encode proteins involved in signal transduction and transcriptional regulation were differentially regulated and may be important in the regulation of biofilm growth. Analysis of the total proteome of *P. gingivalis* cells grown under similar conditions confirmed the widespread changes to the phenotype of the bacterium when grown in a biofilm (Ang *et al.* 2008). Similar studies are now being performed on mixed cultures of periodontal organisms grown together in biofilms to determine the influence that intimate association between these organisms will have on the patterns of gene and protein expression (Zainal-Abidin *et al.* 2012).

The recognition that growth in a biofilm leads to profound changes in the properties of bacteria has led to the development of experimental systems to study the growth and biologic features of bacterial populations grown under sessile conditions. An example of one such system, in this case using a mixture of supragingival and subgingival microorganism, is shown in Fig. 10-13. The formation of organized structures of microcolonies of different organisms with discrete spatial localization and the presence of channels through these structures mimics the patterns of microbial organization observed in the *ex vivo* dental plaque samples in Fig. 10-12. Models of this kind therefore have great utility for the study of the growth of periodontal bacteria in mixed culture in a biofilm state in order to address issues pertinent to dental plaque development and accumulation, and control using antiseptic and host-derived antimicrobial systems. Furthermore, when grown under conditions mimicking the *in vivo* state, they provide experimentally important bacteria and bacterial products for further phenotypic analysis and use in *in vitro* systems of virulence.

Periodontal bacteria and virulence

The virulence of a microbial pathogen is generally defined as the degree of pathogenicity or ability of the organism to cause disease as measured by an experimental procedure. It represents a combination of highly complex parameters and depends upon both the relative infectivity of the organism and the severity of the disease produced. However, in all cases, these two parameters of infectivity and disease severity are profoundly influenced by the nature and status of the host organism or the site of colonization in that host. Thus, a breach in the normal defensive barriers of the host through, for example, trauma, immunosuppression/dysfunction or co-infection by another organism, can dramatically increase the virulence of a given organism. Hence, any description of microbial virulence is fundamentally reliant on an understanding of the relative susceptibility of the colonized host.

The requisite stages in the life cycle and spread of one organism which parasitizes another are presented in Fig. 10-14. The key steps are: initial colonization and attachment; multiplication and nutrition; evasion of the host defenses; (in some cases) invasion; and, lastly, exit in order to disseminate to a new host. Specific gene products (presumptive virulence factors) are required to facilitate each of these processes, and these products will vary from organism to organism dependent upon the particular strategy employed to satisfy each element of the life cycle. The gene products or traits associated with each step in the life cycle presented in Fig. 10-14 represent examples drawn from multiple organisms. Disease can be defined as the unfavorable outcome in the host from the application of these life cycle stages of the pathogen in a *susceptible* host background.

The virulence determinants of a pathogen can simply be defined as those gene products which facilitate colonization, growth, and survival within the diseased host organism and spread to a new host. Examples of the virulence properties of some key periodontal organisms, *P. gingivalis, A. actinomycetemcomitans, T. forsythia*, and *T. denticola*, are given in Table 10-3. In most cases, the rationale for considering these determinants to be important determinants of the virulence of these organisms is derived from a wealth of *in vitro* investigations and/or animal models employing isogenic mutants of the gene of interest. Further details of the properties of these organisms in relation to the pathogenesis of disease can be found in recent reviews on this subject (Hajishengallis 2009; Henderson *et al.* 2010; Sharma 2010; Dashper *et al.* 2011; Bostanci & Belibasakis 2012). However, an emerging key

property of several of these organisms concerns the strategies they appear to employ in order to evade the host defenses operative in the periodontium.

It is becoming increasingly evident that microbial organisms, having co-evolved with the innate defense systems of their respective hosts, have developed strategies not only to overcome protective host barriers but also to manipulate these systems to their own advantage. One example of this phenomenon is the ability of cell surface proteins of both Gram-negative and Gram-positive bacteria, including *A. actinomycetemcomitans* and *P. gingivalis*, to influence the pattern of cytokine expression by host cells. The term "bacterial modulins" was introduced by Henderson, Poole, and Wilson to describe these bacterial cytokine-inducing molecules because of their ability to modulate eukaryotic cell behavior (Henderson *et al.* 1996). More recently, a sophisticated manipulation of the host response by *P. gingivalis* has been described as a consequence of the biologic properties of different molecular species of the lipid A portion of the lipopolysaccharide (LPS) of this bacterium (Darveau *et al.* 2004). Some of these lipid A species are able to act as agonists of the host response through Toll-like receptor signaling, and thus have similar biologic properties to the hexa-acylated lipid A species of enteric

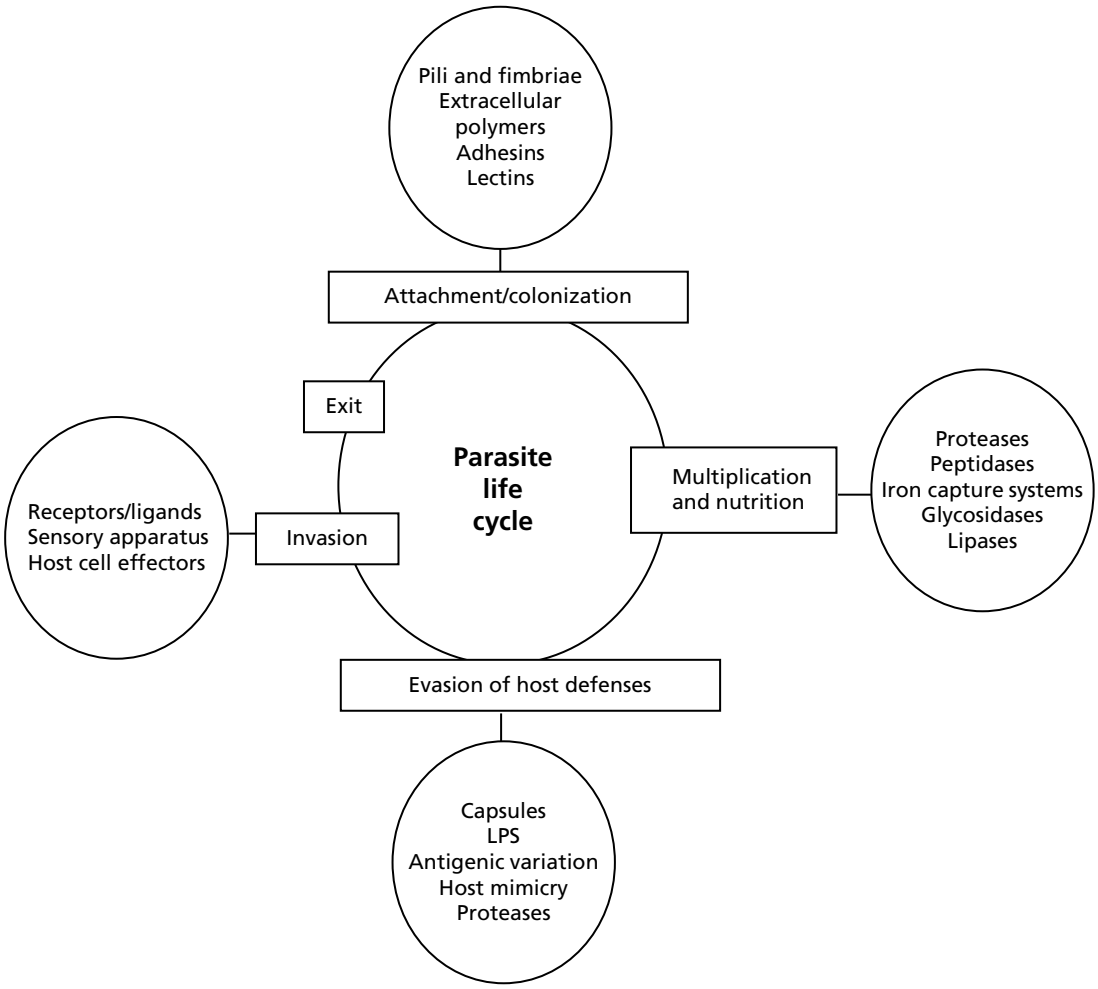

Fig. 10-14 Essential components of the parasite life cycle. Successful colonization and transmission of a parasite is dependent upon the ability to attach, multiply, evade host defenses, invade and exit the host. These processes each require specialized gene products and processes. (LPS, lipopolysaccharide.) (Adapted from Curtis *et al*. 2005, from John Wiley & Sons.)

organisms. Conversely, other lipid A moieties produced by *P. gingivalis* act as antagonists of this signaling pathway and are able to block the activity of the pro-inflammatory lipid A forms. This has led to the suggestion that by altering the proportions of the different lipid A components, *P. gingivalis* may be able to manipulate the innate response in order, for example, to down-regulate the inflammatory response as a defensive measure.

An additional evasive measure practiced by some of the better characterized periodontal bacteria, a component of the so-called "stealth technology", involves entry into other host cells, primarily epithelial cells, to gain access to an immune-privileged site (Lamont & Jenkinson 1998; Fives-Taylor *et al.* 1999; Meyer *et al.* 1999). Verification of this process *in vivo* is now emerging from the detection of these and other species using fluorescent labeling within buccal epithelial cells taken directly from the mouth (Fig. 10-15) (Rudney *et al.* 2005). In the case of *P. gingivalis*, the organism has been shown to rapidly invade epithelial cells derived from the human gingiva and accumulate and persist in high numbers with a perinuclear localization (Lamont & Jenkinson 2000).This positioning is similar to the localization observed for purified preparations of RgpA, which is able to translocate the plasma membrane of epithelial cells (Scragg *et al.* 2002). While the precise mechanism is still under investigation, FimA, a major fimbriae, and the gingipain proteinases are required for the attachment and internalization of the bacterial cells. In the case of *A. actinomycetemcomitans*, while the precise details of the mechanism are unknown, there is a suggestion that the invasion process may be augmented by soluble CD14 derived from saliva (Takayama *et al.* 2003).

The recognition that the virulence properties of some of the key organisms involved in periodontal disease may be more directed towards an anti-inflammatory or subversive phenotype is leading to a new appreciation of the etiopathogenesis of the disease process and this is presented in the final section of this chapter.

Microbial pathogenesis of periodontal disease

The extensive microbiologic analyses of periodontal infections over the last 100 years have led to the formulation of a number of hypotheses on the fundamental nature of the pathogenesis of the disease. In each

TLR, Toll-like receptor; IL-8, interleukin-8.

case, bacteria in dental plaque are acknowledged to be the critically important agent in driving an inflammatory response in the periodontal tissues, which can ultimately lead to destructive disease. Hence, whilst the processes of irreversible destruction of the soft tissues of the periodontium and the bony support structures of the teeth occur through host-mediated mechanisms, these are dependent upon stimulation by a bacterial challenge. However, the underlying principles of each of these hypotheses differ significantly.

It was first believed that periodontal disease was the cumulative effect of all the bacterial species found

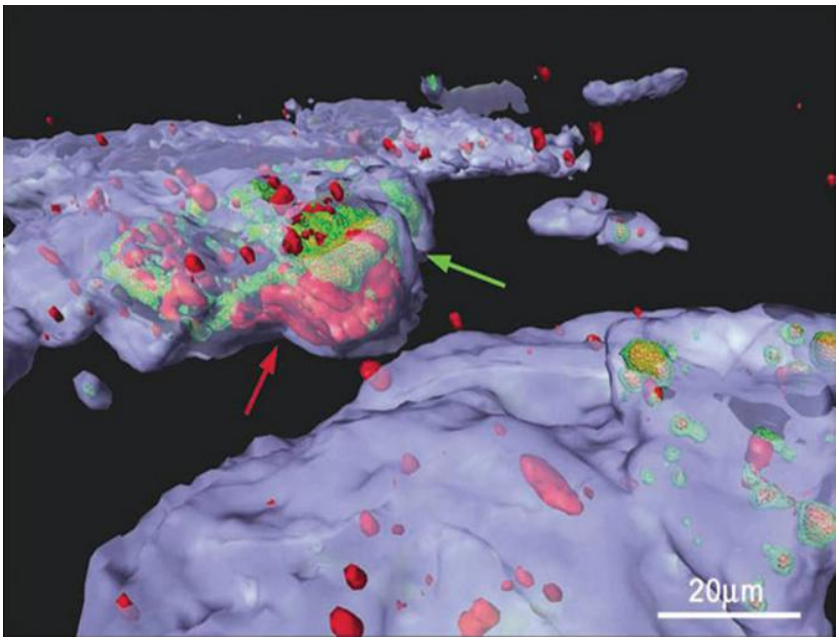

Fig. 10-15 Intracellular bacteria in buccal epithelial cells. A three-dimensional reconstruction of buccal epithelial cells stained using a specific probe for *A. actinomycetemcomitans* (green) and a universal probe for all bacteria (red). Bacteria recognized only by the universal probe are shown in solid red, while co-localization of the *A. actinomycetemcomitans* and universal probes is depicted by a green wireframe over a red interior. Reconstructed buccal epithelial cell surfaces are presented in blue. The red and green colors are muted when bacterial masses are intracellular, and brighter when bacteria appear to project out of the surface. The large mass which appeared to have a lobular structure was seen to be a cohesive unit containing *A. actinomycetemcomitans* in direct proximity to other species (red and green arrows). (Adapted from Rudney *et al*. 2005, from Sage.)

in dental plaque. This *non-specific plaque hypothesis* held that the precise microbial composition of dental plaque was not the critical determinant of disease, rather it was the magnitude of the total bacterial challenge, or the amount of dental plaque, in juxtaposition with the periodontal tissues, that was the overriding factor determining the balance between health and disease. The origins of this hypothesis extend as far back as the end of the 19th century when bacterial isolation and identification techniques were still in their infancy. Gradually, this non-specific view of the etiology came under increasing scrutiny. First, it was clear that the presence of large accumulations of dental plaque in some individuals did not lead to destructive disease or, in some instances, even mild symptoms of inflammation. Furthermore, the increased sophistication of clinical microbiology was beginning to demonstrate that there were very marked differences in the microbial composition of dental plaque taken from sites in patients with disease in comparison to healthy sites in the same patient or indeed from healthy individuals. Hence, the prevailing view altered to one in which the presence and potential overgrowth of specific bacteria, or periodontal pathogens, was decisive.

The *specific plaque hypothesis* (Loesche 1979) has since provided the conceptual framework for much of the investigation of the microbial etiology of periodontal disease. More detailed investigations of the microbiota has led to the identification of increasing numbers of bacterial species which appear to be more associated with disease than health. Patterns in the association between different bacterial species in different clinical conditions were observed and encouraged the view that there may be specific combinations or complexes of species that are the most critical in the development of disease. Importantly, the pathogenic potential of some of these candidate species, either singly or in combination, came under investigation in both animal models and *in vitro* systems. This led to the development of plausible biologic mechanisms by which these specific organisms could contribute to the promotion or deregulation of an inflammatory response and/or impaired immune defense of the periodontal tissues.

The diagnostic and treatment implications of the specific plaque hypothesis are self-evident. If specific bacterial species are the driving force of the disease, then identification of the presence of these organisms in an individual ought to be helpful in predicting clinical outcome. Furthermore, targeted treatment strategies which aim to eliminate or at least control these particular organisms, rather than necessarily attempting to eliminate the entire microbial population, should be clinically beneficial. The specific plaque hypothesis also raises the issue of where and how these organisms are acquired. If they are acquired exogenously, that is transmitted from another individual rather than being component members of the oral microbiota acquired early in life, then strategies which prevent or limit transmission in the human population could be considered beneficial in the same way as prevention of transmission of more well-known medically important human pathogens is an accepted and successful public health measure.

This latter issue has been subsequently addressed by an alternative hypothesis – the *ecological plaque hypothesis* (Marsh 2003). In this thesis, the contribution of the environment in which the bacteria of dental plaque reside is paramount. The varying abilities of different bacteria to grow and proliferate under different environmental conditions will dictate the balance of microbial communities at any given site on the tooth surface. For example, in a periodontal pocket where the pH can rise to well over 7, those bacteria most well suited to grow at alkaline pH will be able to out compete those bacteria most suited to more acidic conditions. Similarly, organisms able to withstand the antimicrobial properties of the host's inflammatory response will be more predominant at inflamed sites in the periodontium than those bacteria ill-equipped for this injurious environment. Hence, the composition of microbial communities in disease will be intimately linked to the environmental conditions prevalent at a diseased site.

Shifts in the environmental conditions due to, for example, the introduction of different nutrients with the arrival of a plasma exudate in the form of gingival crevicular fluid (GSF), will lead to concomitant shifts in the microbial community. Organisms previously limited in their growth due to, for example, only very low concentrations of the iron source, hemin, will have the nutritional capacity to increase in number and potentially out compete those bacteria most frequently found in health where low or no GCF is present. Those bacteria able to withstand the killing effects of migratory phagocytic cells will be able to increase in number at the expense of those organisms susceptible to these killing mechanisms. In so doing, the newly selected microbial community will present a different and potentially more injurious challenge to the periodontal tissues and hence the escalation of increasing inflammation coupled to frustrated bacterial clearance will continue. Importantly, the ecological plaque hypothesis allows for the fact that potential periodontal pathogens may be present in health, albeit in relatively low numbers, but with the capacity to become more dominant members of the community when the environmental conditions favor their competitiveness over the other, more health-associated, members of the microbiota. Thus, this hypothesis can explain the microbial specificity of the disease without the requirement for the acquisition of these periodontal pathogens via an exogenous route of transmission in order to initiate the disease.

This evolving view of the pathogenesis of periodontal disease now has a further modification which incorporates elements of all the preceding views, both specific and non-specific, and acknowledges the fundamental importance of dysbiosis of the normally benign microbial populations of the tooth surface in the development of disease (Darveau *et al.* 2012). The essence of this more recent concept of pathogenesis comes primarily from the recognition of the global population changes that occur to the microbiota in periodontal disease. However, it is significantly reinforced by observations in the mouse model of periodontal disease showing that one of the presumed key specific agents of the disease, *P. gingivalis* – a member of the "red complex" of periodontal bacteria, contributes to disease by altering the normal oral microbiota to a dysbiotic state (Hajishengallis *et al.*, 2011). These studies demonstrated that the oral commensal microbiota is responsible for the tissue and bone destruction associated with periodontitis when just low numbers of *P. gingivalis* are present.

This finding helps explain an apparent paradox associated with *P. gingivalis* being regarded as a key specific agent in periodontal disease when several lines of investigation have demonstrated that this bacterium is not a potent inducer of inflammation (Curtis *et al.* 2011). For example, as described earlier in this chapter, the LPS of *P. gingivalis* has an unusually low inflammatory potency and furthermore this bacterium is able to synthesize a lipid A structure that inhibits rather than promotes inflammation through antagonism of one of the innate immune receptors for LPS, Toll-like receptor 4. This is in stark contrast to the highly inflammatory properties of the LPS produced by most other bacteria and challenges the view that exacerbation of the inflammatory response by *P. gingivalis* is a driving force in the development of periodontal disease. In addition, *P. gingivalis* is unusual in that it does not induce secretion of interleukin-8 (IL-8) by gingival epithelial cells, unlike a variety of other oral bacteria. Instead, it actually inhibits the secretion of this potent chemokine for neutrophil recruitment through a phenomenon termed local chemokine paralysis (Darveau *et al.* 1998). Once again, such an anti-inflammatory property, in this case down-regulation of phagocytic cell trafficking into the periodontium, is contrary to the properties one would anticipate to be a prerequisite of an organism which drives the disease process through up-regulation of the inflammatory response. These apparent paradoxes can however be explained if periodontitis is viewed as a community disease reliant upon an entire dysfunctional microbiota as opposed to the traditional view of a conventional infectious disease caused by a single, multiple or indeed complexes of periodontal pathogens.

The evidence that the commensal microbiota may significantly contribute to periodontitis was obtained when the disease experience of germ-free mice, which are not colonized with any bacteria, was compared to that of the well-established *P. gingivalis* murine model of periodontal disease with an intact commensal microbiota. Although both groups of mice were colonized in the oral cavity to the same extent with *P. gingivalis*, only the mice with a commensal microbiota developed bone loss. Furthermore, in the conventional animals, there was a very significant change in the commensal microbiota. First, the total load of the commensal organisms rose by approximately 2 log10 units. Second, there was a qualitative shift in the

population structure of this commensal microbiota, leading to loss of detection of some organisms and the appearance of others. The demonstration that *P. gingivalis* colonized both germ-free and conventional animals, yet only the conventional mice developed disease, and the very significant changes in the oral commensal community in these animals, indicated that the commensal bacteria themselves are necessary for and directly contribute to the bone loss observed in this model. In addition, and based upon the fact that *P. gingivalis* was present in very low abundance yet had such a profound effect on both the amount and composition of the oral microbiota and resulted in periodontal disease, this bacterium was designated a "keystone" species in this work. The concept of a keystone species derives from ecologic studies and is defined as a species that is present in low abundance yet provides a major supporting role for an entire ecologic community (Hajishengallis *et al.* 2012).

Hence, admittedly only in a model of the disease, *P. gingivalis* contributes to destructive periodontitis in an indirect fashion. Rather than a direct effect on host tissue function, its presence, even at low abundance, alters the total commensal microbial load and composition which overwhelms normal host tissue protective mechanisms and results in disease. The qualitative changes in the microbiota may include an increase in the numbers of more harmful bacteria and/or a shift in the balance of the microbiota away from organisms which are potentially protective. The mechanisms through which *P. gingivalis* accomplishes this significant microbial change are still only partially understood, but are probably related to inhibition of key features of the normal host protective mechanisms in the periodontium, as shown in Fig. 10-16. Consistent with a keystone contribution of *P. gingivalis* to disease, studies in humans have shown that *P. gingivalis* is frequently present in low abundance when compared to the total oral microbiota in diseased sites (Kumar *et al.* 2006). It remains to be determined whether other members of the oral microbiota designated as periodontal pathogens in Table 10-3 share similar "keystone species"-like properties to *P. gingivalis* in being able to shape the quantity and qualitative nature of the entire microbial community; this model leaves open that possibility. However, the key features of this model are consistent with many of the microbiologic observations of periodontal infections and combine elements of both the non-specific hypothesis, through Acknowledgment of the fundamental importance of the total microbial load of the entire microbiota, and of the specific plaque hypothesis, through acknowledging the role of individual bacterial species.

Conclusion

Our understanding of the microbial pathogenesis of periodontal disease has undergone significant changes over the last century and continues to be

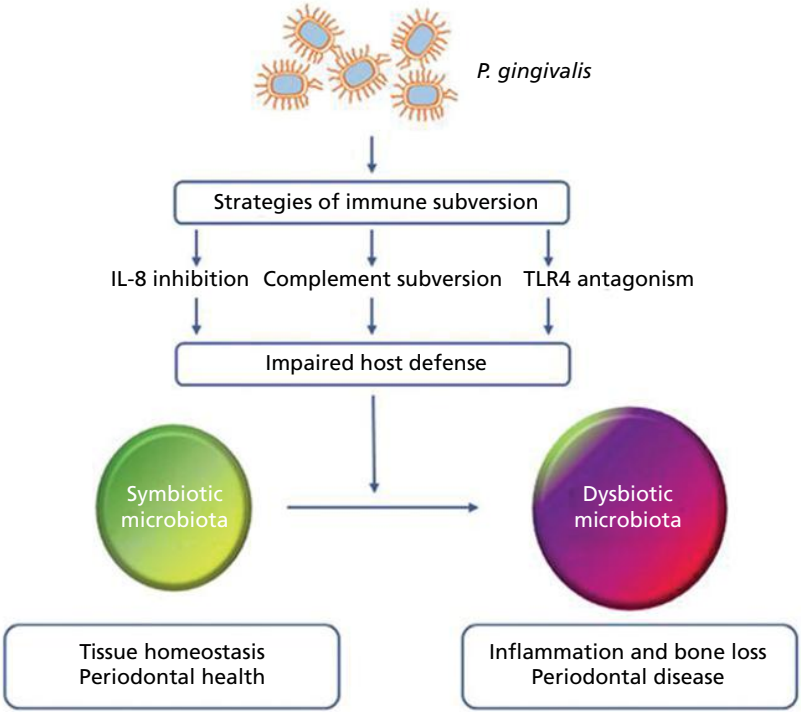

Fig. 10-16 Red complex bacterium *P. gingivalis* causes inflammation and bone loss by remodeling the oral commensal microbiota. *P. gingivalis* modulates innate host defense functions that can have global effects on the oral commensal community. Immune subversion of interleukin-8 (IL-8) secretion, complement activity, or Toll-like receptor 4 (TLR4) activation can result in an impaired host defense. The inability of the host to control the oral commensal microbial community in turn results in an altered oral microbial composition and an increased microbial load. This alteration from a symbiotic to a dysbiotic microbiota is responsible for pathologic inflammation and bone loss. (Source: Darveau *et al.* 2012. Reproduced with permission from SAGE Publications.)

refined to this day through more detailed analyses of clinical samples, improved understanding of the biology of the component organisms of this microbiota, and application of experimental model systems. In this chapter, the central role of a dysbiotic microbiota has been highlighted, similar to our understanding of the etiology of diseases with a complex microbial etiology at other sites of the human body. In all of these cases, disease is a consequence of a breakdown in the normally homeostatic balance between the commensal microbiota and the immune and inflammatory systems of the tissues. In this regard, periodontal infections and the response to them represent an excellent, accessible, and tractable system to understand the underlying principles of a wide range of inflammatory diseases of humans characterized by a dysbiotic commensal microbiome.

Acknowledgment

This chapter relies significantly upon the Periodontal Infections chapter by Sigmund Socransky and Anne Haffajee in the fifth edition of this text book and this author is highly indebted to them. The author gratefully acknowledges the help of Joseph Aduse-Opoku in the comparative genomic analysis of *P. gingivalis* and Juliet Ellwood in the preparation of this manuscript.

Chapter 11

Peri-implant Infections

Introduction

With a large and increasing number of implants being placed worldwide, it is expected that there will be an increase in the number of patients diagnosed with peri-implant infections. Peri-implant infections or peri-implant diseases are defined as either (1) peri-implant mucositis, where there are clinical signs of inflammation (bleeding on gentle probing, 0.25 N) of the peri-implant mucosa without loss of supporting bone, or (2) peri-implantitis, where there is concomitant loss of supporting bone. In the case of peri-implantitis, probing depths ≥5 mm and suppuration are frequently present (Lang & Berglundh 2011) (Fig. 11-1). This chapter addresses the etiology of peri-implant infections, describing the microbiota associated with healthy and diseased peri-implant tissues in both partially dentate and edentulous subjects. Factors influencing peri-implant biofilm formation and risks for peri-implant infection, including material surface characteristics, local environment, and reconstruction design, are discussed. Similarities and differences in the microbiota associated with periodontal and peri-implant infections are outlined, and the clinical implications discussed. Finally, effects on the microbiota of an anti-infective approach in the management of peri-implant infections are described.

Fig. 11-1 Clinical appearance of a peri-implant infection with suppuration and bleeding following probing of the deep (>6 mm) peri-implant pocket.

Peri-implant biofilm formation

When a dental implant is placed, the endosseous part of the implant should ideally be surrounded by bone and is, therefore, usually not exposed to biofilm formation. In contrast, the transmucosal part of the implant/abutment, once exposed to the oral cavity, becomes rapidly colonized by microorganisms (Fürst *et al*. 2007), which attach to salivary proteins and peptides constituting the pellicle. The pellicle provides receptors for adhesins present on the cell surface of all

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

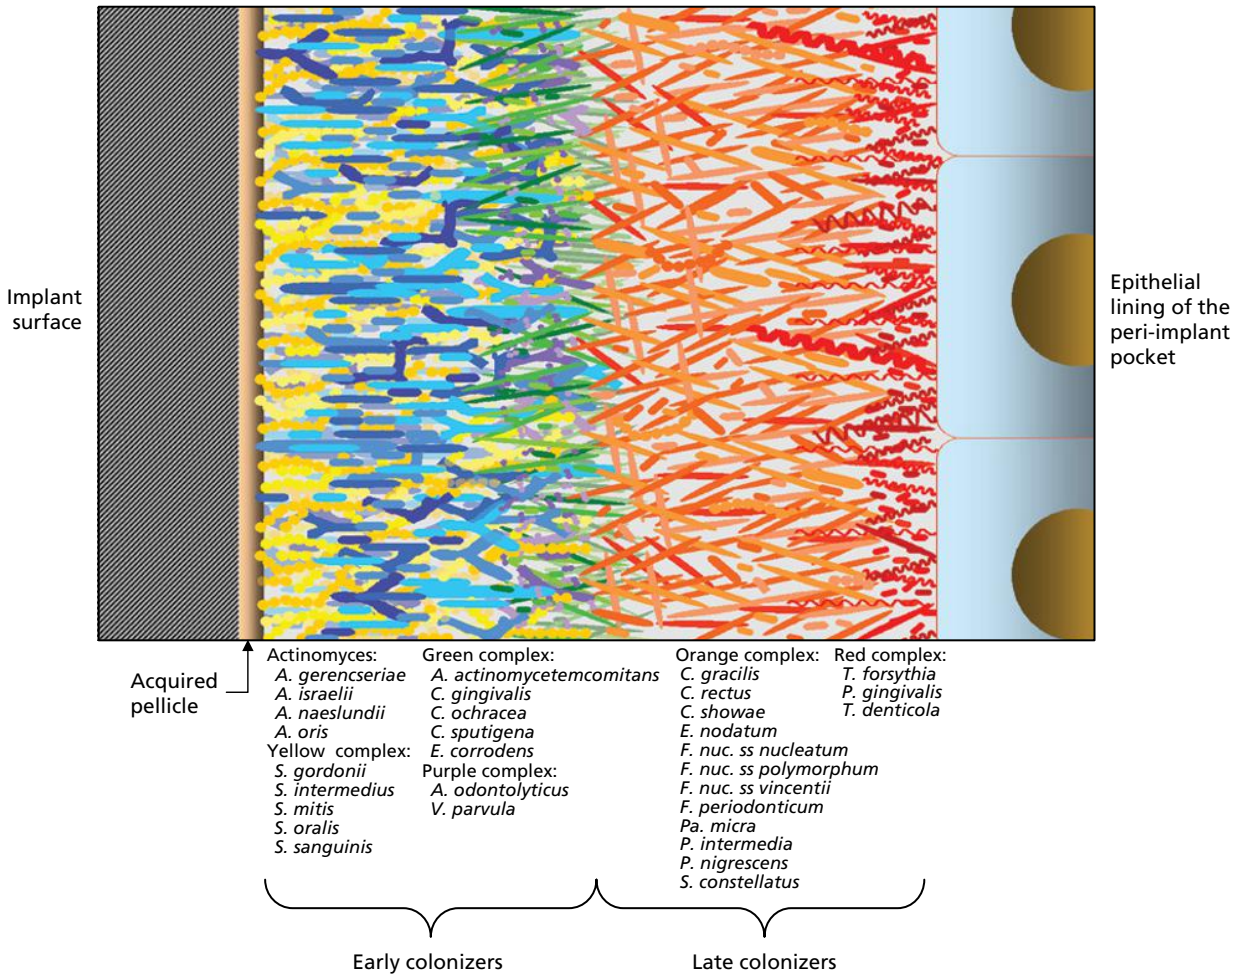

Fig. 11-2 Simplified schematic representation of the microbial succession that may take place on an implant surface exposed to the oral environment. Microbial species are colored according to the microbial complexes described by Socransky *et al*. (1998).

oral bacterial species. Enamel pellicles and titanium pellicles are not identical. Salivary pellicles formed on titanium surfaces *in vitro* have been found to include molecules such as high molecular weight mucins, α-amylase, secretory IgA, and proline-rich proteins, while molecules commonly found on tooth enamel (cystatins and low molecular weight mucins) were not detected (Edgerton *et al*. 1996). Although the salivary pellicle that forms on titanium surfaces might differ from that forming on enamel surfaces, the differences do not seem to influence the bacterial composition of the biofilm formation (Leonhardt *et al*. 1995).

Due to a common ecologic environment, the principles and sequence of biofilm formation at teeth and implants are similar (Lang & Berglundh 2011). Biofilm formation is initiated by adhesion of early colonizers such as *Streptococcus sanguinis* and *Actinomyces naeslundii*, through interactions with the salivary pellicle. The early colonizers grow, modify the environment, and promote the adhesion of secondary colonizers via co-aggregation (Fig.11-2). The biofilm with its diverse community of interacting organisms, glycocalyx matrix, and complex structure becomes stable over time, affording a protective environment from host defenses and antimicrobial agents (Marsh 2005; Socransky & Haffajee 2005; Kolenbrander *et al*. 2006). Figure 11-3 shows a series of scanning electron micrographs illustrating different stages of biofilm formation on a titanium implant surface.

Factors which may influence microbial colonization include the surface characteristics of the implant/abutment, local environment, resident oral microbiota, and implant prosthesis design and its accessibility for oral hygiene.

Surface characteristics of the implant/abutment

Surface characteristics of the implant/abutment and restorative components, including chemical composition, surface free energy (SFE; wettability), and surface roughness, may impact biofilm formation. Both *in vitro* and *in vivo* studies have indicated that increasing the surface roughness of titanium results in greater bacterial adhesion and biofilm accumulation (Teughels *et al*. 2006; Subramani *et al*. 2009; Burgers *et al*. 2010; Fröjd *et al*. 2011). An *in vitro* scanning electron microscope study investigating attachment of oral species to titanium disks with various surface characteristics, demonstrated an increased bacterial attachment to rough surfaces (Wu-Yuan *et al*. 1995). In a series of split-mouth studies, it was

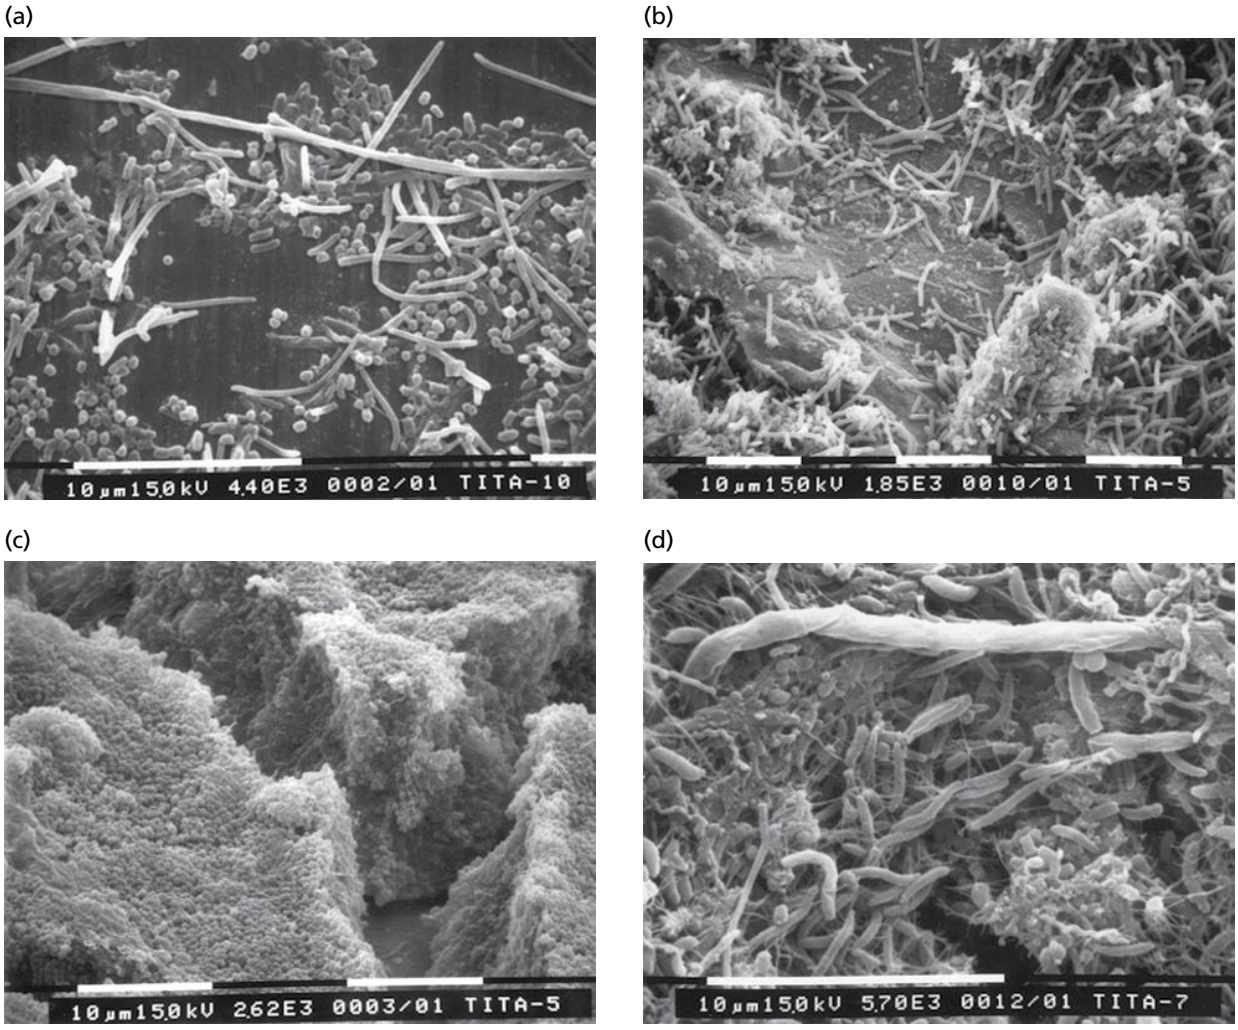

Fig. 11-3 Scanning electron micrographs showing different stages of biofilm formation on a titanium implant surface. One can observe the initial colonization by a small number of cells and a limited variety of bacterial morphotypes (a, b), followed by an increase in the biomass due to the proliferation of early colonizers (c) and the subsequent establishment of a complex climax community (d). (Courtesy of C. Cobb.)

demonstrated that an increase in the surface roughness (Ra) above a threshold of 0.2 μm and/or an increase in the SFE facilitated biofilm formation on restorative materials (Teughels *et al*. 2006). The effect of SFE on supra- and sub-mucosal plaque maturation around implants was investigated by comparing plaque from abutments with either a high (titanium) or a low (teflon coating) SFE (Quirynen *et al*. 1993). The teflon-coated titanium abutments harbored a less mature biofilm characterized by a higher proportion of cocci and a lower proportion of motile organisms and spirochetes than the uncoated titanium abutments (Quirynen *et al*. 1993). When both surface characteristics interact with each other, surface roughness was found to be predominant (Teughels *et al*. 2006). The impact of surface roughness on biofilm formation can be explained by several factors, including the protection from shear forces, increased area for adhesion, and difficulty in cleaning rough surfaces which enables rapid regrowth of the biofilm by multiplication of resident bacterial species (Quirynen & Bollen 1995).

Quantitative analysis of 14-day supra- and submucosal biofilm formation on titanium healing abutments in 10 subjects, showed that biofilm formation was significantly increased by higher surface roughness in supramucosal areas, with no influence of increased surface roughness in the submucosal environment (Elter *et al*. 2008).

An *in vitro* study examined the effect of surface characteristics on biofilm formation, using two and three-species biofilm models, 16S ribosomal RNA (rRNA) fluorescence, and confocal scanning laser microscopy (CSLM) (Fröjd *et al*. 2011). After 2 hours, surfaces with increased surface roughness had higher bacterial adhesion, most likely the result of protection of bacteria from shear forces. However, after 14 hours the volume of biofilm was similar on all surfaces, indicating that the influence of surface characteristics on adhesion was surpassed by biofilm development (Fröjd *et al*. 2011).

A range of restorative materials is available for fabrication of implant components, including titanium, gold, ceramics, and zirconium. Due to an increased demand for tooth-colored restorations, zirconium oxide ceramics (zirconia) have become more widely used as materials for implant abutments and transmucosal components of implant prostheses. In an *in vivo* study using CSLM to investigate the formation

of oral biofilm on various dental ceramics, zirconia was shown to exhibit low biofilm accumulation when used intraorally (Bremer *et al*. 2011). Several randomized controlled studies have compared the early bacterial colonization of periodontal pathogens at zirconium oxide abutments to titanium alloy abutments. While zirconium oxide abutments showed lower SFE than titanium abutments, there was no difference in the adhesion of *Aggregatibacter actinomycetemcomitans* and *Porphyromonas gingivalis*, 5 weeks after abutment connection (Salihoglu *et al*. 2011). This lack of difference between zirconium and titanium was confirmed in a similar study evaluating bacterial counts of seven bacterial species 2 weeks and 3 months following abutment connection (van Brakel *et al*. 2011).

Based on the surface roughness value Sa (average 3D height deviation), a proposal to categorize the surfaces of titanium implants as smooth (Sa <0.5 μm), minimally rough (Sa 0.5–1.0 μm), moderately rough (Sa 1.1–2.0 μm), and rough (Sa >2.0 μm) was made (Albrektsson & Wennerberg 2004). The original Brånemark turned machined surface was a minimally rough surface. More recently, the surfaces of commercially available titanium implants have been modified to promote osseointegration and are moderately rough or rough. If these implant surfaces become exposed to the oral environment, due to loss of supporting peri-implant marginal bone, the roughened surface may enhance biofilm formation and contamination of the implant surface. While there is no evidence that surface roughness of a properly placed and integrated implant influences the development of peri-implant infection, it has been documented that rough surface implants [titanium plasma sprayed (TPS)] are more likely to develop peri-implantitis than minimally rough implant surfaces if the implant surface becomes exposed to the oral environment (Lang & Berglundh 2011).

Local oral environment

Peri-implant colonization has been studied in both edentulous and partially dentate patients. A cause and effect relationship between biofilm formation on implants and peri-implant mucositis has been demonstrated in humans (Pontoriero *et al*. 1994; Zitzmann *et al*. 2001; Salvi *et al*. 2012). In these studies, when oral hygiene was discontinued in order to allow undisturbed plaque accumulation, clinical signs of peri-implant inflammation appeared after a few days and resolved when oral hygiene was reinstated. Not surprisingly, the composition of peri-implant biofilms associated with this inflammation, which may lead to further peri-implant infection in a susceptible host, is influenced by the local environment and the microbiota on the remaining teeth in partially dentate subjects. Cross-sectional studies have shown that the microbiota identified in the peri-implant sulci are nearly identical to those found at neighboring teeth (Quirynen & Listgarten 1990; Leonhardt *et al*. 1993; Mombelli *et al*. 1995b; Lee *et al*. 1999; Hultin *et al*. 2000; Agerbaek *et al*. 2006). It has been shown that deeper periodontal pockets harbor a greater number and proportion of periodontal pathogens (Socransky *et al*. 1991), serving as a potential reservoir for recolonization.

Transmission of bacteria from periodontal pockets to the peri-implant region of newly placed implants has been suggested in longitudinal studies (Mombelli *et al*. 1995a; Quirynen *et al*. 1996). A number of studies have used techniques to identify individual strains of bacteria in order to determine if transmission from a periodontal site to an implant site can occur in a patient (Sumida *et al*. 2002; Takanashi *et al*. 2004). Using pulsed field gel electrophoresis (PFGE), chromosomal DNA segmentation patterns of isolates of *P. gingivalis* and *Prevotella intermedia* obtained from implants and natural teeth in the same subjects were found to be identical, while PFGE patterns differed among samples from different subjects (Sumida *et al*. 2002). Similarly, it was found that 75% of the *P. gingivalis* isolates in samples from teeth and implants were the same in one subject, while 100% of the *P. intermedia* strains within a subject were a perfect match, clearly demonstrating transmission from the natural teeth to the implant sites (Takanashi *et al*. 2004). Although the remaining dentition seems to be the primary source of bacteria for the colonization of implant surfaces in partially dentate subjects, the potential role of soft tissue surfaces, crypts of the tongue or tonsils, and saliva as reservoirs for implant colonization should also be considered. A comprehensive assessment of the microbiota associated with oral mucosal surfaces in edentulous subjects wearing complete dentures, outlined the numerous habitats colonized by biofilms of differing complexities, unique to each individual (Sachdeo *et al*. 2008). Biofilm samples were taken from the dentures, the dorsal, lateral, and ventral surfaces of the tongue, the floor of the mouth, buccal mucosa, hard palate, vestibule/lip, and saliva. Checkerboard DNA–DNA hybridization was used to analyze the levels and proportions of 41 different species. Distinct patterns of microbial colonization were seen on different soft tissue surfaces and in saliva. One of the more important findings of this investigation was the detection of the periodontal pathogens *A. actinomycetemcomitans* and *P. gingivalis* in these edentulous subjects, as it was previously thought that these species would not be present following removal of all teeth (Sachdeo *et al*. 2008). Other studies have also reported the presence of periodontal pathogens in edentulous subjects (Danser *et al*. 1998; Cortelli *et al*. 2008) and in edentulous subjects in an elderly population who had never worn dentures but had a history of periodontitis (Fernandes *et al*. 2010).

These findings have clinical implications for the prevention of peri-implant infections. Pathologic conditions in the oral environment, such as the persistence of untreated periodontal disease, could induce changes in the ecosystem that may favor the colonization of pathogenic microorganisms at implant sites (Lang & Berglundh 2011). Treatment of

periodontal disease prior to implant placement, and provision of adequate supportive periodontal/peri-implant maintenance care in order to reduce the reservoir of potential periodontal pathogens, may reduce the risk of peri-implant infections.

Oral hygiene and accessibility

The importance of maintenance care in the prevention of peri-implant infections has been demonstrated in several studies where subjects who did not follow a structured maintenance care program had a greater incidence of peri-implant infections than those who followed a maintenance care program (Roccuzzo *et al*. 2010; Costa *et al*. 2012). The importance of good compliance following treatment [adhering to the recommended prophylaxis/supportive periodontal therapy (SPT) interval, and maintaining a full-mouth plaque score of <20% (O'Leary *et al*. 1972)] was also highlighted in a cross-sectional study where the prevalence of peri-implantitis was associated with poor compliance (Rinke *et al*. 2011).

Peri-implant infection has been linked with poor oral hygiene (Lindquist *et al*. 1997; Ferreira *et al*. 2006) (Fig. 11-4). Higher plaque scores, assessed using the modified Plaque Index (mPI) (Mombelli *et al*. 1987), were significantly associated with peri-implant infection in a cross-sectional study evaluating 212 partially dentate subjects with implant-supported prostheses (Ferreira *et al*. 2006). One pertinent study underlined the importance of designing implant prostheses with adequate access for cleaning (Serino & Ström 2009). Subjects who were referred for treatment of peri-implantitis at one or more of their implants were found to have no access for appropriate oral hygiene measures in a high proportion of the implants diagnosed with peri-implantitis, while good access for oral hygiene was rarely associated with peri-implantitis (Serino & Ström 2009). Implant reconstructions should be designed to enable access for regular self-performed biofilm removal, and for early detection of clinical signs of peri-implant infection (Fig. 11-5).

Cemented prostheses should be designed with accessible cement margins. Peri-implant infection was associated with the presence of excess luting cement, acting as a foreign body, in the peri-implant sulcus of 81% of 39 cases following cementation of prostheses (Wilson 2009). Once the excess cement was removed, the clinical signs of infection resolved in 74% of cases (Wilson 2009).

Microbiota associated with peri-implant mucosal health

An understanding of the nature and composition of biofilms associated with peri-implant health and disease is important in order to develop targeted and effective preventive and treatment strategies for the management of peri-implant infections.

A peri-implant biofilm is formed within minutes of exposure to the oral cavity, and a multispecies supra- and sub-mucosal complex community develops within weeks to months of exposure to the oral cavity (Quirynen *et al*. 2005; Fürst *et al*. 2007). This is similar to the dynamics of biofilm formation at teeth (Socransky & Haffajee 1997; Li *et al*. 2004; Kolenbrander *et al*. 2006), although it has been suggested that it may take longer for a mature biofilm to develop at implant sites (Papaioannou *et al*. 1995; Sbordone *et al*. 1999). Figures 11-6 and 11-7 illustrate the similarity of the microbiota colonizing tooth and implant sites within the same subject (Quirynen *et al*. 2006). Figure 11-8 illustrates the increase in detection frequency of *P. gingivalis* and *Tannerella forsythia* over time after non-submerged implant placement in 22 partially dentate subjects with a history of treated aggressive periodontitis (De Boever & De Boever 2006).

Early investigations characterized the peri-implant microbiota using darkfield microscopy and culture analyses to examine samples taken from the peri-implant sulci of newly placed implants in edentulous subjects (Mombelli *et al*. 1987, 1988; Mombelli & Mericske-Stern 1990). The microbiota associated with peri-implant health was described as predominantly Gram-positive facultative cocci, with high levels of *Actinomyces* and *Veillonella* spp., low total anaerobic counts, low levels of Gram-negative anaerobic rods, and low proportions of *Fusobacterium* spp., spirochetes, fusiforms, motile and curved rods. Thus, the microbiota appeared similar to that associated with healthy periodontal sites in healthy periodontal subjects (Socransky & Haffajee 2005).

As previously discussed, the lack of detection of species such as *P. gingivalis* in edentulous patients (Mombelli *et al*. 1987; Danser *et al*. 1994, 1995, 1997) and edentulous patients with implants (Mombelli *et al*. 1987; Ong *et al*. 1992) led to the suggestion that periodontal pathogens do not colonize dental implants placed in edentulous individuals. However, subsequent investigations incorporating more sensitive molecular techniques for analyses [including polymerase chain reaction (PCR), DNA–DNA checkerboard hybridization] have shown this

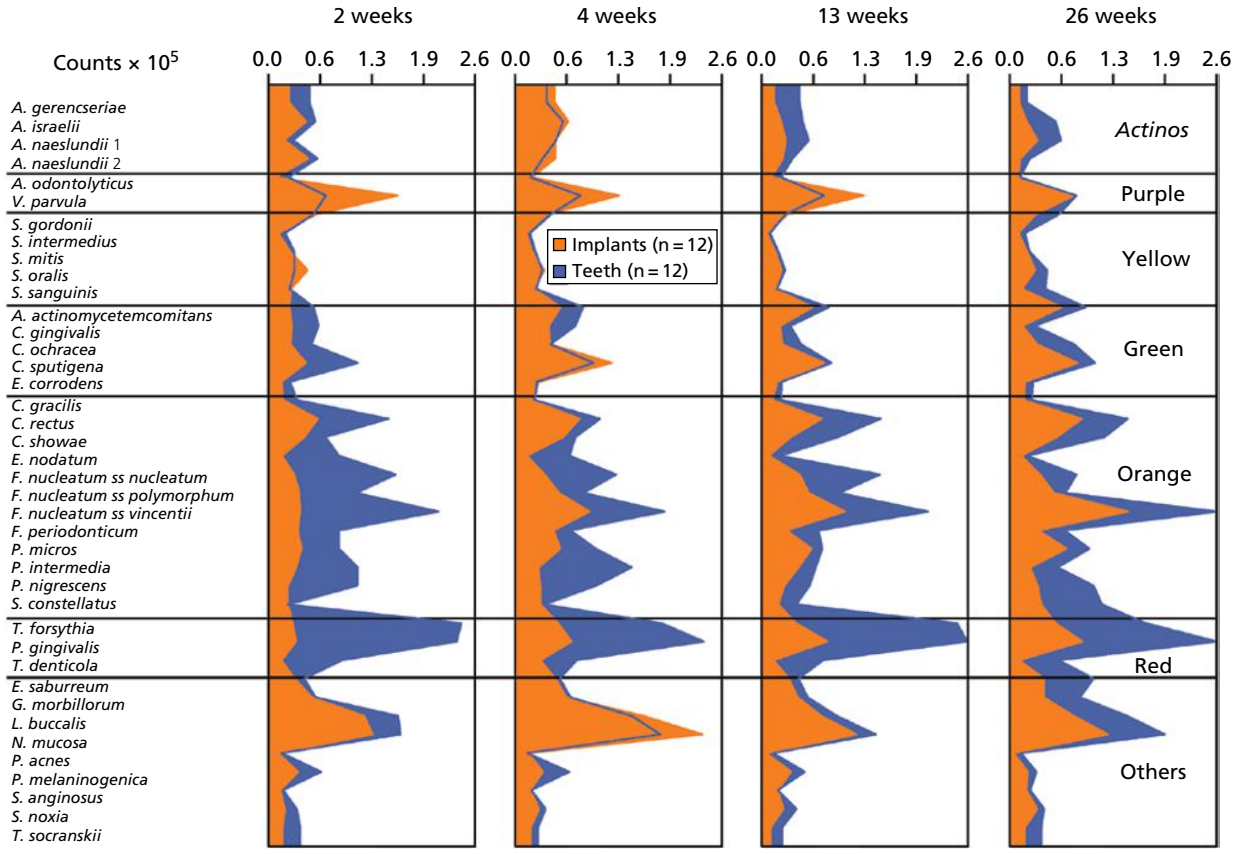

Fig. 11-6 Mean counts (×10[5]) of 40 species in samples from 48 implants and 48 teeth in 12 subjects at 2, 4, 13, and 26 weeks after exposure of the implant to the oral environment. Mean counts of each species were computed by averaging the data for each site category separately in each subject, and then averaging across subjects at each time point separately. Significance of differences between site categories was sought using the Mann–Whitney test. No significant differences were found after adjusting for multiple comparisons (Socransky *et al*. 1991). The species were ordered and grouped according to the complexes described by Socransky *et al*. (1998). (Data adapted from Quirynen *et al*. (2006).)

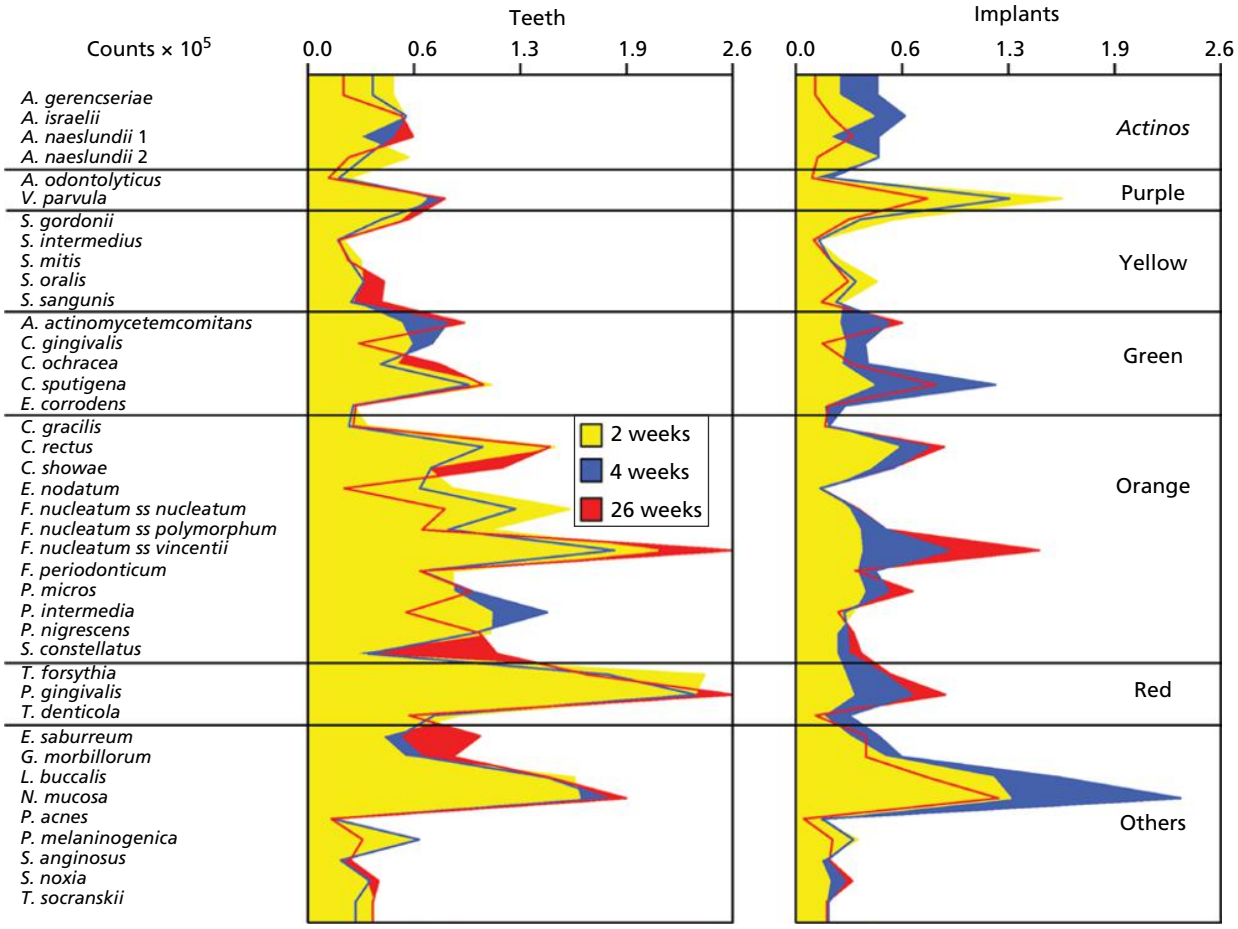

Fig. 11-7 Mean counts (×10[5]) of 40 species at 2, 4, and 26 weeks after implant exposure in samples from 48 teeth (left panel) and 48 implants (right panel) from 12 subjects. Mean counts of each species were computed by averaging the data for each site category separately in each subject, and then averaging across subjects at each time point separately. Significance of differences over time was sought using the Friedman test. No significant differences were detected after adjusting for multiple comparisons (Socransky *et al*. 1991). The species were ordered and grouped according to the complexes described by Socransky *et al*. (1998). (Data adapted from Quirynen *et al*. (2006).)

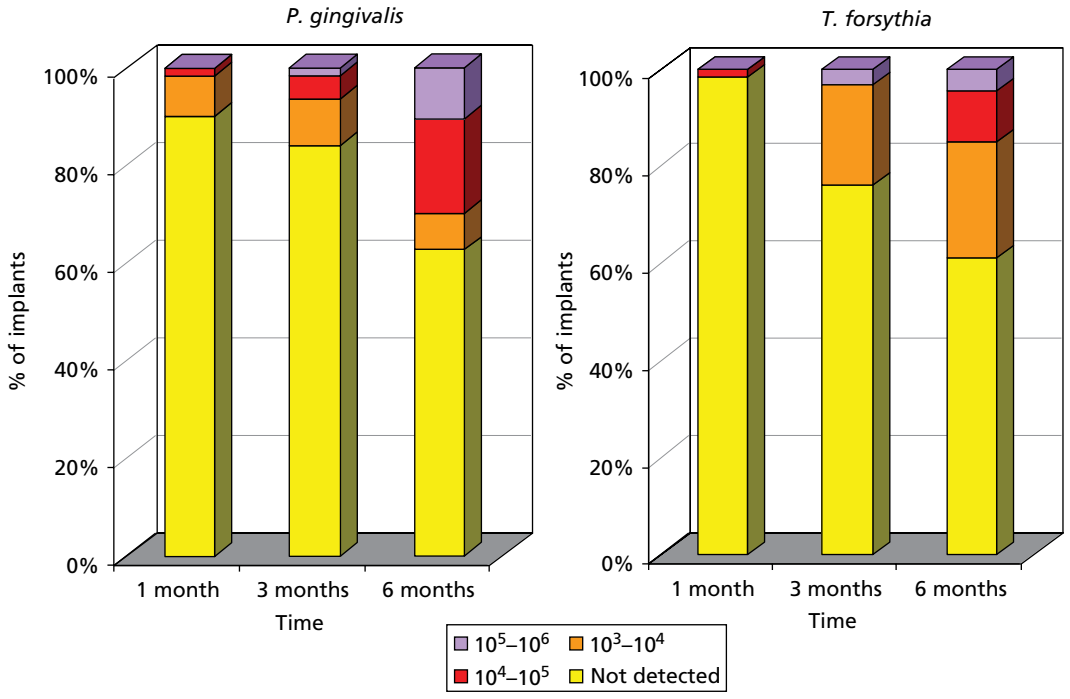

Fig. 11-8 Stacked bar charts of the frequency of detection of *Porphyromonas gingivalis* (left panel) and *Tannerella forsythia* (right panel) at different levels on 68 implants inserted in 22 subjects with a history of treated aggressive periodontitis at different time points. The bar colors indicate the different levels of detection of *P. gingivalis* and *T. forsythia* using DNA probes. (Data adapted from De Boever & De Boever (2006).)

not to be the case. Using molecular techniques, the presence of periodontal pathogens (including *P. gingivalis, T. forsythia, A. actinomycetemcomitans, Treponema denticola, Parvimonas micra, Streptococcus intermedius*) in low proportions and levels were demonstrated in healthy peri-implant sulci in fully edentulous subjects (Lee *et al*. 1999; Hultin *et al*. 2002; Quirynen *et al*. 2005; Devides & Franco 2006; Van Assche *et al*. 2009; Fernandes *et al*. 2010; Quirynen & Van Assche 2011) and partially dentate subjects (Lee *et al*. 1999; Casado *et al*. 2011; Van Assche *et al*. 2011). It should be emphasized that in patients with good oral hygiene and a stable periodontal condition, implants can maintain a successful treatment outcome without peri-implant infection despite the presence of periodontal pathogens (Van Assche *et al*. 2011).

Microbiota associated with peri-implant infections

The characteristics of biofilms associated with peri-implant disease (peri-implant mucositis and peri-implantitis) have been studied using various microbiologic techniques and sampling methods, most of which disrupt the three-dimensional structure of the biofilm. While the majority of studies have found the composition of the submucosal microbiota to be similar to that in chronic periodontitis, with a mixed anaerobic infection dominated by Gram-negative bacteria, some studies have found high numbers of other microorganisms not commonly associated with periodontal diseases, including enteric rods and yeasts, or microorganisms associated with extraoral infections such as staphylococci (i.e. *Staphylococcus aureus* and *Staphylococcus epidermidis*) or peptostreptococci (Leonhardt *et al*. 2003; Fürst *et al*. 2007; Persson *et al*. 2010).

Numerous studies have documented the presence of periodontal pathogens at peri-implantitis sites (Rams & Link 1983; Rams *et al*. 1984; Mombelli *et al*. 1987, 1988; Becker *et al*. 1990; Sanz *et al*. 1990; Alcoforado *et al*. 1991; Rams *et al*. 1991; Rosenberg *et al*. 1991; Mombelli & Lang 1992; Augthun & Conrads 1997; Danser *et al*. 1997; Salcetti *et al*. 1997; Kalykakis *et al*. 1998; Muller *et al*. 1999; Hultin *et al*. 2000; Mombelli *et al*. 2001; Rutar *et al*. 2001; Leonhardt *et al*. 2003; Botero *et al*. 2005; Covani *et al*. 2006; Persson *et al*. 2006; Shibli *et al*. 2008; Emrani *et al*. 2009; Maximo *et al*. 2009; Tabanella *et al*. 2009; Persson *et al*. 2010). Figure 11-9 illustrates the microbial complexity of a submucosal biofilm associated with a peri-implantitis lesion. Some studies have examined the microbiota of healthy peri-implant sites, comparing that found in the context of an otherwise healthy mouth versus that found when peri-implantitis was present at some implants, noting an increased level of pathogens even in healthy sites in patients with peri-implantitis (Fig. 11-10). The findings of the mentioned studies outline the similarities in microbiota found at sites with peri-implant infection and periodontitis.

Fig. 11-9 Scanning electron micrograph showing the complexity of the microbial composition of a submucosal biofilm associated with a peri-implantitis lesion. (Courtesy of C. Cobb.)

The microbiota associated with peri-implant mucositis appears to be similar to that associated with peri-implantitis (Maximo *et al*. 2009; Casado *et al*. 2011), suggesting that supramucosal plaque formation and development of peri-implant mucositis is the precursor to peri-implantitis. Plaque samples, analyzed using checkerboard DNA–DNA hybridization for 40 bacterial species, from 13 subjects with peri-implantitis and 12 subjects with peri-implant mucositis found similar levels of all species with the exception of three species (*T. forsythia*: higher levels in peri-implantitis; *Actinomyces gerencseriae* and *Campylobacter ochracea*: lower levels in peri-implantitis) (Maximo *et al*. 2009) (Fig. 11-11).

In another study evaluating the presence and levels of 36 species by DNA–DNA hybridization, there were no significant differences observed in supra- and sub-mucosal microbial profiles from the same implant site, in 22 subjects with peri-implantitis (Shibli *et al*. 2008) (Fig. 11-12). Deeper peri-implant pockets harbor greater total anaerobic counts and presence of *P. gingivalis* compared to shallower peri-implant pockets (Rutar *et al*. 2001). Human cytomegalovirus (HCMV) and Epstein–Barr virus (EBV) have also been associated with peri-implant infection, suggesting a possible etiologic role via local immune suppression allowing overgrowth of periodontal pathogens (Jankovic *et al*. 2011). HCMV was detected in 65% and EBV in 45% of the 20 peri-implantitis sites evaluated, while co-infection was reported in 33% of peri-implantitis sites. In healthy and peri-implant mucositis sites, no co-infection was detected (Jankovic *et al*. 2011).

There is no histologic documentation of bacterial invasion of the peri-implant tissues, although it has been suggested that this may occur due to the epithelial ulceration and disruption of connective tissue

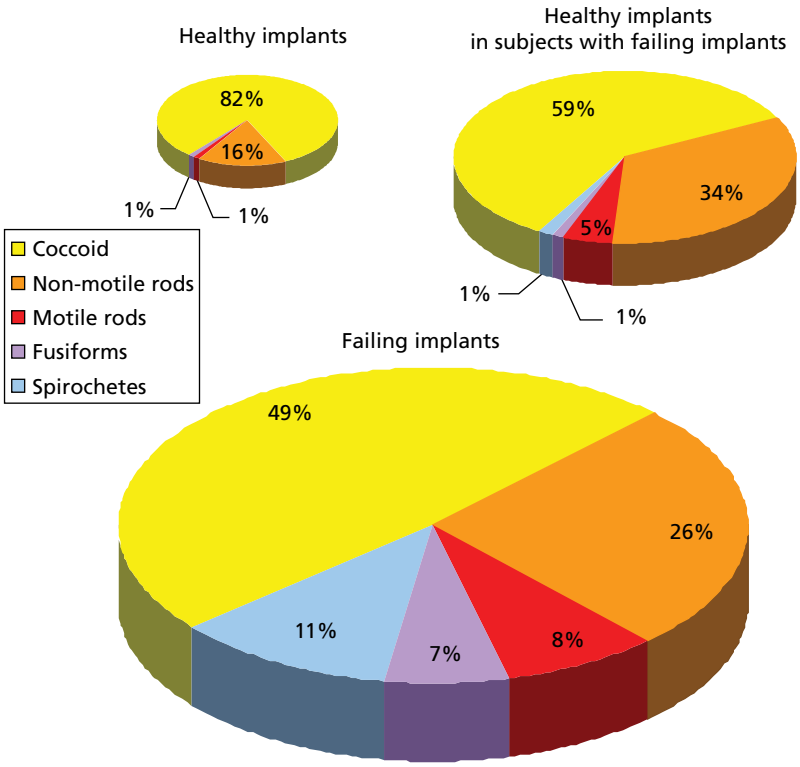

Fig. 11-10 Pie charts of the mean percentage of different morphotypes in the microbiota of samples from 10 healthy implant sites in subjects with only successful implants, samples from six healthy implant sites and from eight peri-implantitis sites in subjects with peri-implantitis. The numbers correspond to the mean percentage of each morphotype within the microbiota. The areas of the pie charts have been adjusted to reflect mean total counts of each site category. (Data adapted from Mombelli *et al*. (1987).)

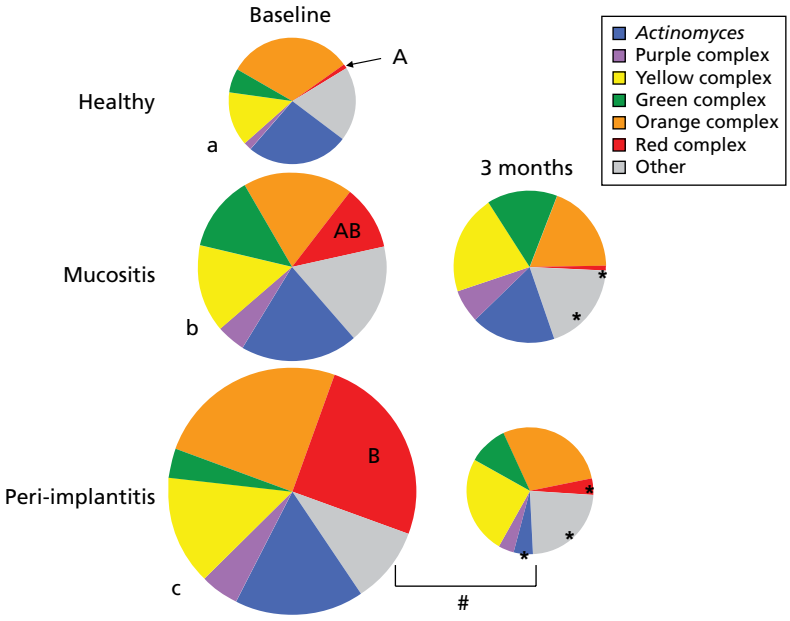

Fig. 11-11 Pie charts of the mean percentage DNA probe count of subgingival microbial complexes (Socransky *et al*. 1998) from samples of submucosal biofilms obtained from healthy implants (n = 10), implants with mucositis (n = 12), and implants with peri-implantitis (n = 13) at baseline and 3 months after mechanical therapy (diseased implants only). The areas of the pie charts were adjusted to reflect the mean total counts of each clinical group. Significance of differences between the two time points for the total DNA probe counts ($^{\#}P$ <0.05) and the proportions of each complex ($^{*}P$ <0.05) was tested using the Wilcoxon signed-rank test. Different uppercase letters indicate differences in proportions of microbial complexes among groups at baseline using the Kruskal–Wallis and Dunn *post-hoc* tests. Different lowercase letters indicate differences in the mean total DNA probe counts at baseline using the Kruskal–Wallis and Dunn *post-hoc* tests. (Data adapted from Maximo *et al*. (2009).)

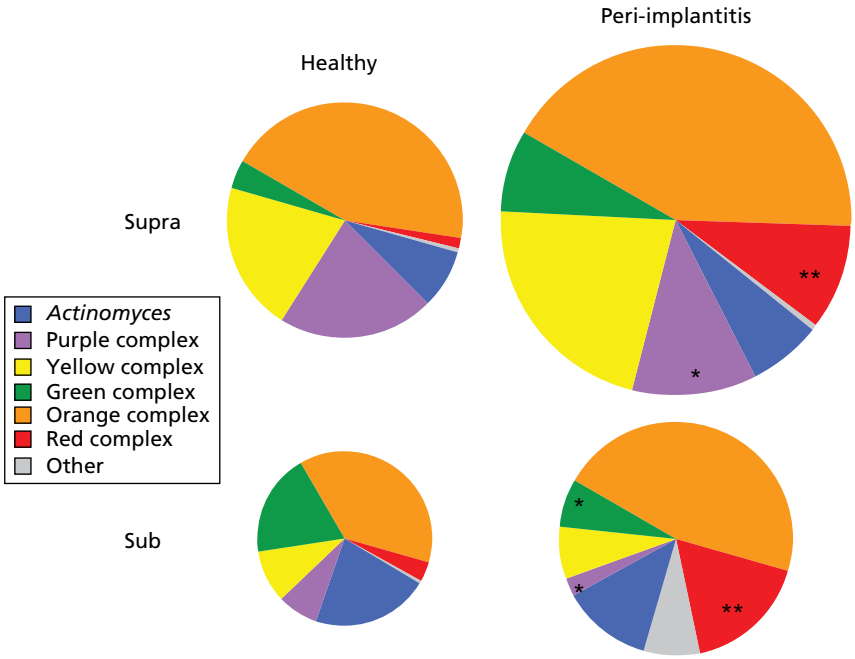

Fig. 11-12 Pie charts of the mean percentage DNA probe count of microbial complexes (Socransky *et al*. 1998) in samples of supra- and sub-mucosal biofilms obtained from healthy implants (n = 22) and implants with peri-implantitis (n = 22). Areas of the pie charts were adjusted to reflect the mean total DNA probe counts of each sample type. Significance of differences between the two clinical groups for the proportions of each complex was tested for supra- and sub-mucosal samples separately using the Mann–Whitney U-test ($^{*}P$ <0.05; $^{**}P$ <0.01). (Data adapted from Shibli *et al*. (2008).)

adhesion observed in experimental peri-implantitis studies (Lang & Berglundh 2011).

Molecular techniques, including *16S rRNA* gene sequencing, have led to the identification and discovery of previously unrecognized microorganisms in the oral cavity (Faveri *et al*. 2008; Ahn *et al*. 2011; Wade 2011). Due to these advances, researchers are now recognizing the diversity of both the periodontal and peri-implant microbiota. Phyla including Chloroflexi, Tenericutis, and Synergistes, and species including *P. micra*, *Peptostreptococcus stomatis*, *Pseudoramibacter alactolyticus*, and *Solobacterium moorei*, have been identified from peri-implantitis sites (Koyanagi *et al*. 2010) (Fig. 11-13). Furthermore, Archaea, a distinct group of single-cell microorganisms that produce methane gas and have been associated with periodontal disease severity (Lepp *et al*. 2004) have also been identified using *16S rRNA* clonal analyses at peri-implantitis sites, suggesting a role in the etiology of peri-implant infection (Faveri *et al*. 2011). Subgingival/submucosal samples were obtained from 50 periodontally healthy sites, 50 healthy peri-implant sites, and 25 peri-implantitis sites. The prevalence of Archaea (*Methanobrevibacter oralis*) was significantly higher at peri-implantitis sites compared to healthy sites at implants and teeth (Faveri *et al*. 2011).

The true nature, role, and diversity of the microbiota associated with peri-implant infections may only be realized as future investigations focus on the study of non-cultivable organisms, using techniques which do not disrupt the three-dimensional structure of the biofilm.

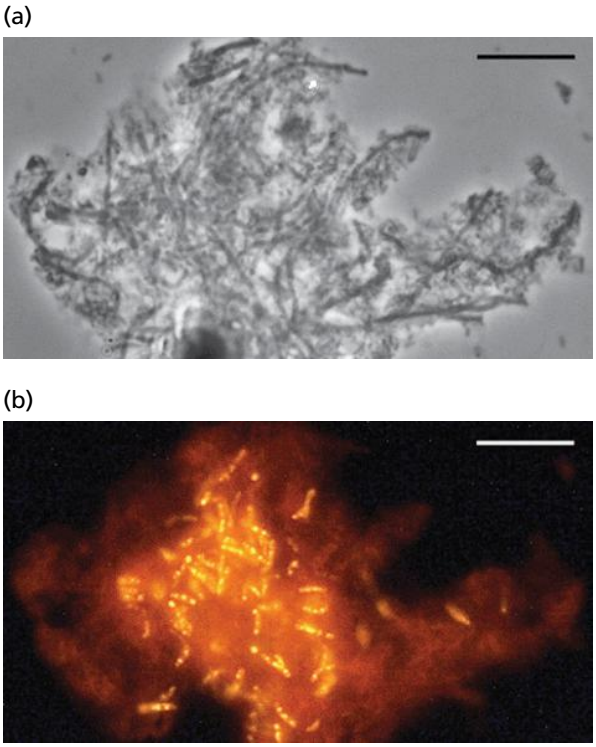

Fig. 11-13 (a) Inverted light microscopy of a subgingival biofilm obtained from a peri-implantitis site. Belimpasakis and Helga Lüthi-Schaller, University of Zürich.)

Patients at risk for peri-implant infections

There is emerging evidence that patients who have a history of treated periodontitis have an increased risk for peri-implant infections (Hardt *et al*. 2002; Karoussis *et al*. 2003, 2004; Heitz-Mayfield 2008; Ong *et al*. 2008; Roccuzzo *et al*. 2010). This is perhaps not surprising considering the two diseases share common risk factors, and patients with a host susceptibility to periodontitis will still be susceptible to biofilm infections at implant sites if periodontal pathogens colonize these sites.

This consideration is supported by findings that in patients diagnosed with advanced periodontitis, the persistence of periodontal pathogens was observed following full-mouth extraction and implant placement (Quirynen & Van Assche 2011). Ten patients with advanced periodontitis had all their teeth extracted and 6 months after tooth extraction, implants were placed. Abutment connection was completed 3–6 months later. Plaque samples were collected from the tongue dorsum, saliva, and subgingival/mucosal area (teeth/implants) before extraction and up to 1 year after abutment connection, and analyzed by culture, quantitative PCR, and checkerboard technology. A reduction in the total number of aerobic and anaerobic colony-forming units (CFU)/mL was observed, and there was a reduction in the detection of *P. gingivalis* and *T. forsythia* in the saliva and on the dorsum of the tongue. However, the submucosal areas of the peri-implant sulci were rapidly colonized by these key pathogens, and no changes could be detected for *A. actinomycetemcomitans.* Thus, while the extraction of the remaining periodontally involved teeth resulted in a significant reduction of bacteria related to periodontitis and peri-implantitis, they were not eliminated. The pathogens could then colonize the peri-implant regions and detection frequencies remained high (Quirynen & Van Assche 2011). While it may take many years, peri-implant infections may develop if periodontal pathogens become established in the peri-implant biofilm in a susceptible host.

Furthermore, periodontal patients with residual probing depths of ≥6 mm at remaining teeth were found to have a greater prevalence of peri-implantitis (bone loss and peri-implant probing depth ≥5 mm with bleeding on probing) compared to periodontal patients with no residual pockets, or periodontally healthy subjects (Lee *et al*. 2012). Moreover, a study including patients in maintenance care, with an average follow-up of 8 years, reported that periodontitis-susceptible patients with implants who developed peri-implantitis had significantly more residual periodontal pockets (≥5 mm) at the end of active periodontal therapy than patients who did not develop peri-implantitis (Pjetursson *et al*. 2012). This highlights the maintenance of periodontal health as a critical factor in reducing risk for peri-implant infection. Clinicians should inform patients with a history of periodontitis of their increased risk for peri-implant infections, and of the importance of optimal oral hygiene and regular supportive periodontal/peri-implant care.

Few studies have investigated the presence of specific bacterial species as a risk for the initiation or progression of peri-implantitis. One study found that the addition of a positive DNA test (which determined the presence of *A. actinomycetemcomitans, P. gingivalis, P. intermedia or T. denticola*) enhanced the diagnostic power of the presence of bleeding on gentle probing (0.25 N) to predict progression of peri-implant disease (Luterbacher *et al*. 2000).

Anti-infective treatment and microbiologic effects

Treatment protocols for peri-implant infections have empirically been based on treatment philosophies for the management of periodontal infections, and are aimed at the suppression of the total bacterial load and reduction of the presence and levels of periodontal pathogens. The majority of studies investigating the microbiologic outcomes following peri-implant mucositis/peri-implantitis treatment have incorporated mechanical debridement with or without adjunctive antiseptics and/or antimicrobial agents.

Most studies have reported a reduction in the total bacterial counts and levels of periodontal pathogens in the first 3 months following treatment. However, those with longer follow-up periods have observed a gradual return to baseline levels of the microbiota analyzed.

Non-surgical mechanical therapy

While non-surgical mechanical therapy alone seems to be effective in the treatment of peri-implant mucositis (Heitz-Mayfield & Lang 2004; Maximo *et al.* 2009; Heitz-Mayfield *et al*. 2011), the improvements using this approach at peri-implantitis sites have so far shown limited and unpredictable results (Lindhe & Meyle 2008; Renvert *et al*. 2008b, 2009; Persson *et al*. 2010). Mechanical debridement at peri-implantitis sites using either titanium hand-instruments or ultrasonic devices resulted in transient changes in only a few microbial species, with a return to baseline microbial levels 6 months following treatment (Persson *et al*. 2010). No clinical improvement was observed 6 months following non-surgical mechanical treatment in this study (Persson *et al*. 2010). In a subsequent study, the same group of researchers reported limited microbiologic and clinical improvements following peri-implantitis treatment using either a erbium-doped:yttrium, aluminum, and garnet (Er:YAG) laser or an air-abrasive polishing device (Persson *et al*. 2011). The limited clinical and microbiologic improvements

observed following non-surgical therapy in deep peri-implant pockets can be attributed to the difficulty in gaining access to the biofilm adhering to the implant surface, due to the topography of the implant and its surface characteristics.

Non-surgical mechanical therapy and adjunctive antimicrobial agents

As a result of the inability to resolve peri-implant infections using mechanical means alone, treatment protocols using adjunctive antimicrobial agents have been proposed. However, few studies have evaluated both clinical and microbiologic outcomes following non-surgical mechanical debridement and adjunctive systemic antimicrobials (Mombelli & Lang 1992) or local antimicrobial agents (Mombelli *et al*. 2001; Persson *et al*. 2006; Renvert *et al*. 2006). A case series reported the clinical and microbiologic outcomes of an anti-infective protocol incorporating mechanical debridement, irrigation with 0.5% chlorhexidine, and the systemic administration of ornidazole at 100 mg/day for 10 days (Mombelli & Lang 1992). Microbiologic samples taken at various time points after therapy were examined using anaerobic culture techniques and darkfield microscopy. At 10 days post therapy, there was a dramatic reduction in the total anaerobic microbiota from 3.45×10^6 CFU/mL to 0.04×10^6 CFU/mL. The post-treatment microbiota consisted mainly of Gram-positive facultative cocci (95% of the microbiota). Spirochetes and selected species including *P. intermedia*, *P. gingivalis*, *Fusobacterium* spp., *Actinomyces odontolyticus*, *Selenomonas* spp., *Veillonella* spp., *Campylobacter* spp., *A. naeslundii*, and *Actinomyces oris* (formerly *A. naeslundii* genospecies 1 and 2), could not be recovered in the day 10 samples, despite being present at baseline. After 12 months, the frequency of detection of *P. intermedia*, *Fusobacterium* spp., *A. odontolyticus*, and *Campylobacter* spp. was significantly lower than at baseline and the proportion of Gram-negative anaerobic rods shifted from 39.8% to 15.2% of the total cultivable microbiota. The beneficial changes in the composition of the peri-implant microbiota were accompanied by clinical improvements, including a reduction in bleeding on probing and mean pocket depth over 12 months (Mombelli & Lang 1992).

Clinical improvements accompanied by significant reductions in total bacterial load and levels of putative pathogens (including *A. actinomycetemcomitans*, *P. gingivalis, T. forsythia, T. denticola, P. intermedia, Fusobacterium* spp., *Campylobacter rectus*, and spirochetes) have also been documented following the local delivery of antimicrobials (Mombelli *et al*. 2001; Persson *et al*. 2006). Studies evaluating local delivery devices including non-resorbable tetracycline fibers (Actisite®) (Mombelli *et al*. 2001) and minocycline hydrochloride microspheres (Arestin®) (Renvert *et al*. 2004; Persson *et al*. 2006; Renvert *et al*. 2006; Salvi *et al*. 2007; Renvert *et al*. 2008a) have shown microbiologic improvements for up to 12 months in the majority of patients. However, as previously mentioned, the initial suppression of the microflora was followed by a gradual recolonization, and in some sites recurrent peri-implantitis, requiring further treatment.

Surgical access and implant surface decontamination

The challenge of obtaining access to the implant surface for biofilm removal in non-surgical therapy can be overcome by access flap therapy. Following debridement of the lesion and removal of inflammatory tissue to expose the implant surface and bone defect, an attempt to decontaminate the implant surface is made. Implant surface decontamination methods have been investigated in *in vitro*, experimental, and clinical studies (Kolonidis *et al*. 2003; Schou *et al*. 2003) evaluating a range of chemicals (including citric acid, hydrogen peroxide, saline, chlorhexidine), lasers (including Nd:YAG, CO_2, Er:YAG) (Schwarz *et al*. 2006), photodynamic therapy, and mechanical approaches (including carbon fiber, titanium, and plastic curettes, and ultrasonic and air-abrasive polishing devices). Microbiologic effects following these decontamination procedures have scarcely been evaluated, with the focus of the investigations being on defect fill. Photodynamic therapy, where a photosensitive dye (toluidine blue) was applied to the implant surface following access flap elevation, and activated using a diode laser (wavelength 905 nm), showed promising results in reducing total bacterial counts and levels of specific periodontal pathogens (*A. actinomycetemcomitans, P. gingivalis,* and *P. intermedia*) (Dörtbudak *et al*. 2001). However, no particular implant surface decontamination protocol has been found to be superior in terms of clinical or microbiologic outcomes.

The few studies evaluating the clinical and microbiologic effects of surgical peri-implantitis therapy have included adjunctive systemic antimicrobials, with the exception of one short-term study which documented 3-month microbiologic and clinical improvements following surgical access and debridement without adjunctive systemic antimicrobials (Maximo *et al*. 2009). In this study positive qualitative and quantitative changes were observed, with levels of *T. denticola, T. forsythia, P. micra, Fusobacterium nucleatum ss nucleatum*, *P. gingivalis*, and *Treponema socranskii* significantly reduced 3 months after therapy (Maximo *et al*. 2009) (see Fig. 11-11).

The rationale for combining systemic antimicrobials with surgical interventions is the infectious nature of the disease. A study of nine patients, with 26 implants with peri-implantitis, treated by surgical access and debridement with adjunctive antimicrobials, followed by 3–6-monthly maintenance care, reported clinical and microbiologic findings over a 5-year period (Leonhardt *et al*. 2003). One of six

different systemic antimicrobial agents, based on the results of individual bacterial susceptibility testing, was administered. Seven implants in four patients were lost, and four implants continued to lose bone. *A. actinomycetemcomitans* was present in six of the nine patients prior to treatment, while at 6 months and 5 years this species was not found. *S. aureus* and enteric rods were detected in one and three patients, respectively, prior to treatment, but were not detected in any patients 5 years following treatment. The presence of *P. intermedia* and *Prevotella nigrescens* was not altered following treatment. Therefore, some bacterial species were either not completely removed during debridement or recolonized the peri-implant sites (Leonhardt *et al*. 2003).

In a retrospective study of 245 patients who had received a wide range of peri-implantitis treatments, most involving surgical access with various systemic antimicrobial agents, baseline microbial sampling showed 27% of patients had moderately heavy to heavy levels of *P. intermedia/P. nigrescens* and 19% had moderately heavy to heavy levels of anaerobic Gram-negative bacilli. Success of treatment (absence of bleeding on probing and/or suppuration in conjunction with periodontal depth of <5 mm and stable bone levels) was observed in 45% of all cases. The type and regimens of antimicrobials used during treatment varied greatly, but the majority of cases received a combination of amoxicillin and metronidazole (47%). Baseline microbial data did not correlate with the outcome of treatment (Charalampakis *et al*. 2012).

Treatment of peri-implant infection is challenging and the optimal protocol for successful treatment remains to be elucidated. Once an effective protocol is established, it can be implemented as a control to test other protocols in randomized controlled trials. However, it is obvious that an anti-infective approach is indicated, with the goals being biofilm control, and the establishment of a local environment and peri-implant biofilm compatible with healthy peri-implant tissues. Strategies for preventing peri-implant infection include the identification of high-risk individuals, treatment of periodontitis prior to implant placement, establishment of good oral hygiene practices, implant-supported prostheses designed to give adequate access for self-performed plaque removal, avoidance of iatrogenic problems such as excess restorative cement, and provision of supportive periodontal/peri-implant care.

Introduction

The experimental gingivitis studies of the 1960s (Löe *et al*. 1965) elegantly demonstrated that there is a one-to-one relationship between the development of dental plaque and the development of gingivitis (Figs. 12-1, 12-2). These studies, together with those of more recent times (Trombelli *et al*. 2004a, 2008), also show that there is variation in this response, with some individuals manifesting disease to a greater or lesser degree and at different time periods compared with others. So, while it has been known for many years that plaque is the etiologic agent, the factors contributing to patient susceptibility are still not fully understood. While all individuals with periodontitis will have had, at one stage, gingivitis, not all patients with gingivitis, nor all gingivitis lesions, will necessarily progress to periodontitis. The difficulty arises in identifying those lesions with gingivitis which will progress to periodontitis.

Development of gingival inflammation

The development of gingivitis and periodontitis was loosely classified into the "initial", "early", "established", and "advanced" lesions by Page and Schroeder (1976). The initial and early lesions will be described here, while the established and advanced lesions will be described in Chapter 13.

The initial lesion

The "initial" lesion occurs 2–4 days following the beginning of plaque accumulation. The lesion is subclinical and can only be seen histologically. It is characterized by the formation of edema [manifesting as an increase in gingival crevicular fluid (GCF) flow], an accumulation of polymorphonuclear neutrophils (PMNs), and loss of connective tissue (Fig. 12-3). Streptococci are among the first organisms to colonize the acquired pellicle as plaque develops. These organisms produce a range of enzymes and metabolic end products which increase the permeability of the junctional epithelium, allowing both the ingress of further bacterial products and at the same time the outflow of GCF. At this early stage, the GCF is essentially the same as interstitial fluid, but nevertheless contains many serum proteins, including all the components necessary for the activation of complement.

Lipoteichoic acid and peptidoglycans, which are components of the cell wall of these early colonizers, are capable of activating complement via the so-called "alternative pathway". This occurs in the gingival sulcus and results in the production of the "anaphylatoxins" C3a and C5a, which in turn flow back into the tissues, establishing a concentration gradient from the gingival sulcus into the tissues. Once in the tissue, these anaphylatoxins lead to the release of vasoactive amines from resident mast

cells. In turn, these vasoactive amines lead to an increase in vascular permeability and the formation of edema, one of the hallmarks of inflammation. Mast cells also release preformed cytokines, including tumor necrosis factor-alpha (TNF-α), which results in the expression of adhesion molecules by endothelial cells and the subsequent sticking and migration of PMNs into the gingival tissues. While activation of the alternative complement pathway is essential for the vascular responses, bacterially-derived chemotactic substances together with C5a are responsible for the migration of PMNs into the gingival sulcus. Once in the gingival sulcus however, the PMNs are unable to phagocytose the bacteria, which are beginning to form a biofilm and as such are firmly adherent to the tooth surface. In this situation, the PMNs disgorge their lysosomal contents into the gingival sulcus in what has been termed "abortive phagocytosis". These lysosomal enzymes can then return into the tissues and contribute to the local destruction of connective tissues. In addition, PMNs release structures called neutrophil extracellular traps (NETs) which

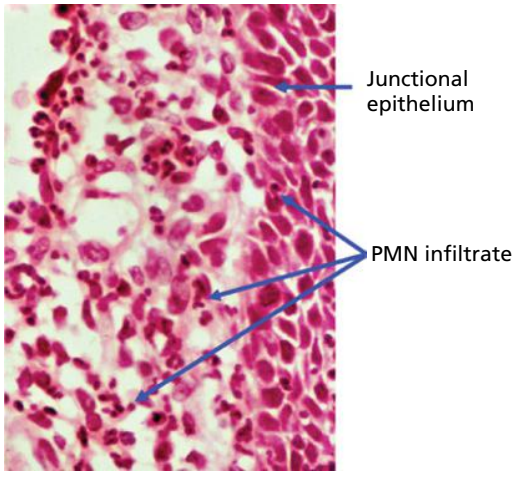

Fig. 12-3 Polymorphonuclear neutrophil (PMN) infiltration with destruction of the infiltrated connective tissue in the initial lesion.

can trap and kill microbial pathogens. These were first described by Brinkman *et al*. (2004) and consist of chromatin structures, nuclear histones, and many granular antimicrobial proteins. NETs are released

during a form of pathogen-induced cell death, recently called NETosis, that differs from apoptosis and necrosis (Steinberg & Grinstein 2007) and represents one of the first lines of defense against pathogens. *In vivo* both dead and viable PMNs can release NETs, which in turn can be associated with severe tissue damage. In addition, a variety of pro-inflammatory stimuli, all of which can be found in the gingival sulcus, such as lipopolysaccharide (LPS), interleukin-8 (IL-8), TNF, as well as the streptococcal M protein can all induce NET formation [ror review, see Remijsen *et al*. (2011)].

While NETs have been described in periodontitis, it is likely that they are also formed in this initial lesion stage of gingivitis and then persist through all stages of gingivitis and periodontitis. Evidence for this however, is at present lacking.

Other cell types, such as eosinophils and mast cells, are also able to release extracellular traps (von Kockritz-Blickwede *et al*. 2008). These mast cell extracellular traps (MCETs) appear to be released in response to the same factors that lead to NET release from PMNs. MCETs are also composed of nuclear histones together with the antimicrobial cathelicidin LL37, as well as tryptase, a granular mast cell marker, and their formation in the tissues would not only limit the ingress of bacteria but also of bacterial vesicles. They may however, contribute to localized tissue destruction. Again, while highly likely, evidence for the formation of both NETs and MCETs in the tissues is lacking. Indeed, the role of mast cells in periodontal disease is largely unknown.

Within the gingival sulcus, PMNs also produce and release a variety of cytokines including IL-1, the IL-1 receptor antagonist (IL-1RA), and high levels of IL-17. IL-17 in turn induces the production of IL-8 by sulcus epithelial cells. IL-8 is not only a very strong chemoattractant for PMNs, but as stated earlier, is also a strong stimulus for NET formation, thus establishing a positive feedback loop in an attempt to contain the developing bacterial infection. Indeed, it is highly likely that the role of IL-17 in periodontal disease is a protective one in that it maintains the PMN barrier in the gingival sulcus. It is well established that loss of this barrier, either due to an absence of PMNs (such as agranulocytosis or cyclic neutropenia) or a defect in their function (either chemotactic or phagocytic), leads to severe and rapid progression of periodontal destruction.

At this initial stage however, the lesion occupies no more than 5–10% of the connective tissues, and is still not evident clinically.

The early lesion

The so-called "early" lesion develops after approximately 4–7 days of plaque accumulation. At this stage the nature of the developing lesion changes from one consisting primarily of PMNs to one with increased numbers of lymphocytes and macrophages

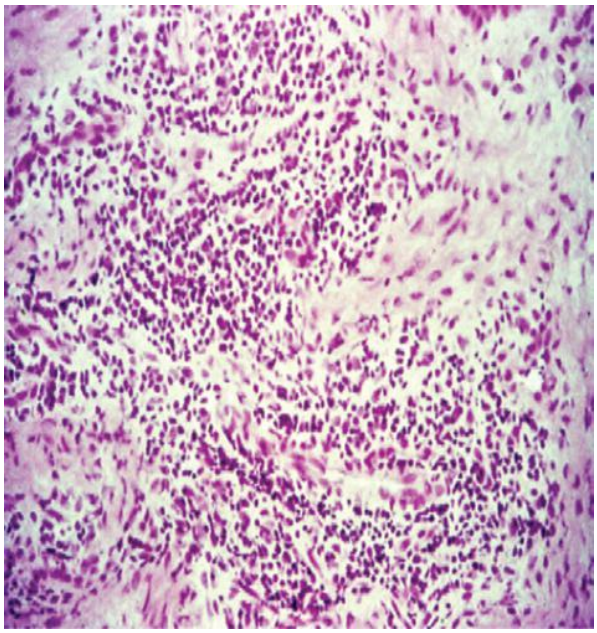

Fig. 12-4 Perivascular lymphocyte/macrophage infiltrate seen in a 21-day experimental gingivitis lesion.

(Fig. 12-4). Vascular changes become more pronounced with the opening of previously dormant capillary beds, the formation of post-capillary venules, increased vascular permeability, and the development of perivascular inflammatory infiltrates. As a result, there is a net increase in the flow of fluid into the affected gingival tissues, and a subsequent increase in the flow of GCF. The nature of the GCF at this stage changes from that of interstitial fluid to that of an inflammatory exudate, in other words edema. An increase in the permeability of the sulcular and junctional epithelia, as a result of widening of the intercellular spaces between the epithelial cells, allows increased ingress of bacterial products into the gingival tissues and escalation of the inflammatory response.

Initially, the lesion develops as small perivascular infiltrates which progressively increase in size and coalesce such that at around day 12–21 following the beginning of plaque accumulation the lesion becomes clinically evident. By day 21, lymphocytes make up 70% of the infiltrate and although there is a four-fold increase in PMN numbers within the junctional epithelium (Lindhe & Rylander 1975). PMNs and plasma cells make up <10% of the total infiltrate (Seymour *et al*. 1983). As with the initial lesion, the release of cytokines such as TNF-α and IL-17 from mast cells and PMNs undergoing NETosis leads to an increase in cell adhesion molecules, such as endothelial cell leukocyte adhesion molecule-1 (ELAM-1) and intercellular adhesion molecule-1 (ICAM-1), which together with an increase in IL-8 production by the epithelial cells help to establish a fast flow of PMNs through the junctional epithelium and into the gingival sulcus (Moughal *et al*. 1992), where they form a barrier against plaque microorganisms (Attstrom

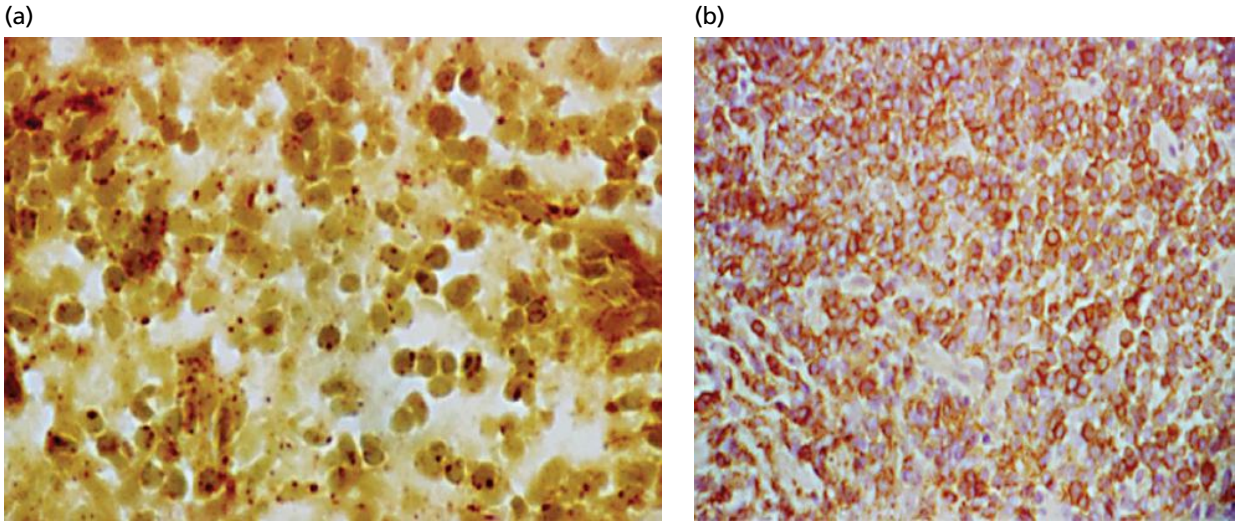

Fig. 12-5 21-Day experimental gingivitis lesion showing the predominance of (a) non-specific esterase-positive and (b) CD3-positive T cells.

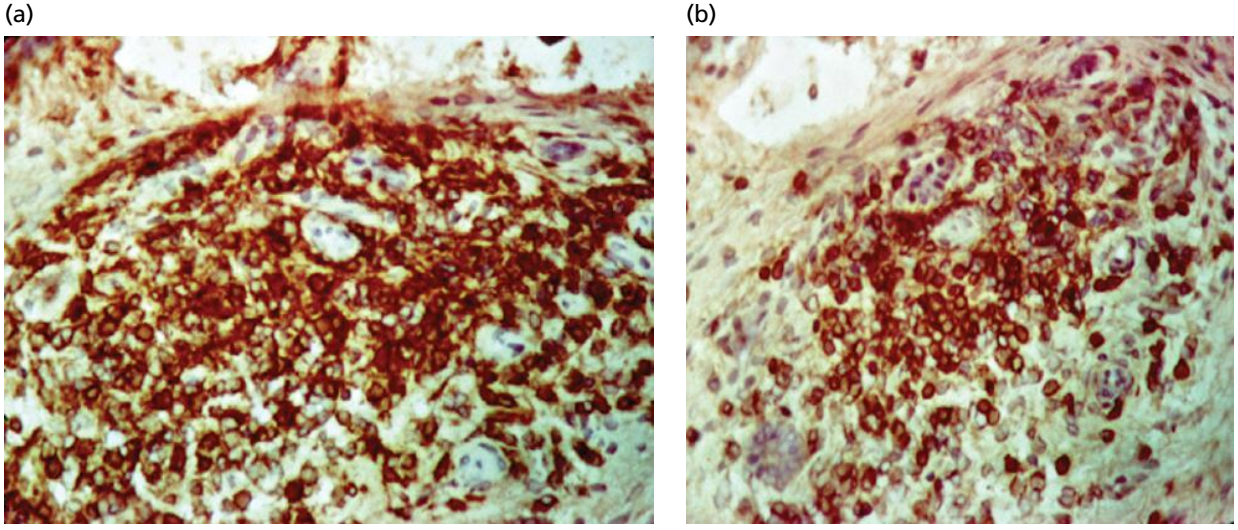

Fig. 12-6 21-Day experimental gingivitis lesion showing a (a) CD4 to (b) CD8 ratio of 2:1.

1971). Although the infiltrated area remains fairly localized at this stage, up to 60–70% of collagen within the infiltrated zone is degraded (Page & Schroeder 1976).

The immunologic events occurring during the development of gingivitis have been described (Seymour *et al*. 1988). These events are identical to the development of delayed-type hypersensitivity (DTH) and involve the formation of perivascular lymphocyte/macrophage infiltrates (Fig. 12-4) which, as they increase in size, coalesce and merge, eventually becoming clinically evident. The infiltrates consist predominantly of T cells (Fig. 12-5), with a CD4:CD8 ratio of around 2:1(Fig. 12-6), together with both dendritic antigen-presenting cells (APCs) and infiltrating phagocytic macrophages. These activated T cells, along with the sulcular epithelial cells, express high levels of MHC class II antigens (HLA-DR and HLA-DQ) (Fig. 12-7). Langerhans cells are seen in increased numbers in both the oral as well as the oral sulcular epithelium (Fig. 12-8a). Less than 5% of the T cells express the IL-2 receptor CD25 (Fig. 12-8b), suggesting that these cells are not proliferating locally. As soluble antigen enters the tissues, it is taken up by the resident Langerhans cells and carried to the regional lymph nodes where antigen-specific T cells are sensitized. These sensitized cells then travel back to the site of original antigen challenge (i.e. the gingival tissues). Once there, following further antigen presentation by dendritic cells, they become activated and together with the infiltrating phagocytic macrophages, they control the ingress of antigen and achieve a balance with the plaque biofilm. While dendritic APCs can be found in the perivascular spaces, the majority of macrophages in the developing lesion are phagocytic cells. The production of interferon gamma (IFN-γ) by the activated CD4 T cells further activates the PMNs and macrophages. Although

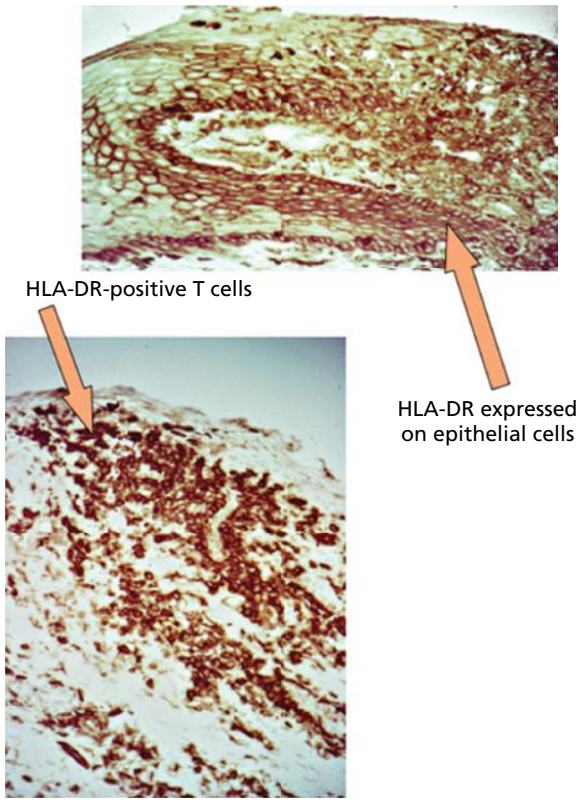

Fig. 12-7 21-Day experimental gingivitis lesion showing HLA-DR-positive activated T cells and HLA-DR-positive epithelial cells.

these cannot eliminate the bacterial challenge, they, via the production of NET in the gingival sulcus and the production of cytokines within the tissues, are able to control the infection. As noted earlier, this sequence of events is identical to that seen in the development of DTH (Poulter *et al*. 1982). The development of DTH is a well-controlled immunologic response which develops in 12–24 hours, peaks within 48 hours, and is gone within a week. In this context, gingivitis can also be considered to be a well-controlled immunologic response but, as noted earlier, because of the persistence of the plaque biofilm, the immunologic response persists rather than resolving. The subsequent, prolonged nature of the inflammatory response results in gingivitis becoming chronic in nature. While in most people the immune response is able to contain the microbial challenge, it is only with mechanical cleaning that the microbial challenge can be cleared. Collagen is degraded in the stable lesion but does not result in any loss of attachment. When the plaque is removed, gingival tissues repair and remodel, and there is no permanent damage to or alteration of tissue architecture.

The end stage of gingivitis is the so-called established lesion, which is distinguished from the early lesion by its increased proportions of B cells and plasma cells. The established gingivitis lesion may be differentiated from the considerably larger

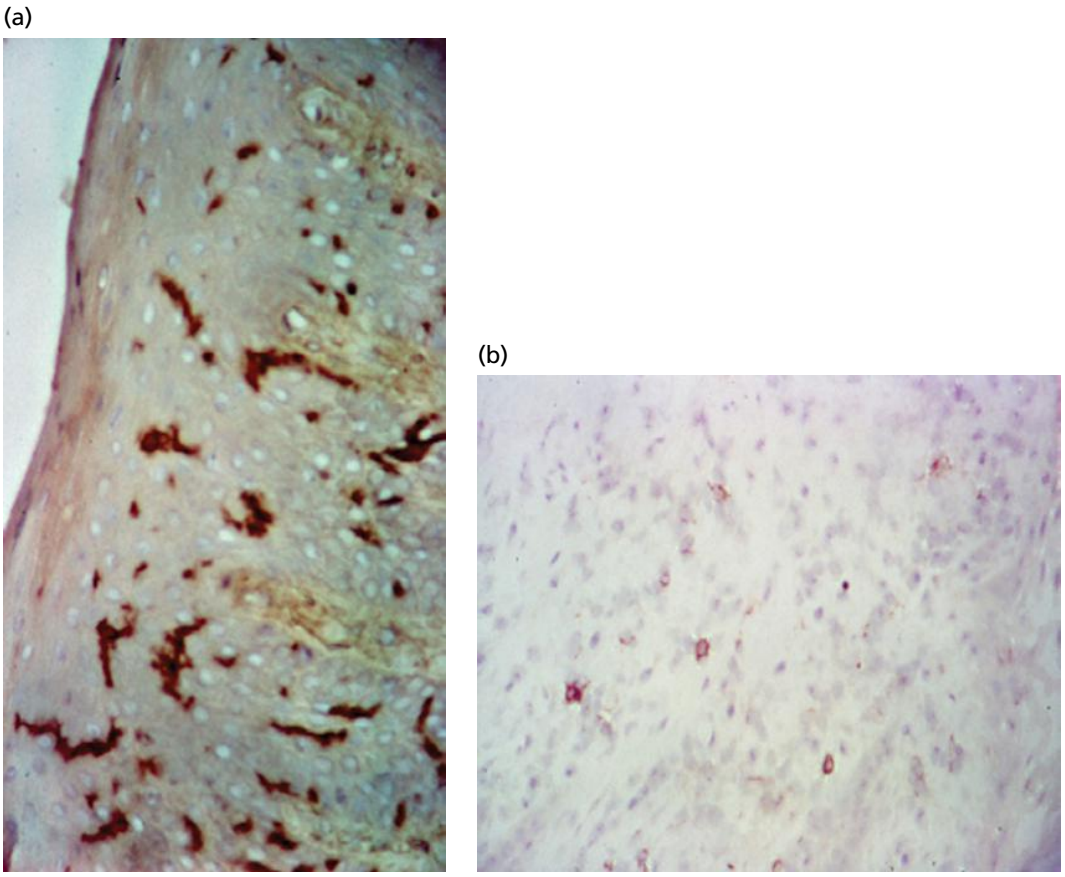

Fig. 12-8 21-Day experimental gingivitis lesion showing (a) increased CD1a-positive Langerhans cells in the oral epithelium and (b) relatively few CD25 (IL-2 receptor)-positive T cells in the infiltrate.

and plasma cell-dominated established periodontitis and advanced periodontitis lesions described in Chapter 13. Clinically it is not yet possible to determine disease activity; hence, it is not possible to say if the increased proportions of B cells and plasma cells in the established gingivitis lesion represent a stable gingivitis lesion or indeed are the beginning of a progressive periodontitis lesion. In this context, and in terms of the development of periodontal disease (gingivitis and periodontitis), it is probably better to consider the established gingivitis lesion and the increasing numbers of plasma cells as a possible transitional lesion between gingivitis and periodontitis.

Individual variations in the development of gingivitis

While experimental gingivitis studies clearly demonstrate that gingivitis is the response of the body to the build-up of dental plaque, there can also be a significant degree of variation between individuals even when there appears to be no quantitative or qualitative difference in plaque accumulation (Abbas *et al*. 1986; Trombelli *et al*. 2004a). It has repeatedly been shown that during a 3-week experimental gingivitis trial, the majority of subjects develop inflammation within the 3-week period (see Figs. 12-1, 12-2); however, some subjects may not develop clinically evident gingivitis despite plaque accumulation, while others may exhibit substantial gingival inflammation within 2 weeks (Wiedemann *et al*. 1979). Whether or not those who exhibit greater than average gingival inflammation in a short period of time represent a "susceptible" group, and those with a consistently below average level of inflammation represent a "resistant" group (Van der Weijden *et al*. 1994), remains to be determined. Two distinct subpopulations of individuals presenting a substantially different gingival inflammatory response to plaque have, however, been identified in a large cohort 21-day experimental gingivitis trial. These individuals showed significantly different severity of gingivitis arising from similar amounts of plaque and similar times of exposure (Trombelli *et al*. 2004a) (Table 12-1). Interestingly, these individuals could be identified after only 7 days of plaque exposure and the differences could still be observed even when oral hygiene and control of supragingival plaque was re-established (Trombelli *et al*. 2004b).

Whether these differences in the gingival inflammatory response under quantitatively and/or qualitatively almost identical bacterial challenge represent normal biologic variation or are an early indication of an individual's responsiveness to plaque bacteria, is not yet known (Tatakis & Trombelli 2004; Scapoli *et al*.

Table 12-1 Descriptive statistics and comparisons for (a) plaque index (mean ± SD) and (b) gingival crevicular fluid volume (in μL; mean ± SD) in test and control quadrants of "low-responder" (LR) and "high-responder" (HR) subjects.

2005, 2007). While some studies report that a percentage of repeatedly tested participants shows consistently high or low inflammatory responses to *de novo* plaque accumulation (van der Weijden *et al*. 1994; Watts 1978; Trombelli *et al*. 2008), others showed that there is little, if any, agreement between individual responses in repeated trials (Shearer *et al*. 2005). Clearly, further work needs to be done in this context.

Further, differences in the composition of the lesions between young and old individuals has been shown using the 3-week experimental gingivitis design. As discussed earlier, in young subjects gingivitis is a lymphocyte/macrophage-dominated lesion and its development is identical to that of DTH (Brecx *et al*. 1988; Seymour *et al*. 1988). In older subjects however, Fransson *et al*. (1996) found that plasma cells tended to dominate in some lesions after the 3-week experimental period. Similar differences were demonstrated between young and old dogs (Berglundh & Lindhe 1993). This difference may reflect the fact that older individuals (or animals) are more likely to have experienced one or more episodes of progressive periodontitis and hence may have a greater tendency to develop another progressive periodontitis lesion within the 3-week experimental period compared with young individuals, although this remains to be determined.

Factors influencing the development of gingivitis

Microbiologic factors

While variations in the development of gingivitis were observed in the initial experimental gingivitis studies (Löe *et al*. 1965; Theilade *et al*. 1966), they have usually been ascribed to differences in plaque accumulation rates (quantitative plaque differences) and/or to differences in the species of bacteria present in the plaque (qualitative plaque differences) (Löe *et al*. 1965; Theilade *et al*. 1966). Under experimental gingivitis conditions, it has long been known that phylogenetic shifts occur in the composition of the plaque microbiota, which parallel the amount of plaque accumulated over time (Theilade *et al*. 1966; Oliver *et al*. 1989). A higher prevalence of specific bacterial species, such as *Porphyromonas gingivalis, Treponema denticola, Parvimonas micra, Fusobacterium nucleatum*, and *Prevotella intermedia,* has been observed at sites where rapid plaque accumulation and severe gingival inflammation occur. However, the prevalence of several of these species (*Tannerella forsythia*, *T. denticola*, *Campylobacter rectus*, *P. micra*, *P. intermedia*, and *F. nucleatum*) was lower than observed in sites presenting with naturally occurring gingivitis (Table 12-2) (Farina *et al*. 2012). It is also interesting to note that there are changes in the bacterial profile of the microbiota of sites associated with gingival bleeding (Löe *et al*. 1965; Theilade *et al*. 1966; Bosman & Powell 1977; Oliver *et al*. 1989; Moritz *et al*. 1998). However, it is not known whether these differences are a cause of the gingival bleeding or are a result of the gingival bleeding and the altered environment.

Predisposing factors

Predisposing factors are defined as those factors which retain or hinder the removal of plaque and therefore are associated with both the maintenance and severity of gingival inflammation. Predisposing factors are largely local with the most common being the formation of dental calculus. Other predisposing factors include developmental or anatomic tooth variations [palatogingival groove (Hou & Tsai 1993), enamel pearls (Goldstein 1979)], pathologic tooth conditions [fractures (Polson 1977), caries (Albandar *et al*. 1995)], gingival anatomic conditions [recession defects (Smukler & Machtei 1987; Goutoudi *et al*. 1997), frenal positions (Addy *et al*. 1987)], crowding (Chung *et al*. 2000), and iatrogenic factors such as subgingival restoration margins (Waerhaug 1975; Bader *et al*. 1991), overhangs (Rodriguez-Ferrer *et al*. 1980; Lang *et al*. 1983), partial dentures (Bissada *et al*. 1974; Yeung *et al*. 2000), and orthodontic appliances (Boyd & Baumrind 1992). Maxillofacial anatomic variants (e.g. inadequate upper lip coverage) and/or upper respiratory obstructions (e.g. epipharyngeal adenoids, deviated nasal septum) may lead to mouth breathing, which has been shown to lead to changes in plaque accumulation and gingivitis expression, particularly in the maxillary anterior segment of the dentition (Jacobson 1973; Addy *et al*. 1987; Wagaiyu & Ashley 1991; Gulati *et al*. 1998), and hence should be considered as a predisposing factor.

In addition, the frequent intake of sucrose, acting at a local level, is well established as being responsible for increased plaque accumulation and concomitantly increased gingival inflammation (Jalil *et al*. 1983; Sidi & Ashley 1984).

Finally, the role of incisor crown form, which relates to periodontal biotype, has been used to explain subject variations in gingivitis expression. Subjects with "long narrow" incisors tend to have significantly higher bleeding scores compared with subjects with "short wide" incisors, irrespective of the amount of plaque accumulation (Trombelli *et al*. 2004c).

Modifying factors

Modifying factors are defined as those factors which alter the nature or course of the inflammatory response. As chronic inflammation can be considered to be comprised of a vascular response and a cellular response together with the simultaneous presence of destruction and repair, anything which alters the vascular response, the cellular response or the repair potential of the tissues can be considered a modifying factor.

Vascular response

Sex hormones

Physiologic and pathologic endocrine changes have long been established as significant modifying factors in the expression of gingivitis (Sooriyamoorthy & Gower 1989; Mariotti 1999; Tatakis & Trombelli 2004).

The variation in sex hormone levels during puberty (Mombelli *et al*. 1989; Bimstein & Matsson 1999), pregnancy (Hugoson 1971), and menstruation (Koreeda *et al*. 2005) has been shown to alter the plaque–gingivitis relationship, resulting in increased levels of inflammation. Gingival and periodontal tissues contain receptors for sex steroid hormones and their physiology is regulated, at least in part, by serum and salivary hormonal levels (Soory 2000). In particular, estrogen has a stimulatory effect on both the metabolism of collagen and on angiogenesis, and at the same time it leads to a decrease in keratinization of the gingival epithelium. However, it is progesterone which is thought to have the major effect in the gingival tissues, both in terms of its effect on the levels of pro-inflammatory mediators (Lapp *et al*. 1995; Markou *et al*. 2011) and on the gingival vasculature. It has been known for many years that progesterone not only increases vascularity of the gingival tissues but also increases their permeability, thus resulting in a highly vascular edematous inflammatory response (Hugoson 1970; Lundgren *et al*. 1973).

Pregnancy

Pregnancy was one of the first conditions identified as having an impact on the expression of gingivitis (Ziskin *et al*. 1946; Löe & Silness 1963; Silness & Löe 1964). In particular, increases in both the prevalence and severity of gingivitis were reported during the second and third trimester of pregnancy (Löe & Silness 1963; Löe 1965; Hugoson 1971; Arafat 1974). While the selective growth of specific bacterial species, including some periodontal pathogens, has been reported during pregnancy (Jensen *et al*. 1981; Muramatsu & Takaesu 1994; Di Placido *et al*. 1998), a number of case–control and experimental gingivitis studies have failed to show a correlation between increased gingival inflammation and quantitative variations in plaque levels (Raber-Durlacher *et al*. 1994; Gürsoy *et al*. 2008; Figuero *et al*. 2010). In this context, the generally accepted mechanisms leading to the exaggerated inflammatory response seen in pregnancy are related to the increased levels of progesterone, which lead to increased permeability and dilatation of gingival capillary vessels, resulting in increased vascular flow and exudation (Hugoson 1970; Lundgren *et al*. 1973). These effects are partly mediated by an increased synthesis of prostaglandin (Miyagi *et al*. 1993).

Puberty

With the onset of puberty, an increase in gingival inflammation not associated with a concomitant increase in plaque levels has been reported for both males and females (Parfitt 1957; Sutcliffe 1972; Hefti *et al*. 1981; Mombelli *et al*. 1989). In addition, variations in the severity of gingival inflammation have been described during the menstrual cycle, particularly during the ovulation period, despite unvarying levels of plaque (Koreeda *et al*. 2005). Fluctuation of sex steroid hormones, especially progesterone, is thought to alter the host response, leading to the observed increase in the clinical signs of gingival inflammation (Baser *et al*. 2009; Becerik *et al*. 2010). Sex steroid hormones may affect blood volume, flow rate, and vascular permeability in young females (Lindhe & Attsfrom 1967; Mariotti 1994), leading to the observed increase in gingival exudate during ovulation (Hugoson 1971). The evidence, however, suggests that hormonal variations during the cycle do not affect clinically normal gingiva, but do exacerbate existing chronic gingivitis (Holm-Pedersen & Löe 1967; Kovar *et al*. 1985; Niemi *et al*. 1986; Becerik *et al*. 2010).

Contraceptives

Early clinical studies reported a higher incidence of gingival inflammation in women taking hormonal contraceptives compared with women not taking these agents (Lindhe & Bjorn 1967; El-Ashiry *et al*. 1970; Pankhurst *et al*. 1981). Effects similar to the ones associated with changes in hormone levels during pregnancy have been reported for contraceptives (Lindhe *et al*. 1969; Kalkwarf 1978). Since 1976, however, formulations of oral contraceptives have changed dramatically, resulting in substantially lower concentrations of hormones. More recent studies suggest that the effect of newer contraceptive pills on gingivitis is practically nil (Preshaw *et al*. 2001). Consistently, a comprehensive evaluation of data from two large surveys (National Health and Nutrition Examination Survey I and III) failed to find a strong association between oral contraceptives (either for earlier/high or current/low dosages) and occurrence of plaque-induced gingivitis (Taichman & Eklund 2005). Recently, the periodontal condition of women using contraceptive pills for at least 2 years was compared with that of matched controls not taking an oral contraceptive. In contrast with the above results, current oral contraceptive pill users had higher levels of gingival inflammation and bleeding on probing despite similar amounts of supragingival plaque (Haerian-Ardakani *et al*. 2010).

Diabetes

Diabetes is an endocrine condition with a well-characterized effect on gingivitis. Clinically, subjects with diabetes, whether insulin-dependent or non-insulin dependent, have significantly higher gingival inflammation compared with those who do not have diabetes with similar plaque levels (Bernick *et al*. 1975; Cutler *et al*. 1999; Salvi *et al*. 2005). Data from experimental gingivitis studies support these findings, with individuals with type 1 diabetes showing

more severe inflammation in response to a comparable bacterial challenge than that of subjects without diabetes (Salvi *et al*. 2005, 2010).

At the vascular level, the accumulation of advanced glycation end products (AGEs) alters the function of several intercellular matrix components, including vascular wall collagen, resulting in thickening of the capillary basement membrane and loss of vascular elasticity (Ulrich & Cerami 2001). Results from controlled histologic studies in animals showed that diabetes was associated with changes of the gingival vascular apparatus, such as the formation of new vessels with variable wall thickness, hyperemia, localized moderate-to-severe vasculitis (Tesseromatis *et al*. 2009), increased vascular permeability accompanied by increased leukocyte adhesion molecule expression, and enhanced leukocyte rolling (Sima *et al*. 2010).

Smoking

The effect of smoking on the expression of plaque-induced gingival inflammation is controversial. A number of studies have shown that smokers, when compared with non-smokers, accumulate plaque at the same rate but exhibit significantly less gingival inflammation in experimental gingivitis studies, albeit with similar plaque levels (Bergstrom & Preber 1986; Danielsen *et al*. 1990; Lie *et al*. 1998; Müller *et al*. 2002). In addition, significantly lower GCF volumes were detected at periodontally healthy or slightly inflamed sites in young regular smokers compared with non-smokers (Persson *et al*. 1999). At the same time, a single episode of smoking has been shown to produce a transient increase in GCF volume (McLaughlin *et al*. 1993).

The biologic mechanisms underlying the suppressive effect of smoking on clinical parameters of gingival inflammation are poorly understood. A structural and/or functional impairment of the gingival and periodontal microcirculatory system however, has been put forward (Scott & Singer 2004). In one, albeit small, study, the periodontal vascular system in smokers was found to be composed of smaller numbers of large vessels, but larger numbers of small vessels, compared with non-smokers, with no differences in terms of mean vascular density between smokers and non-smokers (Mirbod *et al*. 2001). This, together with the well-established nicotine-induced peripheral vasoconstriction as well as the reduction in GCF, is consistent with the effect of smoking being mediated, at least in part, by modulation of the local vascular response.

In contrast, Bergstrom *et al*. (1988) showed that after 28 days of experimentally-induced plaque accumulation, smokers had 50% more gingival blood vessels compared with non-smoking controls in spite of similar levels of plaque accumulation.

Further, Baab and Öberg (1987) found that a single episode of cigarette smoking was associated with a transient increase in gingival blood flow compared with sham-smoking in young smokers. Consistently, a modest increase in gingival blood flow was noted during the smoking episode, as well as over the following 10 minutes (Mavropoulos *et al*. 2003). When periodontally healthy sites were compared in terms of gingival blood flow between non-smokers performing sham-smoking, light smokers, and heavy smokers, however, no differences in gingival blood flow were observed between the groups either before, during or after smoking (Meekin *et al*. 2000).

At the present time, there is insufficient data to determine whether and to what extent the suppressive effect of smoking on the plaque-induced gingival inflammatory response may be ascribed to a modulatory effect of smoking on the vascular response.

Cellular response

Blood dyscrasias

The systemic conditions usually identified as affecting the cellular response in gingivitis are the blood dyscrasias, including neutropenias (Andrews *et al*. 1965; Rylander *et al*. 1975; Reichart & Dornow 1978), leukemias (Levin & Kennedy 1973; Bergmann *et al*. 1992), and human immunodeficiency virus/acquired immune deficiency syndrome (AIDS) (Glick *et al*. 1990). These conditions are characterized either by low numbers of functional PMNs (neutropenias) or large numbers of immature dysfunctional leukocytes (leukemias) infiltrating the gingival tissues or, as in the case of AIDS, by a very low CD4-positive T-cell count and the inability to mount an effective T-cell response. Other conditions which are characterized by defective PMN function, either phagocytic (Chédiak–Higashi syndrome) or chemotactic (Down's syndrome) (Izumi *et al*. 1989), also display severe gingival inflammation. These conditions highlight the fact that abnormalities in cell numbers or function can modify the inflammatory response to plaque and manifest as severe gingival inflammation.

Diabetes

As noted earlier, the development of gingivitis involves an initial innate immune response to the formation of plaque. In the presence of a poor innate response and the relative lack of PMNs in the gingival sulcus, a more severe inflammatory response occurs in an attempt to contain the developing infection. In addition to the vascular response noted earlier, hyperglycemia also leads to an impairment of immune cell function (Gugliucci 2000). In this respect, individuals with uncontrolled diabetes show reduced PMN function (Marhoffer *et al*. 1992), defective chemotaxis (Ueta *et al*. 1993), and significantly more severe gingival inflammation compared with those without diabetes with similar plaque levels (Gislen *et al*. 1980; Cianciola *et al*. 1982; Rylander *et al*. 1987; Salvi *et al*. 2005).

Chronic hyperglycemia leads to the accumulation of AGEs, which bind to macrophages and monocytes (Brownlee 1994), resulting in an increased release of

pro-inflammatory mediators (Iacopino 1995) and more severe gingival inflammation with higher levels of IL-1β and matrix metalloproteinase-8 (MMP-8) (Salvi *et al*. 2010).

Smoking

Smoking also has a profound effect on the immune and inflammatory system (Barbour *et al*. 1997; Palmer *et al*. 2005), including reduced migration (Eichel & Shahrik 1969) and phagocytic capacity of PMNs (Kenney *et al*. 1977) and increased numbers of circulating T and B lymphocytes (Sopori & Kozak 1998). However, the relevance of these mechanisms in altering the gingival inflammatory response to the dental biofilm needs to be determined.

Repair potential

The final feature of a chronic inflammatory response is the ability of the tissue to repair itself, such that anything which affects this ability will modify the gingival response to plaque and will either manifest as an enlargement (over response) or loss of connective tissue (impaired response) and progression to periodontitis.

Over response

Several drugs (Seymour 1993), including anticonvulsants such as phenytoin (Angelopoulos 1975a, b), antihypertensive calcium channel blockers such as nifedipine (Nery *et al*. 1995; O'Valle *et al*. 1995), and the immunosuppressant cyclosporine (Seymour & Jacobs 1992; O'Valle *et al*. 1995) cause severe gingival enlargement, a reaction related to the plaque-induced gingival inflammation (Seymour *et al*. 1996). Although these drugs have different pharmacologic mechanisms, a common denominator appears to be their effect on calcium metabolism which has been hypothesized to result in gingival enlargement (Hassell & Hefti 1991). Consistent with this concept is the fact that the clinical and histologic features of gingival enlargements induced by phenytoin, cyclosporine, or nifedipine are all similar (Hassell & Hefti 1991; Seymour *et al*. 1996). Histologic studies have shown that accumulation of extracellular matrix within the gingival connective tissue is the main feature of the overgrown tissues (Rostock *et al*. 1986; Mariani *et al*. 1993).

It is well established that the severity of the gingival enlargement is related to the level of plaque control and the presence of gingivitis (Steinberg & Steinberg 1982; Addy *et al*. 1983; Hassell *et al*. 1984; Tyldesley & Rotter 1984; Daley *et al*. 1986; McGaw *et al*. 1987; Modeer & Dahllof 1987; Yahia *et al*. 1988; Barclay *et al*. 1992; Lin & Yang 2010), which supports the concept that the enlargement reflects an over response of the repair component of the inflammatory reaction. Further, a high concentration of tissue plasminogen activator (t-PA) (Buduneli *et al*. 2004) and plasminogen activator inhibitor type 2 (PAI-2) has been demonstrated in GCF from enlarged sites, which suggests that the enlargement itself may act as a predisposing factor and lead to the aggravation of gingival inflammation (Kinnby *et al*. 1996). However, whether and to what extent the drugs associated with gingival enlargement may intimately modulate the complex host–bacteria interaction leading to gingival inflammation remains to be determined.

Impaired response

An example of how an impaired repair potential can influence the expression of gingivitis can be seen in vitamin C deficiency where an impairment of collagen metabolism results in highly inflamed, friable gingivae in the presence of plaque. Indeed, in both humans (Leggott *et al*. 1986, 1991) and non-human primates (Alvares *et al*. 1981) a subclinical deficiency of ascorbic acid results in increased gingivitis relative to non-deficient controls with similar plaque levels and the same type of microbiota.

Other studies, although preliminary and limited in number, suggest that other nutritional factors, including vitamin E (Cohen & Meyer 1993; Offenbacher *et al*. 1990; Asman *et al*. 1994), riboflavin, calcium, and frequency of fiber intake (Petti *et al*. 2000) may influence the incidence and severity of plaque-induced gingivitis, but their mechanisms are unknown.

Introduction

An understanding of the etiology and pathogenesis of periodontitis is essential for treatment planning. In this context, it is clear that the bacteria in dental plaque are the cause of both gingivitis and periodontitis; however, not all individuals with gingivitis will progress to periodontitis, and not all individuals with periodontitis will progress to tooth loss. The development of gingivitis can be considered to be a well-controlled immunologic response, as outlined in Chapter 12. However, in some people, due to environmental factors, their own innate susceptibility or both, there is loss of connective tissue and bone, apical migration of the junctional epithelium, and development of periodontitis.

The aim of this chapter is to present an understanding of the pathogenesis of periodontitis, which will provide a basis for treatment planning and future risk assessment.

Over the past two decades it has become established that periodontitis results from the interaction of the host's defense mechanisms with biofilms containing complexes including *Porphyromonas gingivalis*, *Tannerella forsythia*, and *Treponema denticola* (Socransky *et al.* 1998). Although present in a large proportion of the normal population (Cullinan *et al*. 2003), *Aggregatibacter actinomycetemcomitans* has been implicated in so-called aggressive periodontitis in some populations. Notwithstanding these observations, it has also been shown that there is a high degree of volatility with respect to the presence and/or absence of these organisms over time, such that it would appear that they are more widespread in the community than previously thought. Indeed, it is now recognized that many people carry the organisms without manifesting disease progression (Cullinan *et al*. 2003). In this context, it is clear that most people are in balance with their biofilm for most of the time and it is only when this balance is disturbed that disease results. Such disturbances may occur as a result of environmental influences leading to an opportunistic increase in the numbers of organisms, or a depression of the host's defense mechanisms or indeed both. Disease expression and progression therefore reflects the interplay between the bacteria, the host's immune system, and environmental factors (Cullinan *et al*. 2001;

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

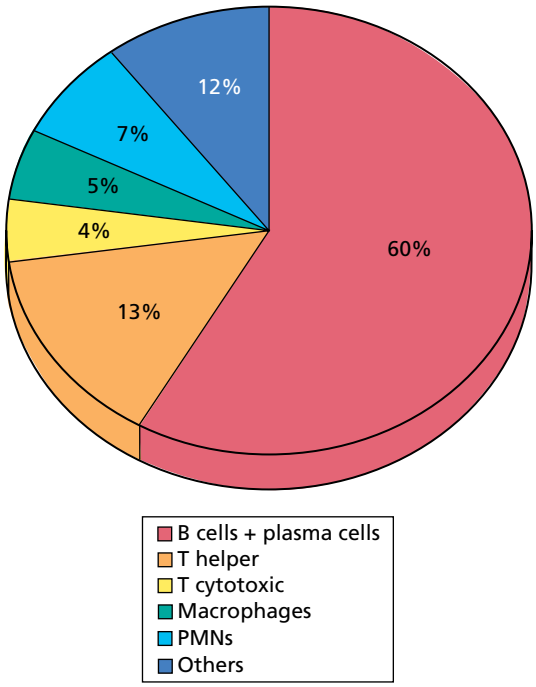

Fig. 13-1 Distribution of cells in periodontitis lesions. (Adapted from Berglundh *et al*. 2011, from John Wiley & Sons.)

Seymour & Taylor 2004), with tissue destruction being due to the response to the patient's specific individual pathogenic microbiota.

In 1965, Brandtzaeg and Kraus (1965) demonstrated the presence of immunoglobulin-producing plasma cells in the gingival tissues of patients with periodontitis. This was the first direct evidence that adaptive immune mechanisms play a role in the pathogenesis of periodontal inflammation. It was not until 1970 however, that Ivanyi and Lehner (1970), using peripheral blood lymphocyte transformation assays, highlighted a role for cell-mediated immunity. However, subsequent studies demonstrated that the periodontitis lesion itself involves predominantly B cells and plasma cells (Fig. 13-1) (Mackler *et al*. 1977; Seymour *et al*. 1978; Seymour & Greenspan 1979; Berglundh *et al*. 2011) and in this context it has been proposed that the development of periodontitis involves a switch from a predominantly T-cell gingivitis lesion to one involving large numbers of B cells and plasma cells (Seymour *et al*. 1979)

Histopathology of periodontitis

As described in Chapter 12, the development of gingivitis and periodontitis can be loosely divided into a series of stages, as described by Page and Schroeder (1976). These authors classified the development of the disease into the "initial", "early", "established", and "advanced"' lesions. The initial and early lesions have been described in Chapter 12. The established and advanced lesions are described here and while they are histopathologically similar, they differ in their clinical expression and degree of destruction.

Established or progressive lesion

The established/progressive lesion is primarily a lymphocyte/plasma cell lesion with the main identifying feature being the predominance of plasma cells within the periodontal connective tissues (Mackler *et al*. 1977; Seymour *et al*. 1978; Seymour & Greenspan 1979). The majority of lymphocytes are immunoglobulin-bearing B cells, although up to 30% of the lymphocytes may be T cells. While the gingivally confined T-cell lesion remains relatively stable, this B-cell/plasma cell lesion progresses and leads to the development of a periodontal pocket. Connective tissue breakdown leads to loss of the connective tissue attachment to the tooth and as a result the junctional epithelium migrates in an apical direction, thus forming a periodontal pocket (Fig. 13-2). This in turn becomes lined by pocket epithelium with in-growth of rete pegs into the surrounding connective tissue (Fig. 13-3). Polymorphonuclear neutrophils (PMNs) continue to migrate through this pocket lining epithelium and into the periodontal pocket where they form a barrier between the tissues and plaque biofilm. Increased permeability and ulceration of the pocket epithelium allows further ingress of microbial products, leading to the continued production of inflammatory cytokines such as interleukin-1 (IL-1), tumor necrosis factor-alpha (TNF-α), and prostaglandin E_2 (PGE_2) [for review, see Gemmell *et al*. (1997)], and perpetuation of the inflammatory process resulting in destruction of both connective tissue and bone (Reynolds & Meikle 1997). Surrounding the inflammatory infiltrate is a fibrous tissue band. This is common to all chronic inflammatory lesions and is an attempt by the lesion to wall off from the surrounding tissues. Indeed, in periodontitis, irrespective of the depth of the pocket, the underlying alveolar bone and periodontal ligament do not become inflamed (Fig. 13-4).

Advanced lesion

The advanced lesion has essentially the same cellular make-up and features as the established lesion. The main difference lies in the overt loss of attachment that is evident clinically and histologically (Figs. 13-5, 13-6). It is now generally accepted that the mechanism of tissue destruction is via the effects of the immune response (Birkedal-Hansen 1993) and is not a direct consequence of the bacteria *per se*. Macrophages are not a dominant feature of the advanced lesion, comprising fewer than 5% of the cells. Fibroblasts, however, when stimulated by the inflammatory cytokines IL-1, IL-6, TNF-α, and

PGE_2, produce matrix metalloproteinases (MMPs), which are a family of proteinases whose primary purpose is the degradation of the extracellular matrix. Collagen molecules are cleaved into smaller fragments, which then become denatured in the extracellular environment or are phagocytosed by surrounding fibroblasts. As the lesion advances, alveolar bone loss becomes apparent. However, the non-infiltrated fibrous band remains adjacent to the crestal bone, effectively encapsulating the progressing lesion and walling it off from the surrounding tissues. It should be noted again that the underlying bone and periodontal ligament remain non-inflamed (Fig. 13-7).

B cells in periodontitis

As noted above, the periodontitis lesion is characterized by large numbers of B cells and plasma cells. Immunoglobulin-bearing B cells in a periodontitis lesion are illustrated in Fig. 13-8. B cells can be activated either by specific antigens or by polyclonal activators. Indeed, a number of the putative periodontal pathogens, including *P. gingivalis*, *A. actinomycetemcomitans*, and *Fusobacterium nucleatum* have been shown to have profound polyclonal B-cell activation properties (Bick *et al*. 1981; Mangan *et al*. 1983; Carpenter *et al*. 1984; Ito *et al*. 1988). However, polyclonal activators do not activate all B cells. Approximately 30% of B cells may be stimulated by a single polyclonal activator, with different activators acting on different B-cell subpopulations. Further, the antibodies produced as a result of this polyclonal activation are likely to be of low affinity and the memory component may not be induced (Tew *et al*. 1989). At the same time, a degree of antigen-specific induction of sensitized B cells is also likely to occur. The principal immunoglobulin class produced in the periodontal tissues is IgG, followed by IgM and some IgA.

The role of specific antibodies in the pathogenesis of chronic periodontitis is poorly understood. High titers of specific antibodies to *P. gingivalis* and *A. actinomycetemcomitans* have been demonstrated in the serum and gingival crevicular fluid (GCF) of subjects with periodontal disease; however, the reports are still conflicting with respect to disease activity (Baranowska *et al*. 1989; Ebersole *et al*. 1995; Nakagawa *et al*. 1994). Immunodominant antigens of *P. gingivalis* and *A. actinomycetemcomitans* have also shown different patterns of immunoreactivity, while anti-*P. gingivalis* antibodies with different avidities have been demonstrated in various forms of periodontal disease (Mooney & Kinane 1994). It has been suggested that antibodies with high avidity confer resistance to continued or repeated infection, whereas non-protective low-avidity antibodies may be incapable of effectively mediating a variety of immune responses (Lopatin & Blackburn 1992; Kinane *et al*. 2008).

While a strong antibody response has been suggested to be generally protective, facilitating

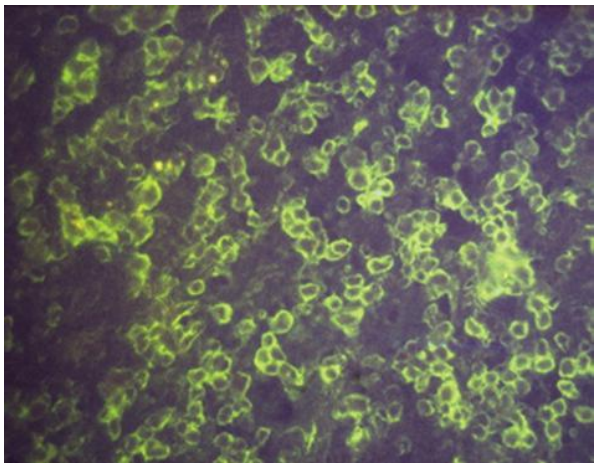

Fig. 13-8 Immunoglobulin-bearing B cells in a periodontitis lesion.

bacterial clearance and arresting disease progression (Offenbacher 1996; Kinane *et al*. 2008), the mechanism by which this is achieved is unclear. Antibodies, by virtue of their molecular size, are unlikely to penetrate the biofilm and hence their ability to clear the subgingival infection is questionable. Equally, PMNs do not penetrate the biofilm, again limiting their ability to clear the infection. Nevertheless, an increased capacity of serum to opsonize *P. gingivalis* has been shown to be a distinctive feature in patients with past destructive periodontal disease (Wilton *et al*. 1993). However, this high level of opsonizing antibody is more likely to be related to past bacteremias and the ability to clear the serum, than an ability to clear the subgingival infection. On the other hand, repeated infection with *A. actinomycetemcomitans* in an animal model has been shown to elicit an anti-leukotoxin antibody which protects PMNs from the leukocidal activity of the leukotoxin (Underwood *et al*. 1993). In this context, specific antibodies to bacterial products may be involved in controlling disease expression rather than clearing the organism from the subgingival biofilm. On the other hand, polyclonal B-cell activation by periodontopathic bacteria and the production of non-specific and/or low-avidity antibodies may not be capable of controlling the disease.

As well as producing immunoglobulins/antibodies, continued B-cell activation leads to the production of high levels of cytokines, including IL-1 and IL-10, which may contribute to subsequent tissue destruction. However, while *P. gingivalis* depresses the gene for IL-1β in T cells, it has been shown to induce an increased percentage of peripheral blood B cells from periodontitis patients to produce IL-1β (Gemmell & Seymour 1998). Since macrophages are not a dominant feature of the advanced lesion (Chapple *et al*. 1998) and suppressed cell-mediated immunity is associated with advanced periodontitis, it may be that B cells are the major source of IL-1 in periodontitis.

T cells in periodontitis: The Th1/Th2 paradigm

The fact that the development of gingivitis is identical to the development of delayed-type hypersensitivity (DTH) and that progressive chronic periodontitis is fundamentally a B-cell lesion, led to the concept that gingivitis and hence the stable periodontal lesion is mediated by Th1 cells, while periodontitis is mediated by Th2 cells (Seymour *et al*. 1993). In this concept it is proposed that a strong innate immune response leads to the production of high levels of IL-12 by both PMNs and macrophages, which in turn leads to a Th1 response, cell-mediated immunity, protective antibody, and a stable periodontal lesion. In contrast, a poor innate immune response with polyclonal B-cell activation leads to a Th2 response, non-protective antibody, and a progressive periodontal lesion. Since being put forward over 20 years ago, this hypothesis has attracted a lot of attention with a number of studies supporting the hypothesis by showing either depressed Th1 responses or increased Th2 responses in periodontitis. In contrast, other studies (primarily in animal models) have implicated increased Th1 responses in periodontitis, while others have highlighted a role for Th0 cells. Nevertheless, it is now generally agreed that periodontitis in humans is mediated by a balance in Th1 and Th2 cells with a shift towards a Th2 profile (Berglundh & Donati 2005; Kinane & Bartold 2007).

Suppression of cell-mediated immunity

The first study to report a possible suppression of cell-mediated immunity in advanced periodontitis subjects was by Ivanyi and Lehner (1970). Subsequently, a number studies have shown that periodontopathic bacteria, including *P. gingivalis*, *A. actinomyetemcomitans*, *T. denticola*, *Capnocytophaga ochracea*, and *F. nucleatum* (Shenker *et al*. 1982; Shenker & Slots 1989; Shenker & Datar 1995) could induce lymphocyte suppression *in vitro*. In addition, T cells extracted from periodontitis lesions not only have a reduced ability to respond in an autologous mixed lymphocyte reaction (AMLR), but also fail to produce IL-2, suggesting that this suppression of cell-mediated responses in periodontitis may also occur *in vivo* (Seymour *et al*. 1985) The fact that the AMLR returns to normal following periodontal therapy (Evans *et al*. 1989) also supports the concept that the suppressive effect of plaque bacteria on cell-mediated immunity (i.e. Th1 responses) may be fundamental in the conversion of a stable to a progressive lesion.

T cells and homeostasis

T cells are involved in nearly all immunoregulatory interactions both *in vivo* and *in vitro*, and a delicate

balance between effector and regulatory subsets is required for immune homeostasis. Th1 cells not only mediate DTH but also increase the ability of macrophages to kill intracellular and extracellular pathogens (Romagnani 1992). Further, there is evidence that T cells are involved in the recruitment and activation of PMNs at the site of infection (Campbell 1990), suggesting that in the stable lesion, activation of PMNs may be crucial in keeping the infection under control. Indeed, a strong innate immune response in the gingival tissues and the production of IL-12 could be critical in the establishment of a Th1 response. The presence of natural killer (NK) cells in gingival tissues has also been demonstrated (Wynne *et al*. 1986) and may also be significant in the establishment of a Th1 response. The production of interferon gamma (IFN-γ) enhances the phagocytic activity of both PMNs and macrophages, and hence containment of the infection.

In contrast, the B-cell nature of the progressive periodontitis lesion suggests either an increase in production of Th2 cytokines or a decline in the production of Th1 cytokines, in other words a shift in the balance towards Th2.

Cytokine profiles

Studies over the past decade have supported the hypothesis that Th1 cells are associated with the stable lesion and Th2 cells with disease progression [for review, see Gemmell *et al*. (2007)]. However, other studies have reported a predominance of Th1-type cells or reduced Th2 responses in diseased tissues (Ebersole & Taubman 1994; Salvi *et al*. 1998; Takeichi *et al*. 2000). More recently, the involvement of both Th1 and Th2 cells in periodontal disease in humans [for review, see Gemmell *et al*. (2007)] has been suggested. However, although cytokine patterns reflecting both subsets can be found in periodontitis tissues (Yamamoto *et al*. 1997), as noted above, it is now agreed (Berglundh & Donati 2005; Kinane & Bartold 2007) that periodontitis in humans is associated with a shift towards a Th2 response. Further circumstantial evidence for this concept is seen in the fact that *P. gingivalis* cysteine proteases (gingipains) hydrolyze IL-12, thereby having the capacity to reduce IL-12–induced IFN-γ production by CD4 cells and so favor a shift to a Th2 response and subsequent disease progression (Yun *et al*. 2001). Also, peripheral blood cells from periodontitis patients produce significantly lower levels of IL-12 (Fokkema *et al*. 2002) and the numbers of IgG4-positive B cells in the gingival tissues have been shown to increase relative to IgG2-positive cells with increasing inflammation, indicating the influence of IL-4 and Th2 responses and a corresponding decrease in IFN-γ and Th1 responses in large infiltrates in periodontitis.

CD8 T cells

The CD4:CD8 ratio in gingivitis is approximately 2:1 (Berglundh *et al*. 2002a; Zitzmann *et al*. 2005). This is consistent with the ratio seen in peripheral blood, in secondary lymphoid organs, and in the development of DTH (Seymour *et al*. 1988) In contrast, early studies on cells extracted from periodontitis lesions (Cole *et al*. 1987; Stoufi *et al*. 1987) reported the CD4:CD8 ratio in periodontitis to be around 1:1. Despite this obvious increase in CD8-positive T-cells, their functional activity in the context of periodontitis is poorly understood. While the majority of CD4 clones established from periodontitis tissues have Th2 phenotypes producing high levels of IL-4 and low levels of IFN-γ, the majority of CD8 clones produce equal amounts of IL-4 and IFN-γ, that is they have a Th0 phenotype (Wassenaar *et al*. 1995). Similar to CD4 cells, two subsets of CD8 clones exist. One, whose primary function is to mediate cytolytic activity, produces high levels of IFN-γ, but no IL-4 or IL-5. These are the classic CD8-positive cytotoxic T cells. The secondary function of this subset is to suppress B cells. The other subset of CD8 cells, whose primary function is to suppress the proliferative response of cytotoxic CD8 T-cell clones and to suppress cell-mediated immunity, produce high levels of IL-4 together with IL-5. These are the classic CD8-positive suppressor cells. The secondary effect of these cells is to provide help to B cells. It has been shown that peripheral blood CD8 cells from highly susceptible patients with severe periodontitis produce high levels of intracellular IL-4. If these cells also occur locally within the periodontal tissues of these susceptible patients, they may participate in the local response by suppressing IFN-γ–producing cells and favoring humoral immune responses (Wassenaar *et al*. 1995), and hence a shift towards a type 2 function. Teng (2003), however, has played down a role for CD8 cells in periodontal disease by concluding that this subset does not participate directly in the destruction during disease progression. Although they may not play a direct role in tissue destruction, CD8-positive T cells do produce cytokines which play a role in both innate and adaptive immune responses and are important in the lysis of bacteria-infected or bacteria-damaged tissues and cells. Overall, the role of CD8-positive T cells in the pathogenesis of periodontitis has been largely overlooked. However, determination of the functions of this subset is paramount in fully understanding the pathogenesis of periodontal disease.

Immunoregulation in periodontitis

While the Th1/Th2 paradigm provides a possible mechanism by which periodontal lesions become progressive or remain stable, an important question that remains is, what causes some lesions to show Th1 characteristics while others show Th2 characteristics? The answers may lie in the nature of the microbial challenge, as well as particular genetic and environmental susceptibility factors. Importantly, some of these factors may be clinically identifiable and modifiable.

It is likely that different T-cell subsets predominate at different phases of disease and the inability to determine disease activity clinically has been a major limitation in all studies. However, it remains clear that the balance of cytokines in inflamed periodontal tissues is what determines whether the disease remains stable or leads to progression and tissue destruction (Seymour & Gemmell 2001). In this context, the control of Th1 and/or Th2 expression is therefore fundamental in understanding the immunoregulatory mechanisms in chronic periodontitis (Fig. 13-9). Factors that control Th1 and Th2 expression include:

- Genetics
- Innate immune response
- Nature of the antigen
- Nature of the antigen-presenting cell (APC)
- Hypothalamic–pituitary–adrenal axis and the sympathetic nervous system
- Treg/Th17 axis.

Genetics

Study of identical twins who were raised apart indicates that between 38% and 80% of the variation in periodontal disease is due to genetics [for review,

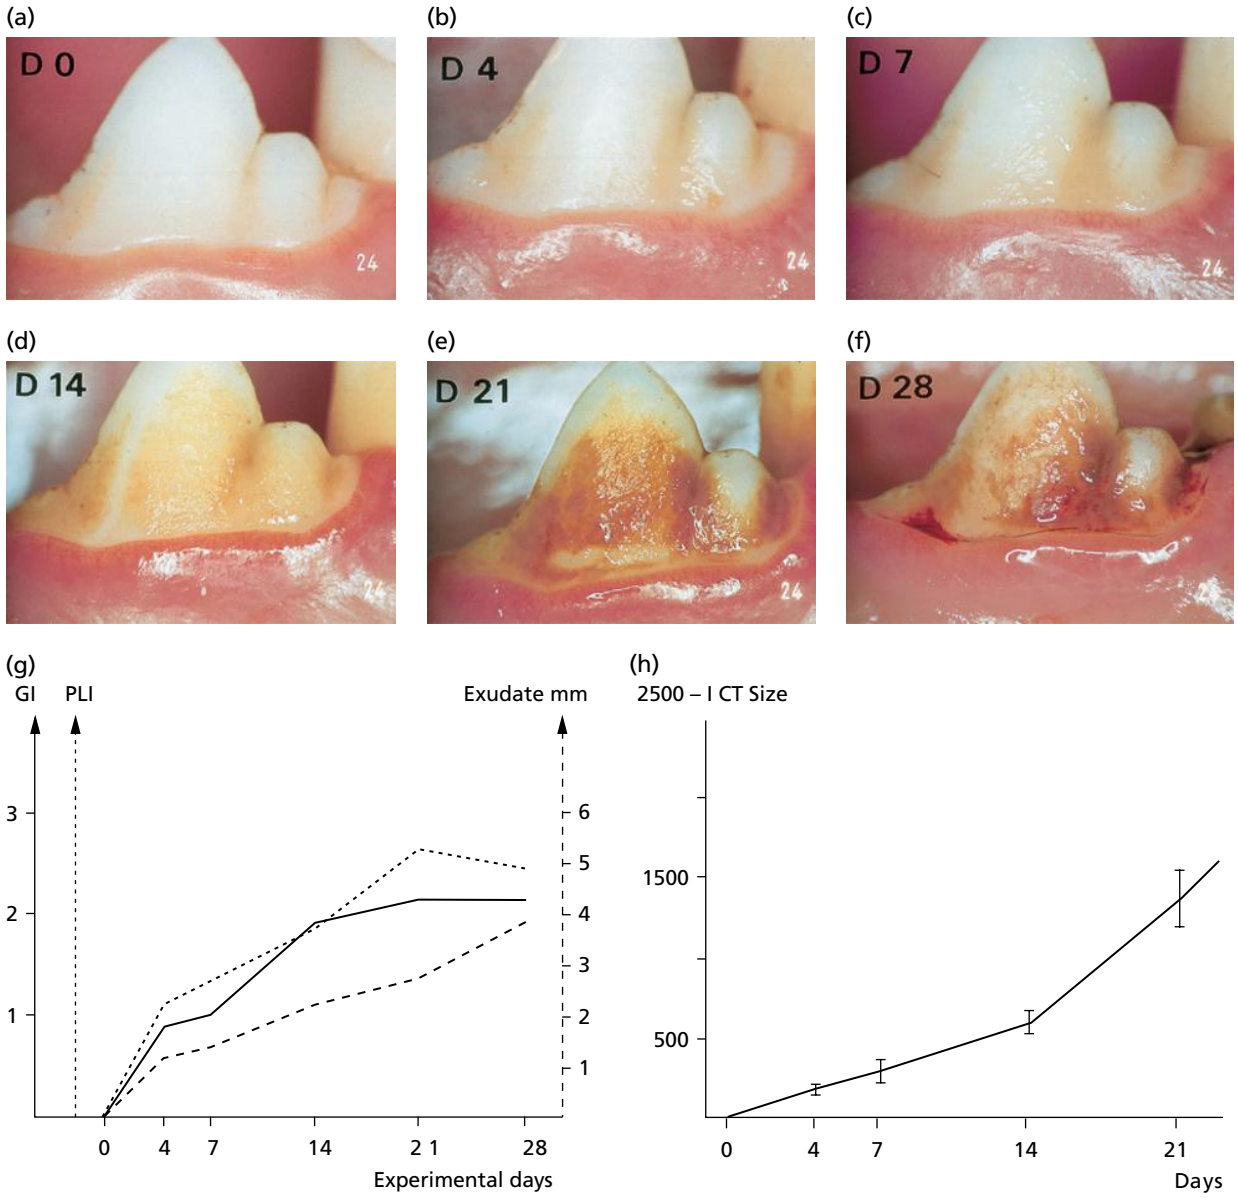

Fig. 13-9 Components involved in immune regulation in periodontitis. APC, antigen-presenting cell; IL, interleukin; IFN, interferon; Pc, plasma cells; TNF, tumor necrosis factor; Treg, regulatory T cell; TCR, T-cell receptor.

see Michalowicz (1994)]. Susceptibility to *P. gingivalis* infection in mice is also genetically determined (Gemmell *et al*. 2002b), although the relevance of this to human periodontal disease remains to be ascertained. However, it is interesting to note that the susceptible strains of mice show low Th1 responses, while the resistant strains show moderate-to-high Th1 responses to *P. gingivalis*.

Innate immune response

It is generally stated that there are two distinct arms of the immune response; the non-specific natural or innate response and the specific or adaptive immune response. In recent years, however, the distinction between these has become blurred with the discovery that, in many respects, the innate immune response determines the nature of the subsequent adaptive response and at the same time aspects of the adaptive response control the effectiveness of the innate response.

IL-12

As noted earlier, PMNs are a consistent feature of the periodontal lesion in both gingivitis and periodontitis, and deficiencies in PMN function are associated with severe and rapidly progressive periodontitis. A strong innate immune response will result in high levels of IL-12 and is therefore associated with a Th1 response, while a poor innate immune response and relatively low levels of IL-12 favor a Th2 response. Support for the concept of a Th1 response in gingivitis came from a study demonstrating significantly higher levels of IL-12 in the GCF from gingivitis sites in both gingivitis and periodontitis patients compared with periodontitis sites from the same periodontitis patients (Orozco *et al*. 2006).

Toll-like receptors

The discovery of toll-like receptors (TLRs) has led to a far greater understanding of innate immunity and the induction of adaptive immunity. TLRs are found on dendritic cells, PMNs, and macrophages among others, and have the ability to recognize structures known as pathogen-associated molecular patterns (PAMPs) that are highly conserved across a wide variety of pathogens. Such PAMPs include lipopolysaccharide (LPS), peptidoglycan, bacterial DNA, double-stranded RNA, and lipoprotein.

Given their role in innate immunity, it is likely that TLRs are important in determining the nature of the host response to plaque. TLR-2 and TLR-4, upon stimulation, may induce markedly different immune responses as determined by the resulting cytokine profiles. When stimulated, TLR-4 has been shown to promote expression of IL-12 and INF-γ–inducible protein-10 (IP-10), which is indicative of a Th1 response. Conversely, TLR-2 promotes the inhibitory IL-12p40, which is characteristic of a Th2 response (Re & Strominger 2001). These differences are reflected in differential cytokine expression by *Escherichia coli*-derived LPS and *P. gingivalis*-derived LPS. *E. coli*-derived LPS, which activates TLR-4, induces a strong Th1 response, while *P. gingivalis*-derived LPS, which activates TLR-2 (Hirschfeld *et al.* 2001), induces a strong Th2 response (Pulendran *et al*. 2001). These findings may indicate a further mechanism of susceptibility to periodontitis.

Nature of the antigen

As noted earlier, biofilms containing complexes of bacteria including *P. gingivalis, T. forsythia,* and *T. denticola* have been related to periodontitis, such that it is unlikely that a single antigen or a single organism is responsible for the disease. Further, there is the possibility that different people may have individually specific pathogenic complexes such that any single complex may not be pathogenic in all people. Indeed, little is actually known of the biofilm-specific antigens involved in periodontal disease and of the immune response to them. T-cell clones derived from mice immunized with *P. gingivalis* alone were found to have a Th1 profile, whereas T-cell clones derived from mice immunized with *F. nucleatum* followed by *P. gingivalis* demonstrated a Th2 profile (Choi *et al*. 2000). This may be due to the fact that *F. nucleatum* is a polyclonal B-cell activator such that B cells subsequently present the *P. gingivalis* antigen. Further, mice immunized with *F. nucleatum* were subsequently unable to make antibody to *P. gingivalis* (Gemmell *et al*. 2002a, 2004). This was not the case if bacteria were injected in the reverse order. These findings, albeit preliminary, nevertheless show that it is possible for co-infection with multiple organisms to modulate the immune response. The level and relevance of this modulation to human periodontal disease however, remains to be demonstrated but it is likely to involve the Th1/Th2 balance.

Nature of the antigen-presenting cell

It has been suggested (Kelso 1995) that Th1 and Th2 cells actually represent a spectrum of cells and, depending upon the conditions, can produce either Th1 or Th2 cytokines. In this context, Th0 cells may represent cells midway in the spectrum as well as naïve or non-committed cells.

The predominant APC in gingivitis tissues is a CD14-positive, CD83-positive dendritic cell (Gemmell *et al*. 2002c). In periodontitis tissues, the predominant APC is a CD19-positive, CD83-positive B cell, although a large number of CD83-positive endothelial cells are also present, suggesting that these cells may also be involved in antigen presentation. The cytokine profile of *P. gingivalis*-specific CD4 T-cell lines can be modified by changing the APC. When

autologous peripheral blood mononuclear cells are used as APCs, the cell lines are predominantly IFN-γ producing with a Th1 profile, but if autologous Epstein–Barr virus (EBV)-transformed B cells are used, the same cell lines become predominantly IL-4 producing, that is they have a Th2 profile (Gemmell & Seymour 1998). These findings suggest that it is possible to modulate the Th1/Th2 profile by varying the nature of the APC. In gingivitis, the predominant APC is a dendritic cell, whereas in periodontitis it is primarily a B cell.

Hypothalamic–pituitary–adrenal axis and the sympathetic nervous system

It is well accepted that stress, or at least the inability to cope with stressful situations, results in rapid progression of periodontitis. Stimulation of the sympathetic nervous system (SNS) as well as hypothalamic–pituitary–adrenal axis (HPA) activation leads to a selective suppression of Th1 responses, a shift towards Th2 dominance, and an increase in periodontitis (Breivik *et al*. 2000; Elenkov 2002).

Treg/Th17 axis

Regulatory T cells

Increased numbers of regulatory T cells (Tregs) have been demonstrated in periodontitis lesions where there are increased proportions of B cells. Foxp3, the forkhead/winged helix transcription factor and a characteristic marker of Tregs, was also shown to be more highly expressed in periodontitis compared with gingivitis tissues (Nakajima *et al.* 2005). The role of these cells in periodontal disease in humans however, is still speculative although they have an important function in the control of autoimmunity and as part of a regulatory axis with the so-called Th17 cells.

Th17 cells

Over the past two decades most attention has focused on Th1 and Th2 cells; however, in recent years a third lineage of T cells has been described, the so-called Th17 cells which selectively produce IL-17. IL-17 induces the secretion of IL-6, IL-8, and PGE_2; hence, these cells are thought to play a crucial role in regulating inflammation. IL-17 is also thought to affect osteoclast activity and thereby mediate bone resorption.

In the mouse, naïve T cells when incubated with TGF-β and IL-2 up-regulate the transcription factor Foxp3 and develop into the so-called Tregs which have an important function in suppressing autoimmune responses. In contrast, when incubated in the presence of transforming growth factor beta (TGF-β) and IL-6, CD4-positive T cells express the transcription factor RORγt and become Th17 cells. While these cells are thought to have a protective role against bacterial infections, they may on the other hand contribute to autoimmune disease. There are however, some important differences between mouse and human Th17 cells. In the human for example, TGF-β is not necessary for Th17 differentiation and there is some doubt over the role of IL-23, with some studies showing that IL-23 is a potent inducer of Th17 cells and others showing that IL-23 alone is relatively ineffective. Activation of monocytes via TLR-2 is an effective stimulus for Th17 differentiation and, while IL-2 initially inhibits Th17 differentiation, ultimately it leads to Th17 expansion [for review, see Laurence & O'Shea (2007)].

P. gingivalis leads to the down-regulation of the IL-17 receptor (*IL-17r*) gene in mice (Gemmell *et al*, 2006). *IL-17r*-deficient mice have a defect or display a significant delay in neutrophil recruitment into infected sites, resulting in susceptibility to infection (Kelly *et al*. 2005). This may account partly for the reported inhibition of entry of PMN into *P. gingivalis*-induced lesions in mice (Gemmell *et al*. 1997). These studies seem to suggest that IL-17 and its ability to enhance PMN activity would have a protective effect in periodontal disease. In contrast to this mouse study, IL-17 expression in human periodontitis tissue is controversial. In periodontitis patients, 51% of gingival T-cell clones were found to express IL-17 compared with only 11% of peripheral blood T-cell clones (Ito *et al*. 2005). Also, stimulation of peripheral blood mononuclear cells by *P. gingivalis* antigen enhanced not only transcription but also translation of the *IL-17* gene (Oda *et al*. 2003). On the other hand, immunohistologic and gene expression studies on diseased human tissue suggest low levels of IL-17 and low expression of IL-17 pathway genes (Okui *et al*. 2012). In addition, Th17 cells show enormous plasticity and are easily converted to Th2 cells *in vivo*: their role and that of the Treg/Th17 axis in human periodontal disease remains to be determined. Recently, a small number of IL-17-positive/Foxp3-positive cells have been identified in periodontal disease tissues (Okui *et al*. 2012), but other preliminary studies (Culshaw *et al*. 2011) seem to question a role for these cells in human periodontitis and suggest that mast cells may be the major source of IL-17 in human periodontitis. Parachuru *et al*. (2014) have also shown very few IL-17-positive cells (<1%) in B-cell/plasma cell-dominated periodontal lesions in humans, but a statistically significant correlation between the numbers of Foxp3-positive cells and the B-cell/plasma cell-to-T-cell ratio in these lesions. They further showed that the majority of IL-17-positive cells present had an ovoid/plasmacytoid morphology and were larger than the surrounding inflammatory cells, suggesting that these cells may be mast cells. In view of the latter findings, the role of IL-17 and especially of Th17 cells in human periodontal disease still remains to be determined.

Autoimmunity

NK T cells

Autoimmunity has been suggested to be a feature of periodontal disease. Cross-reactivity of human heat shock protein (HSP) 60 and *P. gingivalis* GroEL, a bacterial homolog, has been observed in periodontal disease (Tabeta *et al*. 2000; Ford *et al.* 2005). HSP60-specific as well as *P. gingivalis* cross-reactive T cells have also been demonstrated to accumulate in periodontitis lesions (Yamazaki *et al*. 2002). Taken together, these data suggest that both a humoral and a cell-mediated specific immune response to HSP60 may be important in the disease process. Additionally, anticollagen type l and lll antibodies have been demonstrated in the gingivae of periodontitis patients (Hirsch *et al.* 1988) and collagen type I-specific T-cell clones have been identified in inflamed tissues of periodontitis patients (Wassenaar *et al*. 1995).

A subset of T cells that express NK surface receptors are thought to play an important autoimmune immunoregulatory role. An immunohistologic study found that NK T cells were more numerous in periodontitis lesions compared with gingivitis tissues or peripheral blood. These NK T cells also appeared to associate with CD1d-positive cells and it was suggested that they play a regulatory role in periodontal disease (Yamazaki *et al*. 2001).

The role of autoimmunity in chronic inflammation is still not clear. It is possible that autoimmunity is a feature of all chronic inflammatory processes. In this context, it has been known for many years that gingival fibroblasts are able to phagocytose collagen such that anticollagen antibodies may facilitate this phagocytosis and hence the removal of the broken down collagen. At the same time, an anti-HSP response may enhance the removal of dead and dying cells such that these autoimmune responses may be a natural part of chronic inflammation. Control of these responses would therefore be essential. This concept further illustrates that the role of T cells in periodontal disease may be one of immune homeostasis. Further studies are clearly needed to test this hypothesis and to determine the role of regulatory T cells in periodontal inflammation.

B-cell subsets

There are two major subsets of B cells: B-1 and B-2 cells. B-2 cells are recognized as conventional B cells and represent the traditional group of B cells that take an active part in the adaptive host response. They interact with T cells and develop into memory cells and long-lived plasma cells that produce antibodies with high affinity.

B-1 cells, on the other hand, may either be T-cell independent and responsible for early antibody responses with low affinity, or interact with T cells and undergo class switching and produce IgG autoantibodies with high affinity. A specific subset of B-1 cells is the B-1a cell, which expresses the surface marker CD5. B-1a cells produce autoantibodies and are found in large proportions in subjects with autoimmune diseases and periodontitis (Afar *et al*. 1992; Berglundh *et al*. 2002b). The proportions of B-1a cells in peripheral blood are reported to be five to six times greater in subjects with periodontitis than in controls, and up to 40–50% of circulating B cells were positive for the B-1a cell marker CD5 in periodontitis (Berglundh *et al*. 2002b). B-1a cells also occur in large proportions in the gingival lesions of periodontitis patients such that the abundance of plasma cells seen in periodontitis lesions may be the result of both B-2 and B-1a proliferation and differentiation (Donati *et al*. 2009a). A study on experimental gingivitis in periodontitis patients has also demonstrated that B-1a cells are involved in the host response to microbial challenge (Donati *et al*. 2009b).

The large proportion of B-1a cells in periodontitis has also been associated with elevated levels of IL-10. B cells are one source of this cytokine and although IL-10 was previously regarded to play mainly anti-inflammatory roles, it also exhibits several pro-inflammatory functions, including activation of B cells, and serves as an autocrine growth factor for B-1a cells.

Connective tissue matrix destruction

Connective tissue remodeling is regulated by the interplay of cell–cell and cell–matrix interactions involving the production of enzymes, activators and inhibitors, and cytokines and growth factors (Reynolds & Meikle 1997). Proteinases such as the MMPs are key enzymes in tissue degradation. They are produced by resident cells, including fibroblasts, macrophages, and epithelial cells, and are regulated by tissue inhibitors of metalloproteinases (TIMPs).

It has been suggested that tissue destruction in disease processes may be due to an imbalance of MMPs over tissue inhibitors. Greater collagenase activity, which was demonstrated to derive mostly from PMNs, has been found in the GCF of periodontitis patients compared with the GCF of control subjects (Villela *et al*. 1987). MMP-9, which is produced by PMNs, was shown to be prominent not only in the GCF but also in gingival tissue samples from patients with periodontitis. Latent MMP-2 and MMP-9 have been shown to be expressed in the gingival tissues of patients with periodontitis, with the active forms being detected only in tissues associated with clinical disease (Korostoff *et al*. 2000; Seguier *et al*. 2001). Increases in the amounts of MMP-1, -2, -3, and -9, and the active form of MMP-9 have in fact been correlated with the number of CD22-positive B cells. This again suggests a possible mechanism by which B cells contribute to tissue destruction in periodontitis.

Up to 97–99% of the collagen in normal gingiva is made up of collagen types I and III. Collagen type III

represents a minor fraction (about 10%). All other types (IV, V, VI, and VII) are related to basement membranes and together do not exceed 1–3%. Transmission electron microscopy of biopsies from periodontitis patients demonstrated the almost complete destruction of collagen types l and lll in areas with leukocyte infiltration, while the basement membrane-associated collagen types V and Vl seem to remain and are related to the increased vascularity and epithelial proliferation in the inflamed tissue.

Bone loss

Bone resorption in periodontitis is regulated by the interplay between osteoblasts and the activation of osteoclasts. Osteoclasts share a common origin with cells of the macrophage/monocyte lineage and respond to and produce cytokines that regulate cells of this lineage. Osteoblasts originate from bone marrow stromal stem cells of mesenchymal origin and also have the capacity to produce factors which influence lineage development. Upon stimulation, osteoblasts produce a molecule known as receptor activator of nuclear factor-kappa B (NF-κB) ligand (RANKL), also known as osteoprotegerin-L (OPG-L), which regulates osteoclast differentiation and functions via its receptor (RANK). These activated osteoclasts then produce a number of acids and acid hydrolases which decalcify the mineral content of the bone and break down the organic matrix. The osteoclasts further phagocytose the broken down organic matrix, thus resorbing the bone. A variety of cells produce a decoy receptor osteoprotegerin (OPG), which when released binds RANKL to prevent activation of RANK and hence osteoclasts (Simonet *et al.* 1997).

While these factors have potent effects on osteoclast development, they also have regulatory effects on immune cell function (Lorenzo 2000), being critical for T-cell maturation and the production of cytokines such as IFN-γ, IL-2, and IL-4 (Kong *et al*. 1999).

Studies have reported increased concentrations of RANKL and decreased concentrations of OPG in the GCF and tissues from periodontitis patients (Mogi *et al*. 2004; Vernal *et al*. 2004). However, the relationship between this observation and the progression of periodontitis is speculative. Interestingly, human gingival fibroblasts stimulated with bacterial LPS have been shown to express OPG and OPG mRNA rather than RANKL. Supernatants of LPS-stimulated fibroblasts reduced the numbers of tartrate-resistant acid phosphatase (TRAP)-positive osteoclasts generated by monocytes cultured in the presence of RANKL and macrophage colony-stimulating factor (M-CSF), suggesting the inhibition of monocyte-derived osteoclasts via the OPG pathway (Nagasawa *et al*., 2002). RANKL and RANKL mRNA are expressed by inflammatory lymphocytes and macrophages as well as by proliferating epithelium in the vicinity of inflammatory cells. Thus, the high levels of RANKL seen in the GCF of periodontitis patients may be a reflection of the degree of inflammation rather than of bone loss and disease progression *per se*. Although both soluble and membrane-bound RANKL can be produced by activated T cells (Kong *et al*. 1999) and B cells (Taubman *et al*. 2005; Horowitz *et al*. 2010), it is the coupling of osteoblast-produced RANKL with osteoclast-expressed RANK that results in bone loss in periodontitis.

As already stated, IL-1 has a major role in bone resorption in periodontal disease, and both IL-1 and TNF-α have been reported to regulate the balance of RANKL and OPG (Hofbauer *et al*. 1999). Increased IL-1β production by B cells in periodontitis may therefore provide the link between increasing numbers of B cells and alveolar bone destruction in human periodontitis.

Conclusion

While there is no doubt that patient susceptibility determines periodontal disease expression and that this involves the interaction of bacterial, host, and environmental factors, determination of risk in individuals with periodontitis has proven elusive.

Despite over 40 years of research into the immunology of periodontal disease, the precise mechanisms and the role of many cell types remain an enigma. It is clear from the data obtained from a number of *in vitro* human studies and a recent microarray study, albeit in mice (Gemmel *et al.* 2006), that *P. gingivalis* has the ability to down-regulate both CD4 and CD8 cells *in vitro* and *in vivo*. These results, together with the plethora of data on human disease, have led to the development of the hypothesis that the function of the immune response in periodontal disease is to maintain homeostasis in the presence of the plaque biofilm. In this context, it can be seen that a balance between the biofilm and the host is reached. The T-cell response can therefore be considered to be the default response that balances activation with suppression. It is when this balance is disturbed that disease progression occurs.

This hypothesis is based in part on findings using a mouse model of *P. gingivalis* infection. However, mice do not develop periodontal disease and the *P. gingivalis*-induced immune response is a simple response to a single periodontopathic bacterium. In humans, dental plaque is a complex biofilm and the role of and response to biofilm-specific antigens has yet to be established.

The role of autoimmunity in chronic inflammation is also of major interest. In this context it can by postulated that autoimmunity is a critical and integral part of chronic inflammation in that it enhances the removal of collagen by enhancing fibroblast phagocytosis of protease-digested collagen fragments, as well as the removal of destroyed or dying cells. Control of this process by regulatory T cells (Tregs/Th17/NK T) then becomes fundamental and, again, if there is a disturbance in this homeostatic mechanism, enhanced tissue destruction could result.

Chapter 14

Modifying Factors

Evanthia Lalla and Panos N. Papapanou

Division of Periodontics, Section of Oral and Diagnostic Sciences, Columbia University College of Dental Medicine, New York, NY, USA

Introduction

This chapter discusses factors that may modify the host's susceptibility to periodontitis and the disease's clinical phenotype, including its extent, severity, progression, and response to therapy. The emphasis is on the two major modifying factors, diabetes mellitus and tobacco smoking. Aspects related to the epidemiologic evidence for the effect of these factors on periodontitis are reviewed in Chapter 7; thus, here we focus on underlying mechanisms, clinical presentation of affected individuals, and treatment considerations. A list of potential modifiers of periodontal health is shown in Table 14-1. Among these, factors such as puberty, menstruation, pregnancy, and medications that affect only the gingival status are discussed in Chapter 19, and the impact of HIV/AIDS on the periodontium is covered in Chapter 22.

Table 14-1 Potential modifiers of periodontal health.

- Diabetes mellitus
- Tobacco smoking
- Obesity and nutrition
- Osteoporosis and osteopenia
- Psychosocial stress
- Menstrual cycle
- Pregnancy
- Medications
  - Oral contraceptives
  - Anticonvulsants
  - Immunosuppressants
  - Calcium channel blockers
- HIV/AIDS
- Hematologic and genetic disorders and syndromes associated with diagnostic category IV "periodontitis as a manifestation of systemic diseases" (Armitage 1999)

Diabetes mellitus

Diabetes mellitus is a common, chronic condition with serious health implications. It comprises a group of metabolic disorders characterized by defects in insulin production, insulin action, or both, leading to abnormal glucose metabolism. The resulting hyperglycemia that characterizes both major types of diabetes (type 1 and type 2) is associated with a range of acute and chronic complications, and may eventually affect all organs of the body, including the periodontal tissues. Indeed, diabetes is established as a major risk factor for periodontitis.

Mechanisms underlying the effect of diabetes on periodontitis

Early studies exploring the mechanisms that may contribute to the increased prevalence and severity of periodontal destruction observed in patients with diabetes suggested the existence of distinct subgingival microbial profiles or antibody response patterns (Zambon *et al*. 1988). Subsequent reports concluded that the nature of the bacterial challenge in patients with diabetes and periodontitis does not appear to differ from that in those without diabetes (Feitosa *et al*. 1992; Thorstensson *et al*. 1995; Novaes *et al*. 1997;

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Sbordone *et al*. 1998). However, many of these studies included small numbers of individuals, assessed only a handful of bacterial species, and most importantly compared patients with diabetes and periodontitis to controls without diabetes who were periodontally healthy. Taking these limitations into consideration, the subgingival microbial challenge in diabetes was later revisited using a cohort of subjects with type 1 diabetes and a control group of age- and gender-matched individuals without diabetes but with similar levels of periodontitis (Lalla *et al*. 2006b). Bacterial profiles, based on 12 species, as well as the homologous serum antibody responses were found to be comparable between the two groups. Yet, microbial studies to date are restricted to known biofilm species. Future global analyses of the periodontal microbiome may shed further light on this issue. For now, it appears that it is the host response to the bacterial challenge that drives the enhanced susceptibility to periodontal disease in diabetes. Indeed, it was proposed early on that impairment of neutrophil function may facilitate bacterial persistence and increase periodontal destruction (Manouchehr-Pour *et al*. 1981a, b; McMullen *et al*. 1981). Subsequently, neutrophil priming in moderately and poorly controlled patients with diabetes, caused by increased levels and activity of protein kinase, was demonstrated (Karima *et al*. 2005). Other studies suggested a hyperinflammatory monocytic phenotype in diabetes characterized by enhanced levels of pro-inflammatory mediators in gingival crevicular fluid (GCF) or following challenge with lipopolysaccharide (LPS) in culture (Salvi *et al*., 1997, 1998; Yalda *et al*. 1994). In a study employing the experimental gingivitis model approach (i.e. 3-week cessation of oral hygiene resulting in gingivitis, followed by 2 weeks of optimal plaque control resulting in resolution of gingival inflammation), individuals with diabetes were found to develop accelerated and exaggerated gingival inflammation compared to controls without diabetes, despite a similar bacterial challenge (Salvi *et al*. 2005). Effects on other relevant cell types have also been reported, such as decreased collagen production and increased collagenolytic activity by gingival and periodontal ligament fibroblasts (Ramamurthy & Golub 1983; Sasaki *et al.* 1992; Yu *et al*. 2012), and hyperinflammatory response by oral epithelial cells (Amir *et al*. 2011).

Consistent with the evidence in humans, a number of animal studies have demonstrated that diabetes may increase the inflammatory response to bacteria. *Porphyromonas gingivalis* injection into the calvariae of diabetic mice was shown to stimulate an exaggerated cytokine expression and inflammatory infiltrate compared to the response observed in non-diabetic mice (Naguib *et al*. 2004; Graves *et al*. 2005; Nishihara *et al*. 2009). Reduction of inflammation and lesion size by specific inhibition of tumor necrosis factor-alpha (TNF-α) in these studies suggested that cytokine dysregulation represents a mechanism through which diabetes alters the host response to the bacterial challenge (Naguib *et al*. 2004; Takano *et al*. 2010).

A number of other reports, including human studies, have focused on osteoclastogenesis-related factors and explored the role of the receptor activator of nuclear factor-kappa B ligand (RANKL) and osteoprotegerin (OPG) in diabetes associated periodontal infections (Mahamed *et al*. 2005; Duarte *et al*. 2007; Lappin *et al*. 2009; Santos *et al*. 2010). These studies have suggested that hyperglycemia in diabetes may modulate the RANKL:OPG ratio in periodontal tissues and thus contribute to alveolar bone destruction. Along this line, the cycle of bone loss and subsequent bone formation was examined in a model of ligature-induced alveolar bone loss in rats (Liu *et al*. 2006b). Osseous repair was significantly limited by diabetes and the level of apoptosis of bone-lining cells was higher. In the calvarial model, diabetic mice also displayed increased fibroblast apoptosis and reduced fibroblast density following *P. gingivalis*-induced injury (Liu *et al*. 2004). Healing was significantly improved by blocking apoptosis with a caspase inhibitor (Al-Mashat *et al*. 2006) or by anti-TNF-α treatment (Liu *et al*. 2006a). These results were confirmed in diabetic mice with intraoral wounds (Desta *et al*. 2010; Siqueira *et al*. 2010). TNF-α inhibition in diabetic rats with ligature-induced periodontitis was also shown to impair expression of growth factors that control proliferation, differentiation or apoptosis of osteoblasts, to restore the bone coupling process, and to increase the capacity of the animals to form new bone (Pacios *et al*. 2012).

The first attempt to explore more upstream changes induced by diabetes that may explain the observed hyperinflammatory response to infection, focused on the role of the receptor for advanced glycation end products (RAGE), a multiligand signaling receptor and member of the immunoglobulin superfamily of cell-surface molecules. RAGE expression is increased in diabetes and its activation through ligand interaction has an established role in the development and progression of other diabetic complications (Yan *et al*. 2009). First, expression of AGE ligands and of markers of oxidative stress was demonstrated in gingival tissues of patients with diabetes and periodontitis (Schmidt *et al*. 1996). Subsequently, levels of serum AGEs were shown to be significantly associated with the extent of periodontitis in type 2 diabetic adults (Takeda *et al*. 2006) and increased RAGE expression was reported in gingival tissues of individuals with diabetes and periodontitis (Katz *et al*. 2005; Abbass *et al*. 2012; Yu *et al*. 2012,).

In a model of oral infection and diabetes in mice, *P. gingivalis*-induced alveolar bone loss was increased in diabetic animals compared to non-diabetic controls and was accompanied by enhanced expression of RAGE, inflammatory AGEs, and tissue destructive matrix metalloproteinases (MMPs) in the gingival tissues (Lalla *et al*. 1998). In subsequent studies, treatment with soluble RAGE (sRAGE), the

extracellular ligand-binding domain of RAGE which antagonizes interaction of ligands with the whole receptor, decreased levels of TNF-α, interleukin-6 (IL-6), and MMPs in gingival tissues and suppressed alveolar bone loss in a dose-dependent manner in diabetic animals (Lalla *et al*. 2000). Importantly, the beneficial effects of RAGE blockade were paralleled by suppressed expression of the receptor and its ligands in gingival tissues and were independent of the level of glycemia. These findings demonstrated that AGE–RAGE interaction leads to the exaggerated inflammatory response to the bacterial challenge and subsequent tissue destruction seen in diabetes-associated periodontitis. Accumulation of AGEs and their interaction with RAGE have been also suggested to contribute to osteoclastogenesis via increased RANKL expression and OPG down-regulation in various cell types (Ding *et al*. 2006; Yoshida *et al*. 2009).

Moreover, RAGE may contribute to impaired repair following injury, as shown in studies of excisional dermal wounds in diabetic mice, where inhibition of RAGE signaling enhanced the rate of wound closure and repair, and down-regulated MMP activity (Goova *et al*. 2001). Studies of osteoblast cultures and craniotomy defects in mice in the absence of infection have demonstrated the role of RAGE and its interaction with the AGE ligand carboxymethyllysine (CML)–albumin in delayed bone healing (Santana *et al*. 2003). Using the same experimental approach, the apoptotic effect of CML–collagen on osteoblasts was shown to be mediated through RAGE (Alikhani *et al*. 2007).

The basic mechanisms involved in the pathogenesis of diabetes-associated periodontitis are summarized in Fig. 14-1: the hyperglycemia that characterizes diabetes drives the formation of AGEs and leads to increased expression and activation of their chief receptor RAGE. AGEs can impact cellular phenotype directly via receptor-independent pathways but, importantly, the AGE–RAGE interaction negatively affects cellular phenotype and function, leading to enhanced inflammation, production of reactive oxygen species or oxidative stress, and compromised tissue repair. Hyperglycemia also promotes oxidative stress directly, and both inflammation and oxidative stress can contribute to further AGE formation. These mechanisms coupled with the impact of the periodontal pathogens perpetuate this vicious cycle of inflammatory stress and impaired repair in the diabetic periodontium. Of note, there are several links between the various elements shown in Fig. 14-1, but they cannot all be demonstrated in a single diagram. For example, inflammation and oxidative stress amplify one another and can also promote shifts in the subgingival biofilm. The net result of all these complex pathways is the accelerated periodontal tissue destruction observed in diabetes.

Clinical presentation of the periodontal patient with diabetes

Patients with diabetes will often present with pronounced clinical and radiographic signs of periodontitis, including gingival inflammation, increased pocketing, and increased attachment, bone, and tooth

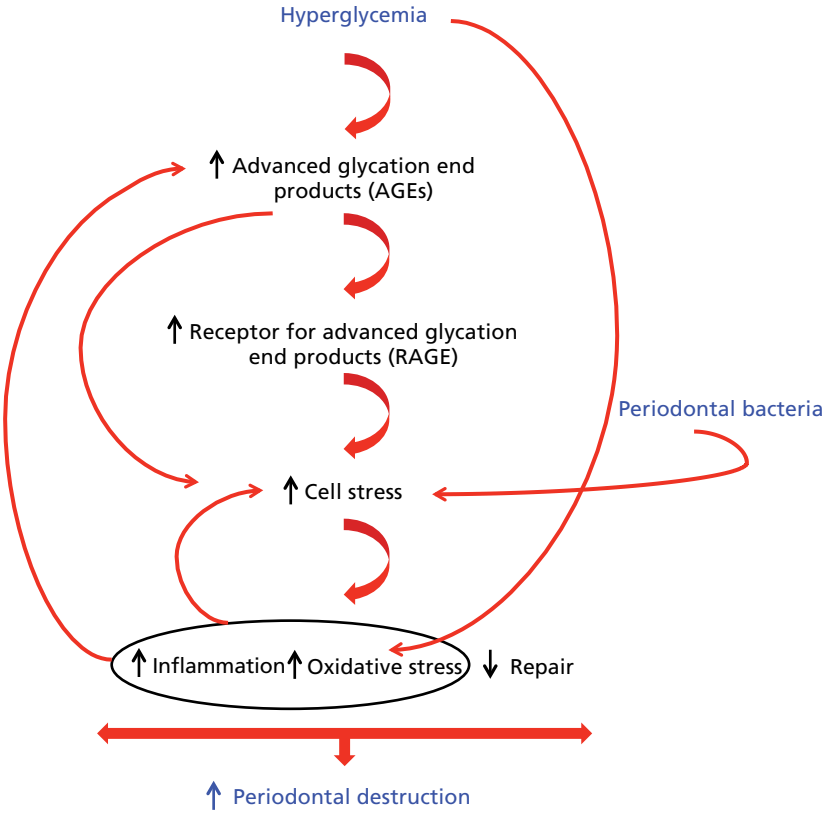

Fig. 14-1 Potential mechanisms in the pathogenesis of diabetes-associated periodontitis (see text).

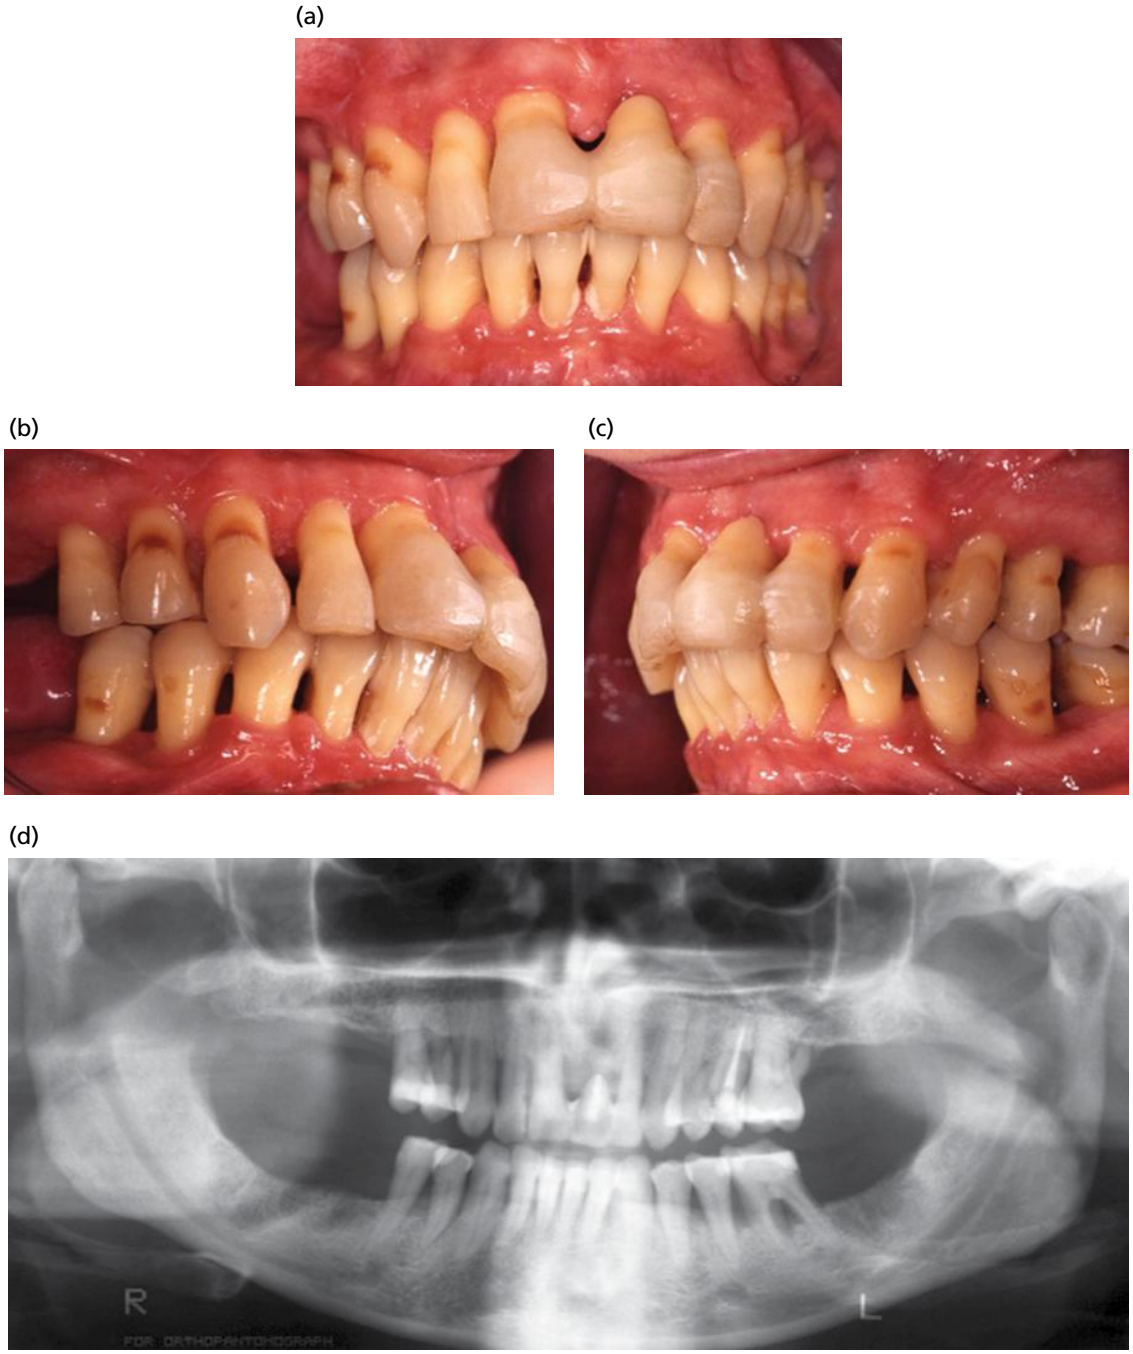

Fig. 14-2 (a–c) Clinical and (d) radiographic presentation of a 38-year-old female patient with type 1 diabetes and severe periodontitis. The patient was diagnosed with diabetes at the age of 10 years, has poor glycemic control, and is also a smoker. (Courtesy of T. Tervonen.)

loss (Figs. 14-2, 14-3, 14-4, 14-5). It is recognized that among those affected by diabetes, patients with poor glycemic control are at a higher risk for presenting with severe periodontitis (Tsai *et al*. 2002). In addition, clinical and radiographic signs of periodontitis progression may be evident (Figs. 14-6, 14-7), especially in periods when glycemic control deteriorates over time (Westfelt *et al.* 1996). Given that many of the effects of hyperglycemia discussed in the section above are irreversible and may have long-lasting effects, poor periodontal status may even be present in patients with adequate current glycemic levels, but past periods of poor metabolic control. Beyond the typical appearance of amplified gingival inflammation and bone or attachment loss, poorly controlled or undiagnosed/untreated patients with diabetes may present with or experience recurrent periodontal abscesses (Harrison *et al*. 1983; Ueta et al. 1993).

Importantly, even children and adolescents with diabetes may present with significant periodontal changes (Cianciola *et al*. 1982). A series of reports in 6–18-year-old individuals (Lalla *et al*. 2006a, 2007a, b) has demonstrated that increased attachment loss manifests much earlier in life in diabetes than previously recognized and is associated with poor glycemic control. Therefore, a thorough periodontal

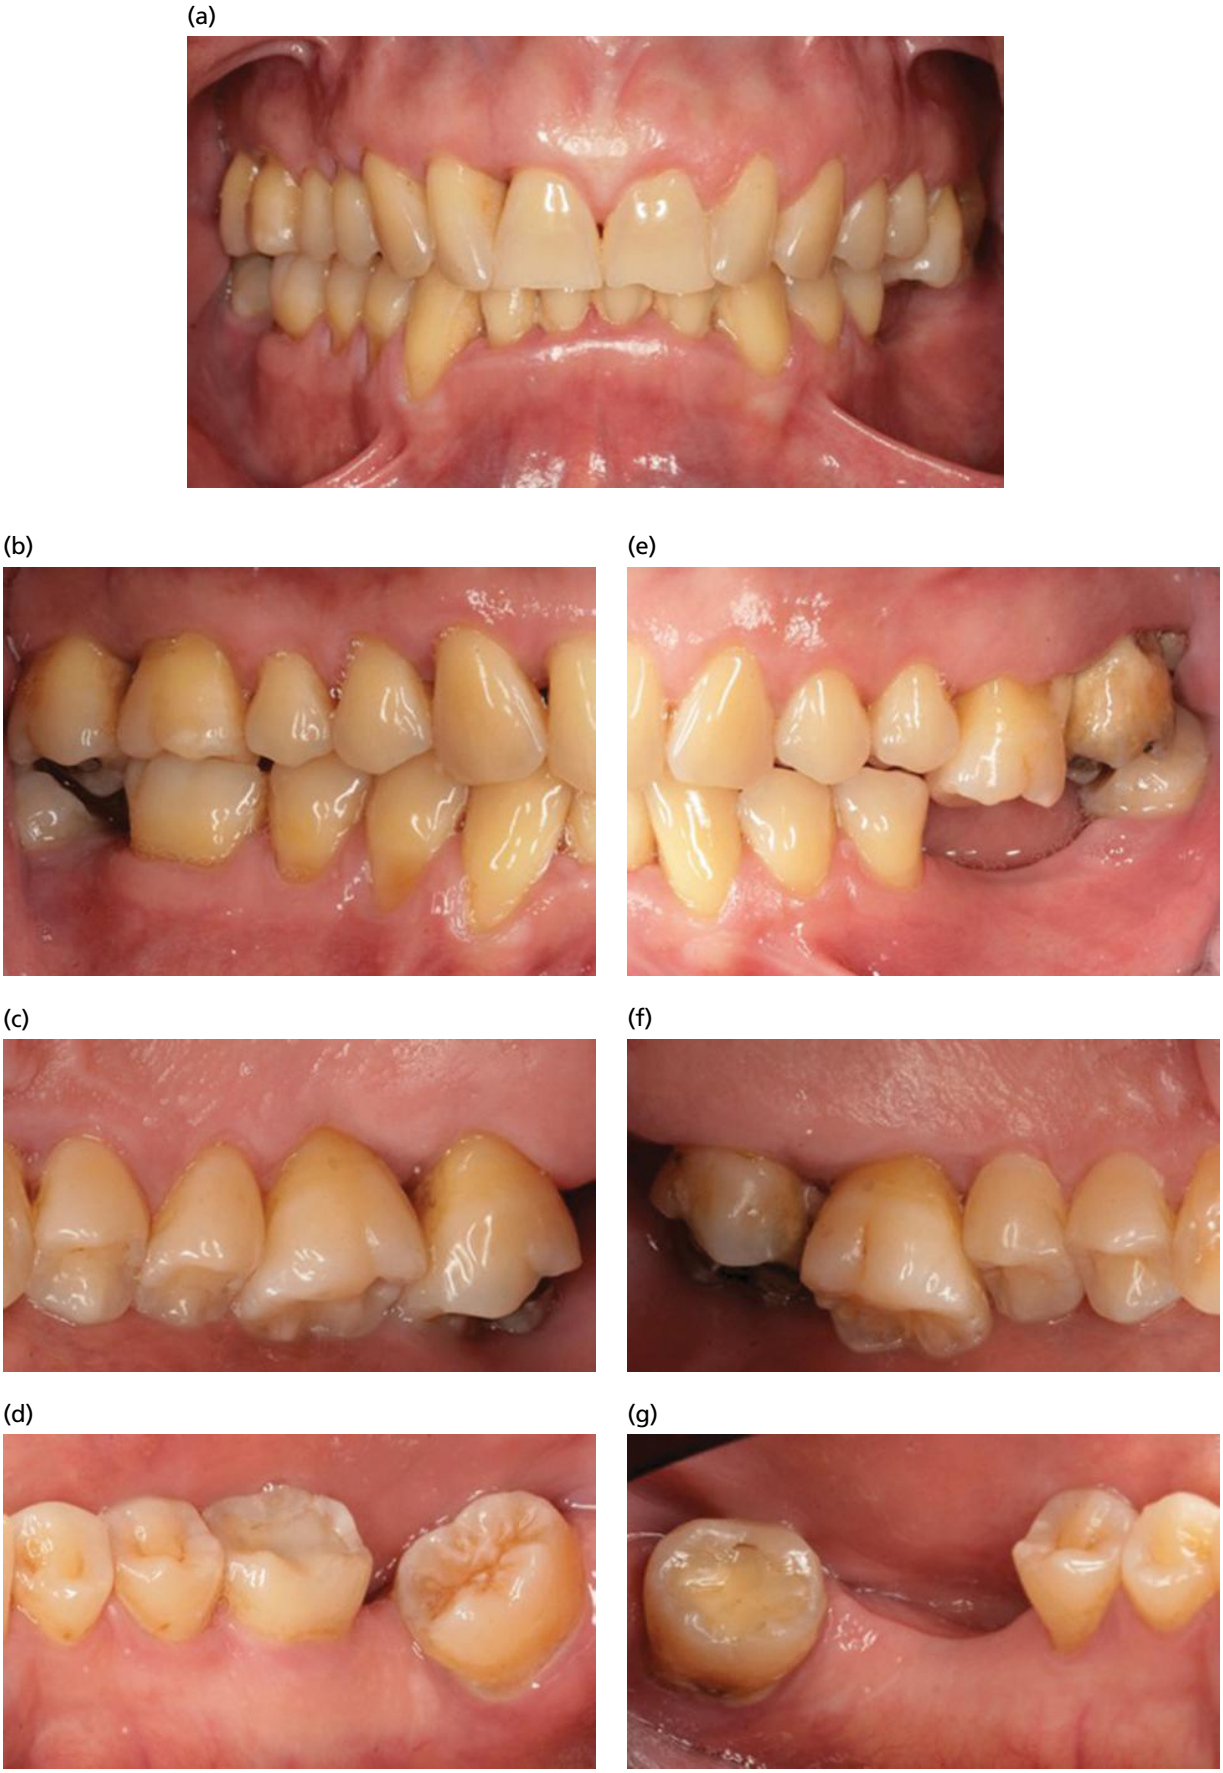

Fig. 14-3 Clinical presentation of a 50-year old male patient with type 2 diabetes. (a) Anterior view; (b–d) right side view; (e–g) left side view. The patient was diagnosed with diabetes 8 years earlier, is poorly controlled, and is a former smoker. Periodontal examination revealed probing depths of up to 10 mm and multiple sites with gingival recession. (Courtesy of T. Spinell.)

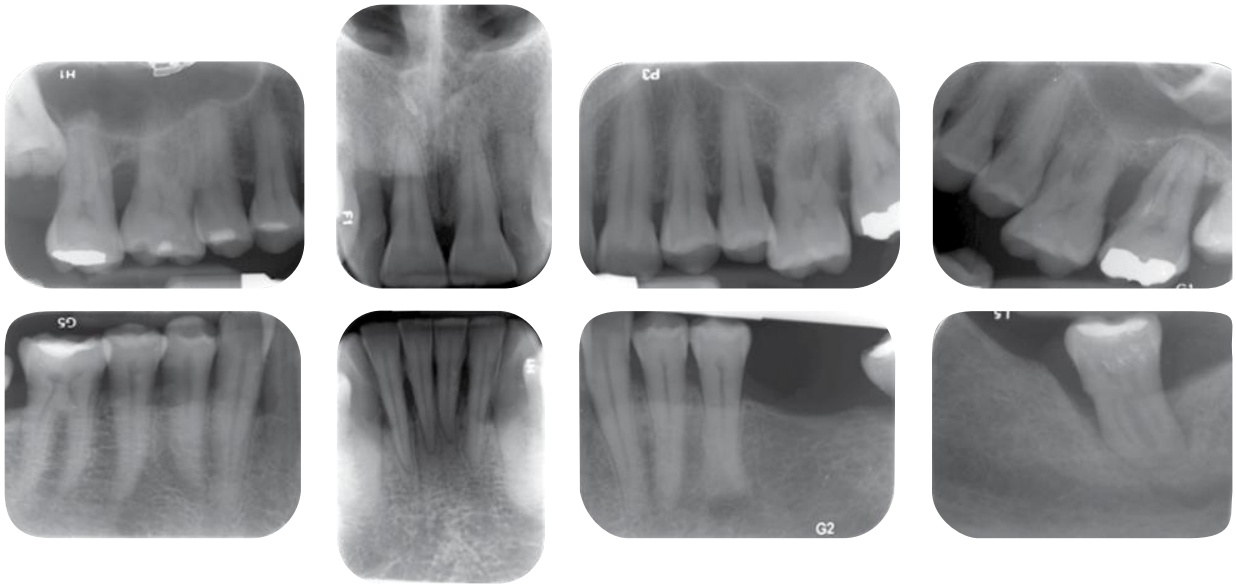

Fig 14-4 Periapical radiographs of the patient shown in Fig. 14-3 reveal areas of severe bone loss. (Coutesy of T. Spinell.)

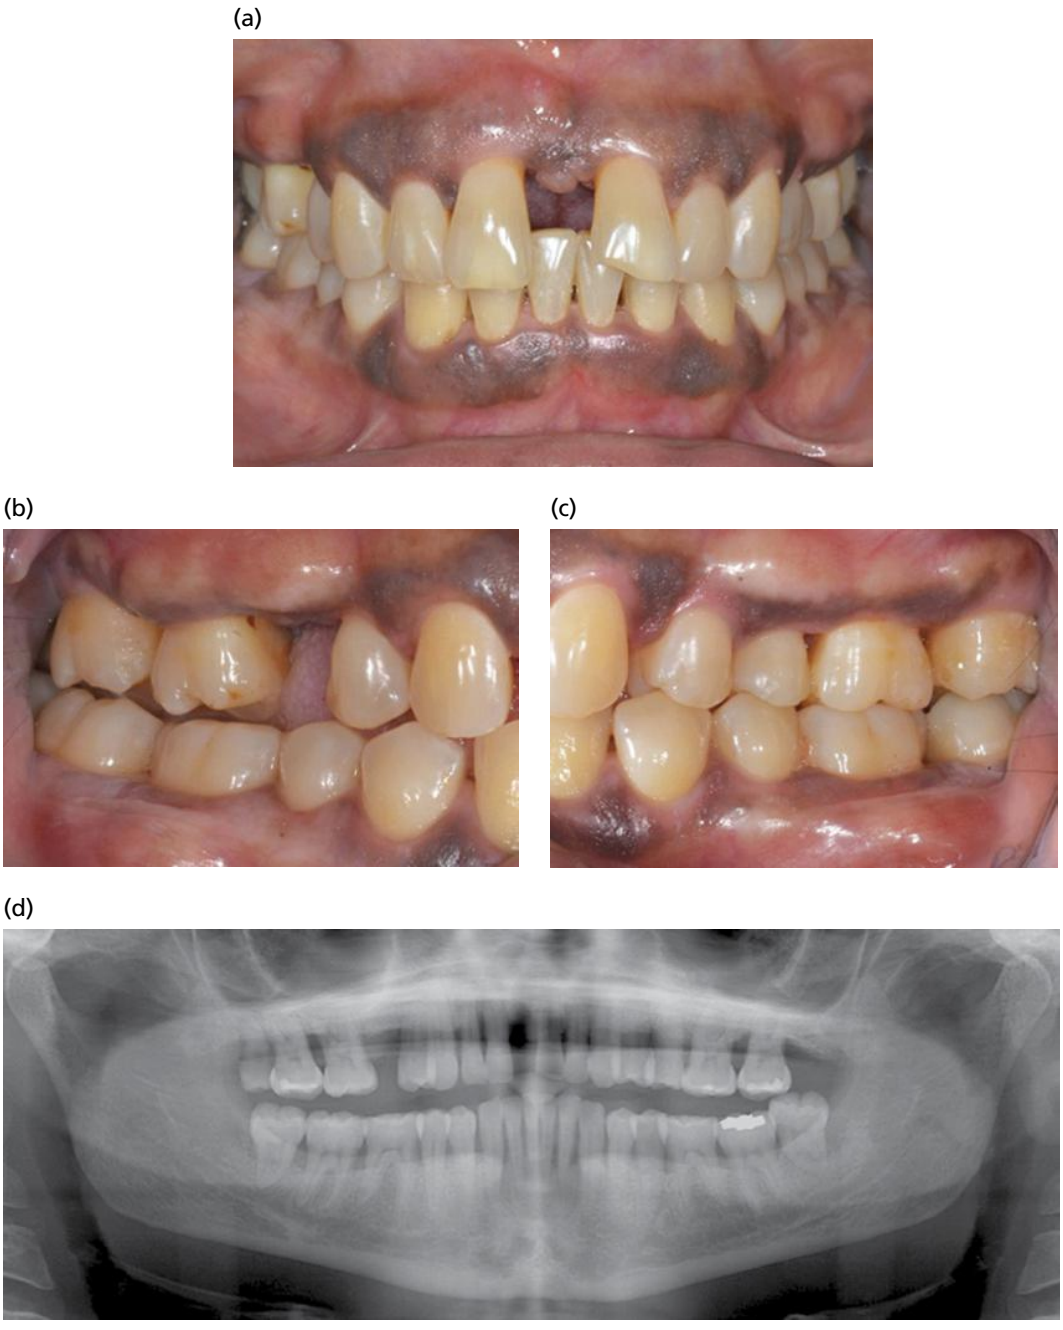

Fig. 14-5 (a–c) Clinical and (d) radiographic presentation of a 41-year-old female patient with type 1 diabetes. The patient was diagnosed with diabetes at the age of 26 years, has poor glycemic control, and is a former smoker. Periodontal examination revealed generalized severe periodontitis with probing depths ranging between 5 and 9 mm on most teeth. (Courtesy of S. Tsuji.)

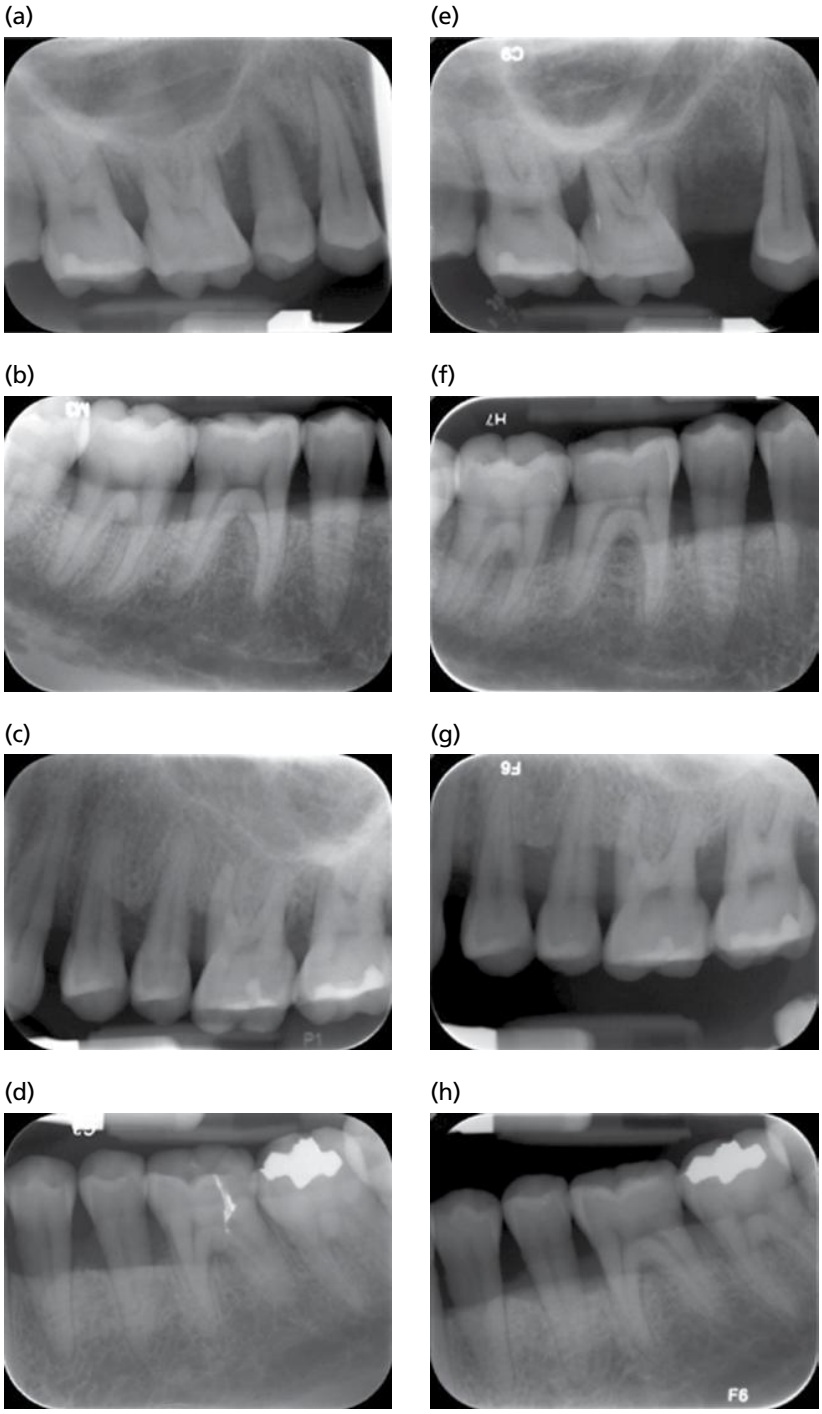

Fig. 14-6 Same patient as in Fig. 14-5. Posterior periapical radiographs at presentation (e–h), and corresponding radiographs taken 17 months earlier (a–d). Comparison reveals progression of bone loss and loss of the upper right second premolar within this short time period, during which glycemic control was poor (HbA1c values of 9–10%). (Courtesy of S. Tsuji.)

evaluation is needed in patients with diabetes across all age groups.

With respect to non-surgical periodontal therapy outcomes, patients with adequately controlled diabetes can respond well and achieve reduced probing depths and attachment gain (Christgau *et al*. 1998). In such patients, periodontal status can remain stable over time following surgical therapy and appropriate maintenance (Westfelt *et al*. 1996). However, in patients with poor glycemic control, long diabetes duration, and other diabetic complications, response to periodontal therapy appears to be unpredictable as tissue repair and wound healing are compromised (Tervonen & Karjalainen 1997). There is little available evidence to date on specific responses to different types of surgical therapy in patients with diabetes. Clinicians may use early responses to non-surgical therapy, especially at the more "predictable" sites (e.g. shallow–moderate pockets, accessible sites, single-rooted teeth), in order to identify potential non-responders early, properly inform/advise such patients, and plan further treatment accordingly.

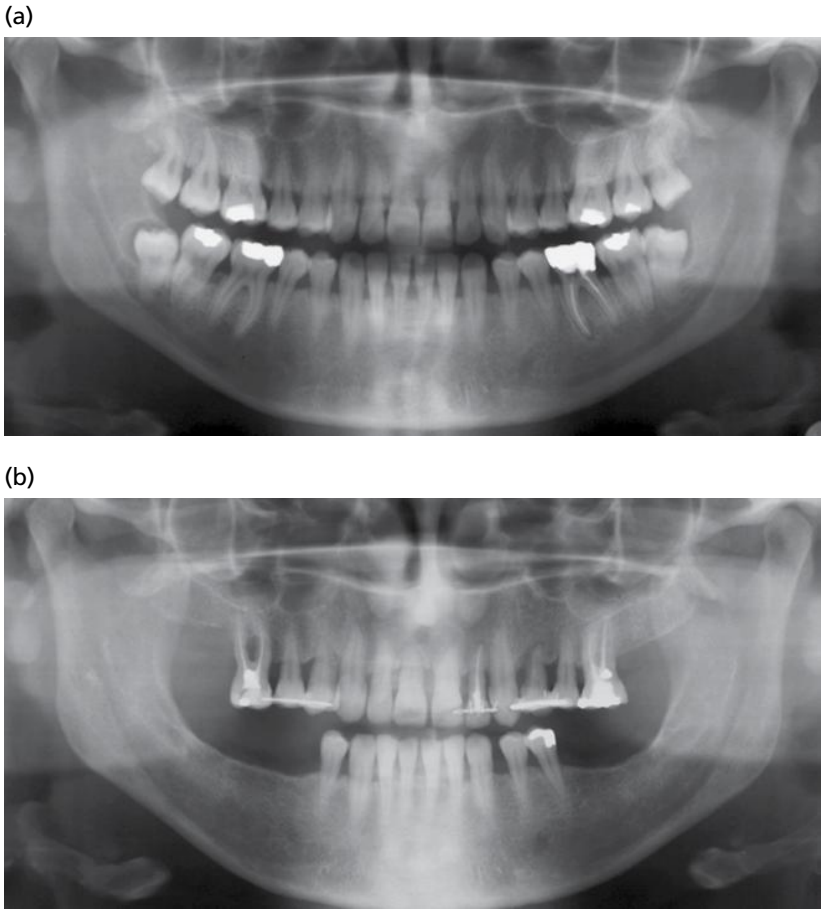

Fig. 14-7 Panoramic radiographs of a female patient with type 1 diabetes (a) at presentation at the age of 29 years and (b) 12 years later. The patient had been diagnosed with diabetes at the age of 12 years, was poorly controlled, and a smoker. She developed nephropathy and was on peritoneal dialysis. Despite comprehensive periodontal therapy, her periodontal status deteriorated significantly. The patient died of a myocardial infarction at age 41. (Courtesy of T. Tervonen.)

Concepts related to patient management

Studies suggest that oral disease awareness among individuals with diabetes is low (Moore *et al*. 2000; Tomar & Lester 2000; Sandberg *et al*. 2001; Jansson *et al*. 2006; Allen *et al*. 2008; Al Habashneh *et al*. 2010). Therefore, dental professionals need to educate their patients with diabetes, young and old, about the link between diabetes and periodontitis, and stress that the two conditions may amplify one another.

Managing the periodontal patient with diabetes who is under good medical care and maintains adequate glycemic control should not generally be difficult. However, as the concepts discussed earlier suggest, patients with poor metabolic control and those who present with other complications and co-morbidities may present a challenge when treated for periodontal conditions. Therefore, special considerations must be taken into account to ensure that the oral care provided is safe and that it leads to predictable outcomes. These considerations include: (1) taking a thorough medical history with a focus on understanding the patient's metabolic profile; (2) establishing communication with the treating physician; (3) performing a careful intraoral evaluation and a comprehensive periodontal examination; (4) addressing other risk factors present, such as smoking or overweight/obesity; and (5) considering co-morbidities and other complications, such as hypertension, vascular or kidney disease.

Initial therapy should focus on the control of acute infections, if present, as these may also have a direct adverse effect on the level of the patient's glycemic control. Good oral and overall health behaviors along with lifestyle changes, as needed, must be promoted. Recommendations for proper home care are very important and a less complex, stepwise periodontal therapy plan should be offered whenever possible. Clinical protocols should be in place for determining frequency of maintenance care (to reinforce oral hygiene and prevent, monitor, and treat any disease reactivation), the need for referral to a periodontist, and the need for medical consultation, referral, and follow-up. An interdisciplinary approach and collaboration beyond professional boundaries is often essential.

Furthermore, extreme glycemic variability is a relatively common medical emergency in a dental care setting. Prevention, early recognition, and proper management of potential hypo- and hyperglycemic episodes are very important. Dental professionals need to remember that, for all people with type 1 and many with advanced type 2 diabetes,

episodes of hypoglycemia are very common and can be precipitated by several factors, including missed or delayed meals, excessive physical activity, stress, or alcohol consumption. Acute hyperglycemic episodes are less common, but also serious. They can be precipitated by pain and stress, that antagonize insulin action, or by under-dosing of diabetic medications prior to the dental appointment. Therefore, consideration must be given to the appropriate timing and duration of appointments: early mornings are preferable, as patients can tolerate stress better due to higher levels of endogenous corticosteroids. Likewise, procedures should preferably be brief and as atraumatic and pain free as possible, requiring profound anesthesia and adequate post-treatment analgesic coverage. In addition, since the patient's ability to eat may be affected by a periodontal procedure, a change in diabetic regimen may be necessary and should be explored in consultation with the treating physician.

A preoperative determination of glucose levels using the patient's glucometer can be very helpful in prevention and/or early identification of episodes of extreme glycemic variability. Early signs of hypoglycemia (glucose levels <70 mg/dL) include shakiness, weakness, hunger, cold and clammy skin, and nausea, and later symptoms include increasingly bizarre behavior, mental confusion, hypotension, and loss of consciousness. If the patient is conscious, 15–20 g of simple carbohydrates should be given orally (e.g. glucose tablets or gel, ½ cup of fruit juice, 1 tablespoon of table sugar). The patient should respond in about 15 minutes and should be then given a snack with complex carbohydrates and protein. If the patient does not respond, treatment can be repeated. If the patient becomes unconscious, glucagon (available as a kit with a 1-mg ampule, diluents, and syringe) can be injected into the upper arm or thigh muscle and medical emergency services must be called. When the patient responds to the glucagon injection and is able to swallow, the oral carbohydrate administration steps described above can be followed until the patient is stabilized. A patient with an acute hyperglycemic emergency (glucose levels >250–300 mg/dL) can present disoriented, thirsty, fatigued or nauseated, with rapid and deep breathing, hot and dry skin, and fruity breath, and can progress to hypotension and loss of consciousness. Such patients require transfer to an emergency room/hospital setting and immediate medical intervention. Again, having a glucometer at hand is very helpful; glucose levels can be assessed when symptoms arise to confirm whether the episode is because of hypo- or hyper-glycemia, and in the case of a hypoglycemic episode, to reassess levels following initial treatment. If a glucometer is not available and the dental professional is unable to differentiate whether the patient is hypo- or hyper-glycemic, treatment for hypoglycemia should be initiated. The patient's treating physician should always be informed of extreme glycemic emergencies that occurred in the dental setting and provided with all related information.

Finally, another concern relates to the large number of people worldwide who have diabetes, but remain undiagnosed, and the even larger number of individuals at risk for diabetes who are unaware of it. Since diabetes has early oral effects and many patients visit a dentist annually, often returning for multiple non-emergent visits, dental care settings are ideal healthcare sites that can be used for the early identification of undiagnosed diabetes. Dental professionals can assess risk factors, refer for testing or "formally" screen, and follow-up on outcomes. Studies based on national data in the US explored the ability of clinical periodontal parameters to identify patients with undiagnosed diabetes and findings suggested that such an approach is promising (Borrell *et al*. 2007; Strauss *et al*. 2010, Li *et al*. 2011, 2013). The first study to prospectively collect data in a clinical setting in order to discern a simple and efficient protocol to identify people with undiagnosed prediabetes or diabetes revealed that two dental parameters (number of missing teeth and percent of teeth with deep periodontal pockets) were effective in correctly identifying the majority of cases of unrecognized dysglycemia (Lalla *et al*. 2011). The addition of a point-of-care HbA1c test result was found to significantly improve the performance of the screening algorithm in the population under investigation. As the performance of this and any similar approaches is tested in diverse populations in the future, we can expect that assessment for undiagnosed dysglycemia may be incorporated into the periodontal evaluation of each patient at risk.

Tobacco smoking

Tobacco smoking is a prevalent behavior with widespread and severe health consequences. Although tobacco use was once classified as a habit, it is now considered an addiction to nicotine and a chronic relapsing medical condition. Smoking has several effects on the oral cavity ranging from simple tooth staining to oral cancer.

As reviewed in Chapter 7, smoking is recognized as an important risk factor for periodontitis, and a multitude of epidemiologic and clinical studies have established its detrimental effects on the periodontium. These effects have been shown to be dose-dependent and can be particularly evident in younger individuals (Stabholz *et al*. 2010). There is also evidence for a link between passive, also termed environmental or second-hand, smoking and periodontal disease (Arbes *et al*. 2001; Nishida *et al*. 2008). Tobacco smoke contains thousands of different substances and most of its harmful effects result through systemic exposure following lung absorption, in addition to the obvious absorption in the oral cavity (Palmer *et al*. 1999).

Mechanisms underlying the effect of smoking on periodontitis

The pathways by which cigarette smoking affects periodontal status are not fully understood; however, various potential mechanisms have been discussed in the literature, including effects on the oral microbiota, the gingival tissues, the inflammatory and immune response, and the healing capacity of the periodontium.

Early reports suggested that the amount of plaque in smokers is higher compared to non-smokers (Preber *et al*. 1980), but studies controlling for confounding factors revealed that smoking does not appear to affect plaque scores, and indeed, in experimental gingivitis models the rate of plaque formation was similar between smokers and non-smokers (Bergstrom 1981; Preber & Bergstrom 1986, Lie *et al*. 1998). Further, certain studies focused on smoking and qualitative changes in subgingival plaque. Zambon *et al*. (1996) found higher prevalence of *Aggregatibacter actinomycetemcomitans*, *Tannerella forsythia*, and *P. gingivalis* in current and former smokers compared with never-smokers. Similarly, Haffajee and Socransky (2001) found a higher prevalence of eight bacterial species in current smokers compared with past smokers and non-smokers. In subsequent reports, tobacco smoking has been shown to affect bacterial acquisition and colonization (Brook 2011; Kumar *et al.* 2011) and bacterial aggregation (Bagaitkar *et al*. 2011), and to promote colonization with key periodontal pathogens (Shchipkova *et al*. 2010; Kubota *et al.* 2011). Based on these studies, it appears that microbiologic differences exist between smokers and non-smokers, but they primarily concern the composition rather than the amount of subgingival plaque.

Importantly, it is well accepted that smoking has the potential to impair several aspects of the innate and immune response and, in the setting of periodontitis, this can tip the balance towards an exaggerated tissue breakdown and impaired repair. To this end, it has been reported that neutrophil migration and chemotaxis in the periodontal tissues are negatively affected in smokers (Pabst *et al*. 1995; Persson *et al*. 2001; Soder *et al*. 2002). Interestingly, neutrophils express functional receptors for many tobacco smoke components and, for example, the numbers of nicotine receptors are increased in smokers and have been shown to decrease following smoking cessation (Ackermann *et al*. 1989; Lebargy *et al.* 1996). Not all data on neutrophil effects are consistent, but overall cigarette smoke appears to shift the balance of neutrophil activities in the more destructive direction (Palmer *et al*. 2005; Matthews *et al*. 2012). The effects of tobacco smoking on T- and B-cell numbers and function are more complex and less consistent across studies, as both immunosuppressive and inhibitory processes have been described (Palmer *et al*. 1999; Loos *et al*. 2004). There is also, mostly *in vitro*, evidence suggesting that gingival and periodontal ligament fibroblast recruitment and adhesion may be negatively affected in smokers, and that collagen production is decreased while collagenolytic activity is increased (Tipton & Dabbous 1995; James *et al*. 1999; Gamal & Bayomy, 2002; Poggi *et al*. 2002). Finally, the reported suppressed gingival inflammation in smokers as evidenced by clinical signs of reduced gingival bleeding and bleeding on probing (Preber & Bergstrom 1985, 1986; Bergstrom *et al*. 1988; Bergstrom & Bostrom 2001) appears to be related to fewer gingival vessels (Rezavandi *et al*. 2002; Palmer *et al.* 2005), rather than to vasoconstriction as originally speculated. The above effects of smoking on the inflammatory response, vasculature, and fibroblast function can also explain its well-described negative effects on healing following non-surgical and surgical periodontal therapy (Kinane & Chestnutt 2000).

Much less is known about the mechanisms underlying the effects of passive smoking on the periodontium. However, there is evidence for increased levels of salivary cotinine (a nicotine metabolite), higher levels of a number of inflammatory mediators, and an increased proportion of phagocytic cells in gingival lesions of individuals exposed to second-hand smoking, possibly indicating an altered host response to the bacterial challenge (Walter *et al*. 2012).

Clinical presentation of the periodontal patient who smokes

The oral effects of smoking become evident relatively early in the course of tobacco use, and smokers often present clinically and radiographically with signs of increased bone, attachment, and tooth loss (Figs. 14-8, 14-9). Deeper pockets in anterior and maxillary palatal sites may often be seen. At the same time, however, smoking masks some other important clinical signs of gingivitis and periodontitis, complicating the usual approach to recognizing these conditions. Indeed, smokers often present with fibrotic gingiva and limited gingival erythema and edema relative to the amount of plaque and the severity of the underlying bone loss (Scott & Singer 2004). Bleeding on probing is reduced in a dose-dependent manner in smokers compared to non-smokers with similar levels of plaque (Bergstrom & Bostrom 2001; Dietrich *et al*. 2004), and it can re-emerge within weeks in patients who quit, even in the presence of improved plaque control (Nair *et al*. 2003).

Moreover, and as described in detail in Chapter 7, multiple studies examining the effects of smoking on periodontal treatment outcomes have demonstrated that response to therapy is compromised in smokers, with current smokers exhibiting less probing depth reduction and/or attachment gain compared to former or never smokers (Heasman *et al*. 2006). Meta-analyses of the effects of smoking on the outcomes of periodontal therapy corroborate these conclusions (Garcia, 2005a, b; Labriola *et al*. 2005a, b; Patel *et al*. 2012a, b) and suggest that a smoker's post-treatment

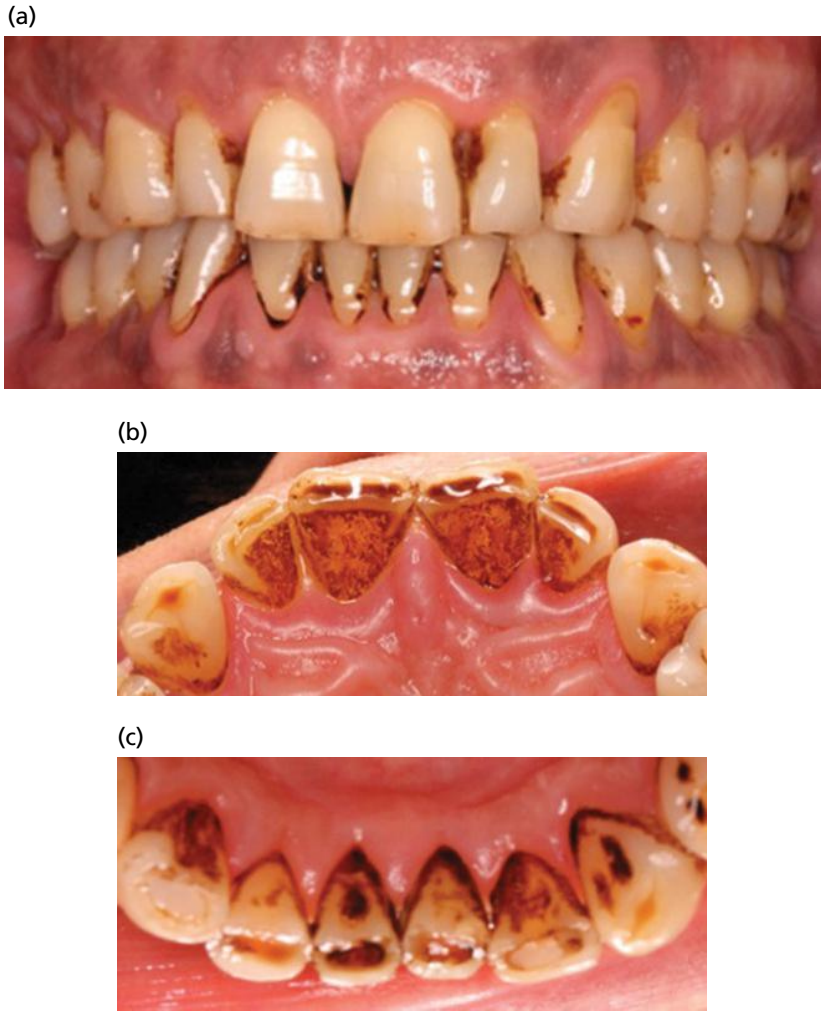

Fig. 14-8 Clinical appearance of a 53-year-old male patient who reports smoking one pack a day for 35 years. (a) Anterior view; (b) palatal view of the maxillary anterior teeth, and (c) lingual view of the mandibular anterior teeth. Note the heavy staining. Periodontal examination revealed probing depths of up to 9 mm, gingival recessions, and furcation involvements at all molars. (Courtesy of M. Hickin.)

clinical presentation may not be compatible with the expected profile of a treated patient.

Concepts related to patient management

The evidence reviewed above has direct patient management implications, especially when surgical and/or regenerative therapy is under consideration. Patients who smoke need to be informed of their enhanced risk for limited or delayed treatment responses and this may actually provide an opportunity to further motivate a patient to consider smoking cessation.

Dental professionals are healthcare providers and, as such, they have the responsibility to advocate smoking cessation among their patients. In doing so, they can contribute to improved patient oral health, overall health, and quality of life. Smoking cessation has been shown in longitudinal studies to have beneficial effects on the periodontal status (Bolin *et al*. 1993; Krall *et al*. 1997; Bergstrom *et al*. 2000; Rosa *et al*. 2011), and smoking cessation alone or in conjunction with non-surgical periodontal therapy appears to result in a subgingival microbiota that comprises higher levels of health-associated species and lower levels of pathogens (Fullmer *et al*. 2009; Delima *et al*. 2010).

There are multiple opportunities to interact with patients and provide tobacco use intervention, especially after initial periodontal evaluation of a new patient and during the long-term maintenance phase of periodontal therapy. Different approaches can be used. Asking every patient about tobacco use, documenting smoking status and motivation to quit, and advising patients to stop are the minimum obligations. A more comprehensive intervention that includes offering smoking cessation counseling with pharmacologic therapy and supportive follow-up is ideal. Complex patients such as those suffering from psychiatric illness or medical co-morbidities should be referred to smoking cessation specialists/clinics where comprehensive treatment can be offered.

Some of the different approaches to smoking cessation that can be considered in the dental setting are briefly discussed below. In general, evidence to date suggests that dental professionals tend to ask their

Fig. 14-9 Same patient as in Fig. 14-8. (a, b) Maxillary left buccal and palatal views and (c) corresponding radiograph; (d, e) mandibular left buccal and lingual views and (f) corresponding radiograph. Heavy staining and advanced bone loss are apparent. (Courtesy of M. Hickin.)

patients about smoking, but do not provide help regarding cessation, and several barriers to delivering smoking cessation intervention by dental professionals have been reported (Albert *et al*. 2005; Kunzel *et al*. 2006; Patel *et al*. 2011). For those providers who identify lack of time or expertise/confidence as barriers, a "brief intervention" approach may be a useful model. The dental team can give patients educational brochures to take home and also provide some encouragement and support by relating tobacco use to medical and oral health risks. This strategy is often effective as the advice of a trusted healthcare provider is always valuable.

If the dental team is willing to be more proactive and the patient is motivated, a more extensive behavioral program can be introduced. The "five A's", from the United States Public Health Service (U.S. Public Health Service 2008), has become the model program:

Ask: Ask about smoking behavior directly and document status (current, former, or never smoker; duration and number of cigarettes per day). Tobacco use status indicators on paper charts or electronic records can make screening easier.

Advise: Advise patient to quit. The message should be clear, strong, and tailored. A good time to do this is after the periodontal examination is completed and when findings, etiology, risk factors, and prognosis are discussed. Several health organizations and internet sites that provide valuable information are available.

Assess: Assess the patient's readiness and motivation to quit. If the patient is willing to attempt cessation, provide assistance as described below. If the patient is clearly unwilling to attempt quitting at this time, offer written materials about quitting and re-assess at future appointments. Improving the patient's interest and readiness level is a successful intervention, even if cessation is not immediately contemplated.

Assist: Assist the patient willing to make a quit attempt by providing a structured plan for quitting. Decide

on a quit date and encourage the patient to seek support from family and friends. Consider the use of pharmacotherapies that have proven effective and are briefly described below. Anticipate challenges that might threaten smoking cessation and decide in advance on a plan of action if/when those arise.

Arrange: Arrange follow-up, including behavioral support and telephone contact/counseling. The first week of cessation is especially critical.

Pharmacologic treatment options include nicotine replacement therapy, sustained-release bupropion, and varenicline (Aubin *et al*. 2011). Nicotine replacement therapy involves the use of products that provide low doses of nicotine, but do not contain the toxins found in smoke. The goal of therapy is to relieve cravings for nicotine and ease the withdrawal symptoms. Nicotine supplements come in different forms: transdermal patch, gum, lozenges, nasal spray, and inhaler. The different forms of replacement therapy can be used alone or in combination, and all work well if they are used correctly. The choice depends on the patient's smoking habits and preferences, and initial treatment lasts for 2–3 months. Side effects include headaches, nausea, and insomnia in the first few days, especially with the patch. Sustained-release bupropion inhibits the neuronal uptake of norepinephrine and dopamine. It can therefore control nicotine withdrawal symptoms and may also help patients manage associated anxiety and depression. Treatment with bupropion should be initiated 1–2 weeks before the quit date, since 1 week is necessary to achieve steady-state blood levels; treatment usually lasts for 2–3 months, but it can continue safely for maintenance for up to 6 months. The use of bupropion is contraindicated for patients with a history of seizures, eating disorders, and those who are on certain antidepressants. Common side effects of bupropion include insomnia and dry mouth, and patients should be monitored closely for unusual changes in behavior, such as agitation, depression, and attempted suicide (Hays & Ebbert 2010). Varenicline is the newest drug for smoking cessation. It has a structure similar to that of nicotine and thus it can antagonize nicotine binding to its receptor sites. As with buproprion, varenicline treatment starts 1 week before the quit date and continues for 3 months; maintenance treatment, if needed, may be for up to 6 months. Common side effects include nausea, trouble sleeping, and abnormal or vivid dreams (Garrison & Dugan 2009; Hays & Ebbert 2010). Patients taking varenicline should be monitored closely for any changes in mood and behavior.

Unfortunately, nicotine dependence is chronic and strong, and therefore the possibility of relapse is high. Smokers often must experience many attempts at cessation before they can remain totally tobacco free. They are certainly more likely to be successful if they have support with quitting. Providing encouragement at every appointment with the dentist and hygienist is key in helping patients to stay smoke free.

Obesity and nutrition

Obesity, a condition characterized by accumulation of excess body fat, is defined in adults as a body mass index (BMI) of ≥30 kg/m^2, while a BMI between 25 and 29.9 kg/m^2 indicates an overweight individual. In the past few decades, many countries in both the industrialized and the developing world have experienced a substantial increase in the prevalence of obesity, which is known to be a major contributor to morbidity. Concomitant occurrence of obesity, insulin resistance, dyslipidemia, and hypertension constitute the metabolic syndrome, a precursor condition to type 2 diabetes and incident cardiovascular disease.

As discussed in Chapter 7, several studies have demonstrated a positive association between obesity/metabolic syndrome and periodontitis. Indeed, a systematic review and meta-analysis (Chaffee & Weston, 2010) confirmed a higher prevalence and severity of periodontitis among obese adults. Although the limited number of longitudinal studies of adequate quality does not facilitate the exact delineation of the temporality of this association at the present time, it is biologically plausible that obesity may contribute to a higher risk for periodontitis.

The function of the adipose tissue as essentially an endocrine organ is central to its role in the association between obesity and periodontitis. Adipocytes secrete a variety of metabolically and immunologically active molecules, termed adipokines, among which leptin, adiponectin, and resistin have been studied the most. The primary function of leptin is to negatively regulate appetite and weight, but it also interacts with other hormones, including insulin (Margetic *et al*. 2002; Guzik *et al*. 2006). Interestingly, there is a negative correlation between GCF and serum levels of leptin in periodontitis, and this association was reported to become stronger with increasing levels of attachment loss (Karthikeyan & Pradeep 2007a, b). In contrast, serum levels of adiponectin are decreased in obesity, insulin resistance, diabetes, and cardiovascular disease (Matsuzawa *et al*. 2004). Adiponectin has been shown to be a potent negative regulator of osteoclast formation in response to challenge by LPS by *A. actinomycetemcomitans* (Yamaguchi *et al*. 2007). However, there is no clear association between its serum levels and periodontal status (Furugen *et al*. 2008; Saito *et al*. 2008), and its levels in GCF have not been studied. In contrast, levels of resistin were found to be higher in patients with periodontitis than in periodontally healthy individuals, and to correlate with the extent of bleeding on probing (Furugen *et al*. 2008; Saito *et al*. 2008). Thus, adipokine action and oxidative stress have been proposed to serve as the common link in the pathobiology of obesity and periodontitis (Bullon *et al*. 2009). Indeed, there is evidence of higher serum levels of markers of oxidative stress and of decreased antioxidant capacity in individuals with periodontitis when compared to periodontally healthy controls (Chapple & Matthews 2007).

Finally, there has been an increased interest in the role of nutritional exposures in the etiology and therapeutic management of periodontitis. The effect of ascorbic acid (vitamin C) deficiency on the gingival tissues has been known since the 18th century, when an association between scurvy and bleeding gums and tooth loss was first observed in sailors who did not have access to fresh fruit and vegetables over prolonged time periods. Vitamin C is a powerful antioxidant radical scavenger (Da Costa *et al*. 2012) that is distributed in many cell types, including polymorphonuclear leukocytes, platelets, and endothelial cells (Evans *et al*. 1982), and which has been shown to exercise effects on osteoclasts and periodontal ligament fibroblasts (Mimori *et al*. 2007). Likewise, while it has long been known that vitamin D and calcium are important for skeletal development and maintenance of bone mass, vitamin D has emerged as an important regulator of innate immune responses in infectious diseases (Adams & Hewison 2008). Additional micronutrients that have been investigated with respect to their association with periodontal status include both antioxidant (vitamin E, carotenoids, polyphenols, glutathione) and non-antioxidant molecules (vitamin B, omega-3 polyunsaturated fatty acids). In general, epidemiologic studies reveal that periodontitis is associated with low serum/plasma micronutrient levels (Van der Velden *et al.* 2011), while early evidence from interventional studies (Campan *et al*. 1997; Staudte *et al*. 2005; Jenzsch *et al*. 2009; Chapple *et al*. 2012) suggests that adjunctive nutritional supplementation may result in improved periodontal therapy outcomes. Additional research from randomized placebo-controlled trials is needed to further document these effects and to facilitate the development of nutritional recommendations in the prevention and control of periodontal diseases.

Osteoporosis and osteopenia

Osteoporosis is a disease characterized by loss of bone mineral density that can lead to bone fragility and increased susceptibility to fractures (Eastell 1998). Female gender, advanced age, family history of osteoporosis, ethnicity (Caucasian or Asian), history of a low-impact bone fracture, thin skeletal frame, and early menopause are non-modifiable risk factors for osteoporosis. High alcohol intake, smoking, low BMI, vitamin D deficiency, and physical inactivity are other important modifiable risk factors. The femur and spine are most commonly affected and bone density at these sites can be quantified using dual-energy X-ray absorptiometry (DXA) scans to define a diagnostic T-score. The T-score compares bone density for a given patient to the mean peak bone density for an individual of the same gender, and is reported as the number of standard deviations below that mean. A T-score of −1 or above is considered normal and a score of −2.5 or lower signifies osteoporosis. Scores <-1.0 and >-2.5 indicate osteopenia, an intermediate state between health and osteoporosis.

Several clinical studies have drawn attention to the possible link between osteoporosis and periodontal disease, as both conditions involve bone loss and may potentially share common risk factors and pathogenic mechanisms (Otomo-Corgel 2012). However, and as reviewed in Chapter 7, many of the clinical studies thus far were uncontrolled, cross-sectional, had small sample sizes, and were restricted to post-menopausal women (von Wowern *et al*. 1994; Mohammad *et al*. 1996, 1997; Tezal *et al*. 2000). Further data from longitudinal studies appear conflicting, and two systematic reviews concluded that the relationship between osteoporosis and periodontitis remains unclear (Martinez-Maestre *et al*. 2010; Megson *et al*. 2010).

It has been proposed that low bone mineral density in the maxilla and mandible as a result of osteoporosis may contribute to periodontal pathology by accelerating alveolar bone resorption that is initiated by the periodontal infection (Wactawski-Wende 2001). In addition, factors affecting systemic bone remodeling (e.g. heredity, estrogen, vitamin D, RANKL, and OPG) may also modify the local tissue response to periodontal infection, increase the release of pro-inflammatory mediators, and lead to enhanced destruction of the periodontal tissues. Studies exploring the potential underlying mechanisms are extremely scarce (Jabbar *et al*. 2011) and although these hypothetical pathways are biologically possible, they are only speculative at present.

Skeletal bone loss in those affected by osteoporosis is usually gradual and painless. Often, there are no obvious symptoms until a fracture occurs and thus early identification of those affected by or at risk for osteoporosis is of importance. Dental professionals may be able to recognize clinical risk factors for osteoporosis among their patients and see radiographic changes, such as thinning and porosity of the inferior border of the mandible in available panoramic radiographs or cone-beam computed tomographs (Horner *et al*. 2010; Koh & Kim 2011). Discussion of such findings and referral for further investigation by a medical colleague of those identified as potentially at risk for osteoporosis can be beneficial in the prevention of osteoporotic fractures.

Finally, it is important for dental professionals to remember that, with increasing longevity, osteoporosis prevalence is on the rise and that many female, and also male, dental patients may be affected and be under lifelong antiresorptive medications. Dentists need to review medications, including method of delivery, duration, and dosages, and consult with the patient's physician if there are concerns regarding necessary periodontal treatment. For those patients on bisphosphonates, careful planning and consultation with the treating physician is important, especially when periodontal therapy may involve extractions or other extensive surgical procedures

and the patient has been on the medication for >2–3 years. Such patients should be informed of the risks and possible effects of bisphosphonates on dental treatment outcomes. Any acute lesions must be treated immediately, oral hygiene instruction must be thorough, and the periodontal condition carefully controlled. Systemic use of antibiotics and use of antimicrobial mouth rinses can be considered. The potential complication that needs to be prevented is osteonecrosis of the jaw (ONJ), defined as an exposure of bone in the mandible or maxilla persisting for >8 weeks in a patient who previously received, or is currently under, treatment with a bisphosphonate and who has no history of radiation therapy to the jaws (Khosla *et al*. 2007). Clinically, ONJ may present as exposed alveolar bone occurring spontaneously or after dental surgery that caused bone trauma. The sites are usually painful, have soft tissue swelling or ulceration, mobile teeth, and induration with drainage. Radiographically, if teeth are present, there may be sclerosis of the alveolar lamina dura, loss of the alveolar lamina dura, and/or widening of the periodontal ligament space. Depending on the severity of ONJ, treatment strategies may include antibacterial mouth rinses, symptomatic treatment with oral antibiotics and analgesics, superficial debridement, and in severe cases, surgical debridement/resection. The patient's treating physician must always be contacted and informed.

Psychosocial stress

Stress results from interactions between individuals and their environment. It has been defined as a state of mental or bodily tension resulting from factors that tend to alter an existent equilibrium, or as a condition or feeling experienced when a person perceives that demands exceed the personal and social resources he/she is able to mobilize. There are numerous emotional and physical disorders that have been linked to stress, including depression, hypertension, cardiovascular and cerebrovascular events, obesity, immune system disturbances that increase susceptibility to infections, viral disorders ranging from the common cold and herpes to AIDS, certain cancers, as well as autoimmune diseases like multiple sclerosis (Spiegel & Giese-Davis 2003; Ziemssen & Kern 2007; Chida *et al*. 2008; Chida & Mao 2009; Falagas *et al*. 2010; Puder & Munsch 2010; Artemiadis *et al*. 2011; Bender & Alloy 2011; Blashill *et al*. 2011; Proietti *et al*. 2011; Wardle *et al*. 2011; Rosenthal & Alter 2012). Stress can also have direct effects on the skin and the gastrointestinal tract, and can contribute to sleep disturbances (Kim & Dimsdale 2007; Basavaraj *et al*. 2011; O'Malley *et al*. 2011).

As expected, psychosocial stress can also affect the periodontium. This concept is not new; stress has been reported as an important risk factor for necrotizing ulcerative gingivitis for many decades. The effects of stress on the periodontium can be described as indirect or direct. Indirect effects are those mediated through lifestyle changes that can exacerbate periodontal destruction, such as compromised oral hygiene, inattention to dental visits for prevention/care, deterioration of metabolic control in diabetes, increase in smoking, and inability to maintain healthy eating habits. Direct effects may be mediated both via modification of the composition of the subgingival biofilm and exaggeration of the host inflammatory response.

In response to stressful events, the hypothalamus–pituitary–adrenal axis is stimulated, leading eventually to increased production and secretion of cortisol, a hormone that can stimulate the immune system. Further, the autonomic nervous system is stimulated, leading to secretion of catecholamine and substance P that can also regulate the immune/inflammatory response and affect bacterial adherence and growth. Indeed, several stress markers have been reported in the blood, saliva, and GCF of periodontitis patients, and may mediate the potential detrimental effects of stress on the periodontal tissues (Axtelius *et al*. 1998; Hilgert *et al*. 2006; Johannsen *et al*. 2006; Ishisaka *et al*. 2007, 2008; Rai *et al*. 2011)

In the first large-scale study aiming to explore the link between stress and periodontal status, 1426 adults in the US were evaluated (Genco *et al*. 1999). Subjects under high levels of financial stress and with poor coping responses were reported to have significantly more severe alveolar bone loss and attachment loss than those with low levels of stress within the same coping group, after adjustment for age, gender, and cigarette smoking. Many other studies in subjects with different types of psychosocial stress, such as academic or job related, and poor coping behaviors have provided similar results (Moss et al. 1996; Croucher *et al*. 1997; Deinzer *et al*. 1998, 1999; Mengel *et al*. 2002; Giannopoulou *et al*. 2003; Kamma *et al*. 2004; Ishisaka *et al*. 2007, 2008; Johannsen *et al*. 2007; Furugen *et al*. 2008, Johannsen *et al*. 2010). Of interest is the fact that adequate coping behaviors, as evidenced by high levels of problem-based coping, may reduce the stress-associated risk.

The variability associated with self-reported measures of psychological stress and the use of different periodontal parameters as outcomes across studies investigating the link between stress and periodontitis make comparisons of such studies and the interpretation or generalizability of results difficult. However, it is fair to conclude that accumulating evidence to date is in the direction of a positive association between psychosocial stressors and poor periodontal status.

Further, experimental studies using animal models and cell culture systems have provided evidence for a link between markers of stress and the severity of periodontal inflammation/destruction, mediated at least in part through pro-inflammatory molecules (Shapira *et al*. 2000; Kim *et al*. 2009; Huang *et al*. 2011; Semenoff-Segundo *et al*. 2012). Similarly, in human

studies, salivary and serum stress marker levels were positively associated with the extent and severity of periodontitis (Hilgert *et al*. 2006; Ishisaka *et al*. 2007, 2008; Rai *et al*. 2011). The potential effect of stress on bacterial growth and virulence, although biologically plausible, is less studied and understood.

Unequivocally, stress is part of human life, is commonly present to varying degrees, and although it may have different consequences in different individuals, its potential effect on periodontal disease presentation and the response to therapy should not be underestimated. The dental team needs to remember that periodontal disease prevention, meticulous monitoring, and careful maintenance strategies are important for patients under stress, especially those who appear to cope inadequately.

Introduction

Periodontitis is a chronic inflammatory disease of the supporting tissues of the teeth. In subjects susceptible to destructive periodontal disease, there is an imbalance between the host's immune system and the oral bacteria. In these individuals, certain microbial pathogens can proliferate and this leads to the induction of inflammatory reactions in the periodontal tissues. These inflammatory reactions slowly destroy the periodontium. If left untreated, the teeth lose their ligamentous support to the alveolar bone and alveolar bone is resorbed, with the consequence that the affected teeth become mobile and are eventually lost.

The oral cavity is one of the most complex ecosystems of the human body and contains myriads of different bacterial species. These species co-evolved with the human organism and the oral microbiota adapted to the environmental conditions provided by the host. The evolution of this ecosystem was subjected to strong selection pressures in a biologically active environment and it is considered to have largely developed for mutual benefit. The normal oral microbiota protects the host from extrinsic pathogens and the immune system controls bacterial proliferation to maintain homeostasis. The complex interplay between environmental factors, that is pathogens in the oral cavity, the immune system, and consequences of lifestyle factors is largely regulated by genes. Genes encode immune receptors as well as molecules, which influence receptor specificity and sensitivity to bacterial species. They regulate and influence the intensity of the inflammatory response by encoding and adapting the signal transduction pathways up- and down-stream of the inflammatory signals, and allow a flexible response of the organism to external and internal stimuli.

The interplay of the microbiota, the immune system, and lifestyle habits (smoking, stress, diet, etc.) underlie the constant changes to which the host's physiology must adapt to maintain health: the bacterial species change in number and proportions, and may also change in characteristics, for example by horizontal gene transfer or mutation. The host's immune system changes over time and can be

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

positively or negatively influenced by lifestyle factors, other diseases, or age. Additionally, the genetic constitution of the host may change during life, for example by epigenetic effects or somatic mutations. As a result, periodontitis is considered to be a complex disease.

Genetic research can improve the understanding of the factors that mediate the immune response and explain why this response often greatly differs between individuals who have the same environmental context and comparable lifestyle habits. An important objective of genetic research is to identify the genes underlying disease and to estimate the genetic effects of potential risk variants within these loci. Genetic variation most often affects the regulatory regions of the genes, which lead to subtle changes in their expression: in the quantity of the transcribed gene products, but also the tissue- and development-specific gene expression. It is important to identify these genetic elements and to characterize their modes of action to understand how the expression of target genes in a tissue is regulated, including their time-specific expression. This knowledge is indispensable for the understanding of the molecular biology of periodontitis.

The genetic basis of periodontitis was demonstrated by formal genetic studies, and many genetic variants were analyzed for their involvement in disease physiology. However, within recent years, there have been enormous developments in the tools for genetic analysis and, for many common, complex human diseases, in knowledge of the relevant genetic factors. In this chapter, instead of discussing a long list of earlier studies and their often ambiguous results, we will describe the underlying concepts and methodologic principles necessary for the understanding of the current genetic basis of periodontitis. We will comment on the limitations of and the progress achieved with recent studies, the different paths that are opening up in the efforts to identify the full spectrum of genetic risk factors for periodontitis, and how this newly acquired knowledge can be used to improve diagnosis and in an emerging personalized medical care. We will also illustrate the current state of genetic research in periodontitis and give an overview on the risk genes that are currently regarded as validated. Additionally, we will discuss the likely directions of genetic research in the field of periodontitis in the near future. We will provide an evaluation of the current predictive ability of genetic tests for monogenetic and complex diseases and give an outlook on future possibilities of personal genome testing.

Evidence for the role of genetics in periodontitis

Until the middle of the last century, it was thought that subjects with a longstanding history of poor oral hygiene develop periodontitis. This was mainly because all forms of periodontitis were largely shown to be associated with specific bacterial pathogens and many studies demonstrated immunologic responses within the oral cavity. In addition, the prevalence and proportions of periodontal pathogens were regarded to be higher in periodontitis patients compared to healthy controls (Griffen *et al*. 1998; Van Winkelhoff *et al*. 2002). It remained an open discussion whether or not periodontitis was solely caused by one or more specific periodontal pathogens. If it were, it should develop in most infected subjects. However, periodontal pathogens show a relatively high prevalence in healthy subjects as well as in subjects with gingivitis or minor periodontitis. For example, in a study of 222 healthy children aged 0–18 years from Ohio, USA, pathogenic strains of *Aggregatibacter actinomycetemcomitans* and *Porphyromonas gingivalis* were detected in 48% and 36% of the children, respectively, and both species were detected in infants as young as 20 days old (Lamell *et al*. 2000). Interestingly, in a large group of subjects with gingivitis or minor periodontitis (mean age 52 years), *A. actinomycetemcomitans* and *P. gingivalis* were similarly prevalent (38% and 32%, respectively) (Wolff *et al*. 1993). In the last decades, epidemiologic studies as well as longitudinal clinical studies have shown that the presence of bacteria does not invariably induce periodontal attachment loss, but that host factors are also required for periodontitis. The concept of high-risk groups was added to the pathogenesis model, and was one of the factors that developed the hypothesis that periodontitis may have a genetic background.

A study from 1966 was one of the earliest to deduce that certain individuals are more at risk for periodontitis than others (Trott & Cross 1966). This study investigated the principal reasons for tooth loss in over 1800 subjects. The study showed that in each age category, many teeth are lost in relatively few patients. This phenomenon was confirmed in a 28-year longitudinal study of a dentate American population. It was found that 14.4% of this population who became edentulous accounted for 64% of all teeth lost in that period. Among those who lost teeth but remained partially dentate, 13.8% were responsible for 60.2% of all teeth lost in that group (Burt *et al*. 1990). The same phenomenon was found in two longitudinal studies, which evaluated the effect of periodontal therapy in periodontitis patients over >15 years (Hirschfeld & Wasserman 1978; McFall 1982). These studies showed that 20% of the patient populations accounted for about 75% of all lost teeth.

The concept of high risk for the development of periodontitis was further confirmed in longitudinal studies investigating the natural history of periodontal disease. In a population in Sri Lanka without access to dental care and absence of oral hygiene, Löe *et al*. (1986) were able to identify three subpopulations: a group with no progression (11%), a group with moderate progression (81%), and a group with

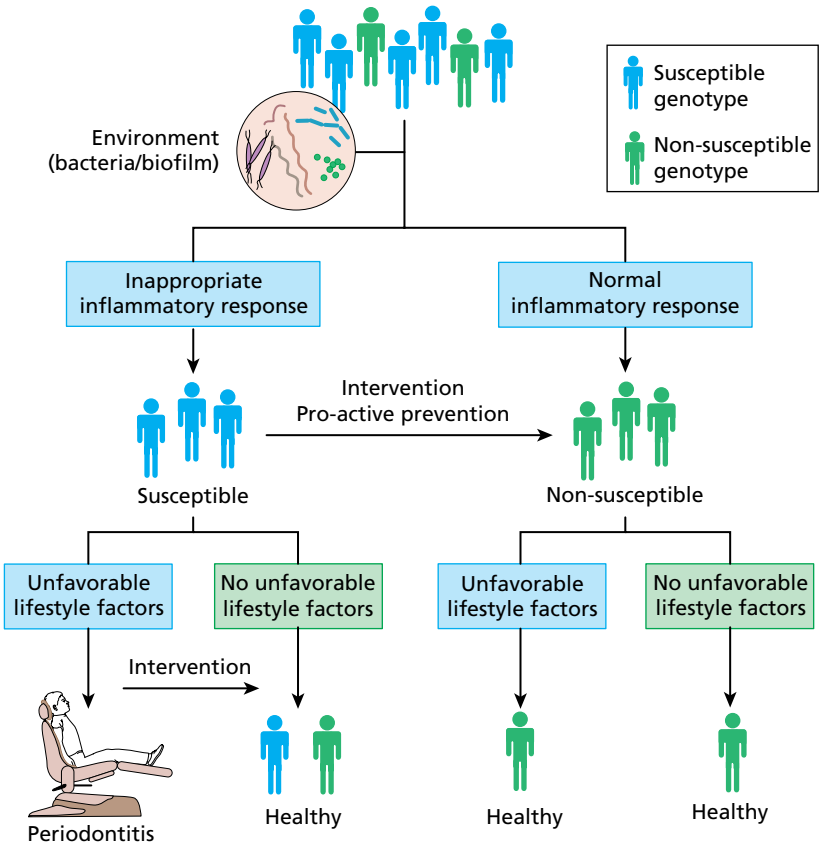

Figure 15-1 Variations in the antimicrobial response of the host may be important features of the pathogenesis of complex diseases such as periodontitis. In this model, the population, consisting of non-susceptible and susceptible hosts, is exposed to prevalent oral bacteria. Non-susceptible individuals with a normal, effective antibacterial response do not develop the disease, whereas susceptible individuals are at risk of developing the disease if key environmental factors are present. An understanding of the immune system alterations that make individuals susceptible may allow for interventions that aim to render the individual insensitive to the environmental stimuli that induce disease (proactive prevention), or that can alleviate or cure the disease after it has become manifest. This model suggests that it is critical to learn more about the factors that influence host–microbial homeostasis. (Adapted from Foxman & Iwasaki 2011, with permission from Macmillan Publishers.)

rapid progression of periodontal breakdown (8%). In a more recent study, the initiation and progression of periodontal breakdown was studied in a remote village in West Java that was deprived of regular dental care (Van der Velden *et al*. 2006). The authors found that 20% of the subjects developed severe breakdown, whereas the remaining population developed minor-to-moderate breakdown, and suggested that not everybody is equally susceptible to periodontitis. This shaped the hypothesis that host susceptibility may have a genetic background: the antimicrobial response of the host is defined in part by genes and can vary across the population. Genetic variants in the genes which encode the pathways of the host's antibacterial response, but also in the bacterial factors that are targeted by the host's immune system, have the potential to deleteriously affect the interplay of the immune system, environment, and lifestyle factors. In some cases they can lead to disease development. Figure 15.1 illustrates this hypothesis and shows how an almost continual exposure to bacteria may or may not cause disease symptoms. It also shows how interventions may be effective before disease manifestation. The individual's immune response, which determines the extent of periodontal destruction, is additionally challenged by other internal and external factors, like systemic diseases (e.g. diabetes), smoking, stress, and age (Kinane *et al*. 2006), which are again determined by the individual's genetic constitution. This interplay between the oral microbiota, internal and external factors which influence the immune system, and the host's general genetic constitution forms the individual susceptibility of a subject to periodontitis.

Heritability

Heritability measures the proportion of phenotypic variation that can be attributed to genetic variation. For example, members of a family may have a large variation of body weight that can be expressed by the body mass index (BMI). The observed variation can be due to different dietary habits among the family members. However, genetic factors can also influence the BMI independent of diet and can be shared between some of the related family members (Schousboe *et al*. 2003; Speliotes *et al*. 2010). Heritability measures the fraction of the phenotype variability that is due to genetic variation between the individuals of the sample. Heritability is also

always specific to a particular population in particular surroundings. If, for example, a family shows uniformity in dietary habits, the heritability will be higher than if the family shows high variation in dietary habits. In the context of oral health, in a sample that shows uniformity in oral hygiene habits, the heritability will be higher compared to a sample that has strong variation in oral hygiene. Table 15-1 shows the wide range of heritability estimates observed for complex diseases and traits, ranging from 22% for happiness to >99% for eye color.

Heritability of aggressive periodontitis (early-onset periodontitis)

Siblings of patients with juvenile periodontitis (JP) frequently also suffer from periodontitis. This observation was based on family studies as well as on reports of single cases. The largest JP family study included 227 probands with aggressive periodontitis (Marazita *et al*. 1994). Of the 227 probands, 104 had at least one first-degree relative who was clinically examined. A segregation analysis was carried out on 100 families, which included 527 cases and healthy subjects. A segregation analysis is a method of formal genetic analysis employed to determine whether or not a phenotype is inherited. It tests whether the transmission pattern in human families over different generations is consistent with the expectations derived from Mendel's first law of segregation. This method also allows the mode of inheritance to be determined, for example if the genetic factor has a dominant or a recessive effect on the phenotype. The authors concluded that the most likely mode of inheritance in the examined families was autosomal dominant (see Box 15-1), with a penetrance of the causative genetic factors of about 70%.

Familial segregation of cases indicates that genetic factors may be important in the susceptibility to periodontitis, but results from segregation analyses need to be interpreted with caution as they may also reflect exposure to common lifestyle factors like oral hygiene, diet, and smoking. Certain infectious agents may also cluster in families. Additionally, segregation studies with human families are hampered by various methodologic factors, which often are the lack of adequate statistical power due to small numbers of families, too small or incomplete families, and a high heterogeneity between families.

A preferred alternative method to determine the evidence for genetic factors in the familial aggregation is the study on monozygotic twins. Twins arise in two ways. The parallel fertilization of two ova by two different spermatozoa results in dizygotic (DZ) twins. These comparatively common cases have the same genetic relationship as siblings. However, infrequently after fertilization by a single spermatozoon, the ovum divides in two, resulting in a pair of monozygotic (MZ) twins who are genetically identical. Severe, early-onset forms of periodontitis,

Box 15-1 Human genes, genetic variation, and useful definitions.

Genes direct the production of proteins with the assistance of enzymes and messenger molecules. In humans, the genes are located on 23 pairs of chromosomes: 22 pairs of *autosomal* chromosomes (autosomes) and one pair of *sex chromosomes* (the gonosomes, XX for females and XY for males). From each pair, one chromosome is inherited from the father and one from the mother. The complete set of chromosomes is called the *genome*. Each chromosome contains a long duplex of deoxyribonucleic acid (DNA). DNA consists of sequences of nucleotides, which are chemically linked by a sugar–phosphate backbone. The nucleotides are the "building blocks" of the DNA and are made up of nitrogenous bases. Four nitrogenous bases exist: adenine (A), guanine (G), cytosine (C), and thymine (T).

In the chromosomes, DNA is arranged in a double helix: two polynucleotide chains are associated together by hydrogen bonding between the nitrogenous bases. The pairing of the two single-stranded nucleotide chains is complementary: G pairs only with C, and A pairs only with T; these are called base pairs (bp). The order of these four nucleotides determines the meaning of the information encoded in that part of the DNA molecule, just as the order of letters determines the meaning of a word. Virtually every single cell in the body contains a complete copy of the approximately 3 milliard (US; English 3 billion) DNA base pairs that make up the genome [National Human Genome Research Institute (NHGRI), National Institute of Health (NIH), www.genome.gov). The genetic code is read in groups of three nucleotides; each trinucleotide sequence (triplet) is called a *codon*, which encodes a specific amino acid.

A gene usually consists of various parts. The *promoter region* is a specific sequence of nucleotides upstream of the coding region that is essential for the regulation and initiation of the transcription of the coding region. *Introns* are sequences of non-protein coding nucleotides and surround the *exons*, which code for the sequence of amino acids of a protein (Fig. 15-2). The collection of known exons in the genome is called the *exome*.

Genes can be transcribed in alternative ways, such that each of the estimated 20 000–25 000 genes in the human genome codes for an average of four proteins (ENCODE-Project-Consortium 2012). Proteins make up body structures like organs and tissues, carry signals between cells, and are the enzymes that control biochemical reactions. If a cell's DNA is mutated, an abnormal protein or abnormal protein quantities may be produced, which can disrupt the body's usual processes and lead to a disease.

For translating the information contained in the DNA into cellular function, the DNA must be transcribed into corresponding molecules of ribonucleic acid (RNA), referred to as transcripts. There are various kinds of RNA transcripts. The type that carries the information that codes the amino acid sequence of the proteins is called messenger RNA (mRNA) and is transcribed from the exons. Non-protein coding RNAs, such as *microRNAs* or long non-coding RNAs (ncRNA), largely function in the regulation of gene expression. The collection of all transcripts present in a given cell is called the *transciptome*.

Sequencing technologies determine the exact order of the nucleotides in a strand of DNA. The international *Human Genome Project* completed the first working draft sequence of the entire human genome in 2000 (Baltimore 2001; Venter *et al*. 2001) and the first high-quality reference sequence in 2003. In May 2006, the finished high-quality version of the sequences of all human chromosomes was published. It showed that >99% of the genomes of any two people are identical, but variations between the individual genomes exist and on average about one in every 1200 bp is different. Differences in individual bases are by far the most common type of genetic variation, and are known as *single nucleotide polymorphisms* (SNPs). Approximately 10 million SNPs are estimated to occur regularly in the human genome (Fig. 15-3) and that in each new generation >30

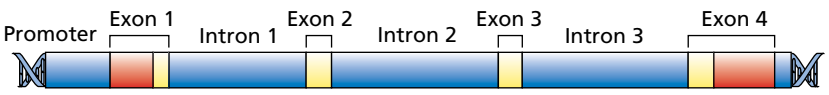

Fig 15-2 Schematic structure of a gene. This gene has four exons (yellow bands), but in reality genes can have many more exons. The first exon is preceded by an untranslated region, the 5′-UTR (left red band), and the last exon is followed by another untranslated region, the 3′-UTR (right red band).

Box 15-1 *Continued*.

de novo mutations arise per individual (Abecasis *et al*. 2010). The great majority of known SNPs are listed in the catalog of common genetic variation, the *HapMap*, which was generated by the HapMap project and first published in 2005 (The-International-HapMap-Consortium 2005; www.hapmap.org). It describes the characteristics of the variants, where they occur in the DNA, and how they are distributed within populations and between populations.

The alternative variants at a specific chromosomal region (*locus*) of the DNA are called *alleles,* and the collection of alleles in an individual's chromosomes is termed the *genotype*. Two or more alleles for a given locus may exist in nature and occur with different frequencies. The *minor allele frequency* (MAF) is the proportion of the least frequent allele in a population and can range from 0–50%. Variants with a MAF of >5% are termed *common variants*. If the MAF of a variant ranges between 1% and 5% it is called a *rare variant*. Genetic variants with frequencies of <1% are called *mutations*.

A mutation or a genetic variant may have no effects or may have moderate to strong effects. For example, if a mutation occurs within the coding region of a gene, it may result in an amino acid substitution and therefore an altered protein structure, which may affect the protein's function (non-synonymous SNP). Or, when such a mutation occurs in a regulatory region of a gene (e.g. the promoter or an enhancer element), it may alter the gene's expression level. Accordingly, genotypic differences among individuals can contribute to phenotypic variation, termed *genetic variance*. The strength with which a genetic variant affects the susceptibility to a disease is defined as the *genotype relative risk* (GRR), the ratio of the risk of disease between individuals with and without the genotype. A ratio of 1.1 equates to a 10% increase in risk and is often expressed as the odds ratio (OR). However, carriership of a genetic variant or mutation does not inevitably lead to disease, as only a proportion of individuals with a mutation or risk variant will develop the disease. This proportion is described as the *penetrance*. The severity of the disease in individuals who have the risk variant and the disease is described as the *expressivity* of the variant.

Despite the existence of many genetic variants, only a fraction of the genotypic differences contributes to phenotypic variation. Where in the chromosomes the causative variants are located and how they interact is mostly unknown. Testing all of the several millions of common and rare SNPs in a person's chromosomes would be extremely expensive. Variants that are near each other tend to be inherited together; for example, individuals who have an A rather than a G at a particular location in the chromosome can have identical genetic variants at other SNPs in the chromosomal region surrounding the A. This non-random association between alleles at different loci is termed *linkage disequilibrium* (LD) and the regions of linked variants are known as *haplotypes* (www.hapmap.ncbi.nlm.nih.gov). Determining the identity of a common SNP on a haplotype, the *tag SNP*, uniquely identifies all other linked variants on the same haplotype. Identifying an individual's tag SNPs, a process known as *genotyping*, enables the haplotypes in the chromosomes to be identified. If patients with the same disease tend to share a particular haplotype, variants contributing to the disease might be somewhere within or near that haplotype. The number of tag SNPs that contain most of the information about the patterns of genetic variation of a genome is estimated to be 300 000–600 000, which is far fewer than 10 million common SNPs, and much less expensive to genotype. Thus, the information from the HapMap has been instrumental in mapping variants contributing to the disease.

such as aggressive periodontitis, for which it is believed that genetic factors are particularly important in influencing disease susceptibility, have a comparatively low prevalence in the general population and it is very difficult to identify enough affected MZ twins to provide sufficient statistical power to test the concordance of this disease phenotype. Nevertheless, the most conclusive indication of whether or not the disease has a genetic cause is obtained by a comparison of the presence of the same disease phenotype in both members of a pair of twins. This is expressed by a comparison of the concordance rate of MZ and DZ twins. For example, twins are concordant when both have or both lack a given phenotype. There are two alternative measures of twin concordance. The pair-wise concordance expresses the probability that both twins of a pair show the disease phenotype, if one of the twins already has the disease. The proband-wise concordance expresses the probability that one twin is diseased, given that the other twin is diseased. Geneticists and twin researchers have long debated the relative merits of the two methods of expressing twin concordance. It was shown that for most applications, the proband-wise rate is the more accurate in genetic twin studies (McGue 1992).

Ciancio *et al*. (1969) addressed the concordance of the periodontal condition in twins, but the study design and the low sample numbers (seven MZ and 19 DZ twin pairs ranging in age from 12 to 17 years) did not allow a clear conclusion on the concordance rate of early-onset periodontitis.

Table 15-2 Concordance rates for early-onset periodontitis in twins.

	n	Concordance rate
Monozygotic	116	0.38
Dizygotic	233	0.16

A twin pair was considered to be concordant if information was provided by one or both pair members and indicated that both pair members were affected.
Data from Corey *et al*. (1993).

Table 15-3 Heritability estimates for measures of chronic periodontitis.

	Age and gender adjusted	Fully adjusted[c]
Attachment loss[a] (%)	52	50
Deepened probing depth[b] (%)	50	50
Gingival index (%)	52	0

[a]Mean percentage of teeth with attachment loss of ≥3 mm.
[b]Mean percentage of teeth with probing depth of ≥4 mm.
[c]Adjustments for age, gender, and oral hygiene as described in Michalowicz *et al*. (2000).

Pair-wise and proband-wise rates were used to estimate the degree of concordance of early-onset periodontitis in MZ and DZ twins (Corey *et al*. 1993). Information on periodontal disease was available for 4908 twin pairs. The mean age at diagnosis of periodontitis in these twins was 31 years. A total of 349 twins reported a history of periodontal disease in one or both pair members. Of these, 116 were MZ and 233 were DZ twins; 70 twins were concordant. The concordance rate for the history of periodontal disease in MZ and DZ twin pairs based on this study is given in Table 15-2. The proband-wise concordance rate showed more than a two-fold increased risk for early-onset periodontitis for the genetically identical MZ twins compared to the DZ twins. It also indicated that in a high proportion of cases factors other than genetic factors were important in triggering this disease phenotype. The mean age difference at diagnosis for the concordant MZ twin pairs was 1 year, while the corresponding difference in concordant DZ twin pairs was 5.4 years (information on age at diagnosis of periodontal disease was only available for both members in 34 of the 70 concordant twin pairs). This reduced mean difference of age at first diagnosis for the MZ twins may also point to an influence of heritable factors in periodontitis.

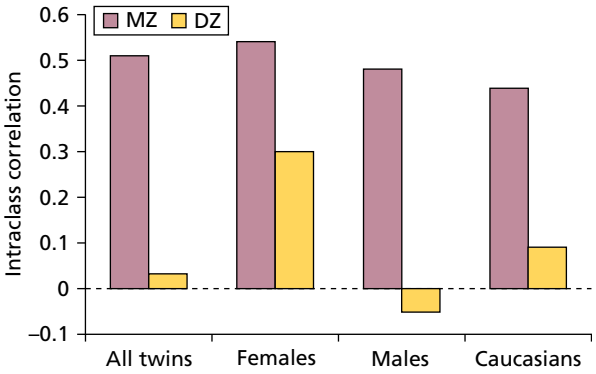

Fig 15-4 Twin intraclass correlations for mean attachment loss in subgroups of different gender and race. The monozygotic (MZ) correlations are remarkably stable among the subgroups. However, the dizygotic (DZ) correlations vary by gender. As indicated by Michalowicz *et al*. (2000), this variation may reflect sampling errors or, more unlikely, gender-specific genetic effects of the DZ twins. MZ = 82 females, 46 males; DZ = 64 females, 42 males. (Source: Michalowicz *et al*. 2000. Reproduced from the American Academy of Periodontology and with permission from K. Murphy.)

Heritability of chronic periodontitis

A few twin studies have assessed the heritability of a periodontal disease status in adults and almost all have reported a heritable component for chronic periodontitis (Corey *et al*. 1993; Michalowicz *et al*. 1991; Michalowicz 1994; Michalowicz *et al*. 2000). One of the first studies included 110 pairs of adult twins (mean age 40.3 years), including 63 MZ and 33 DZ twin pairs reared together, and 14 MZ twin pairs reared apart. The periodontal parameters probing depth, clinical attachment loss, gingivitis, and plaque were examined, and it was estimated that 38–82% of the variance in these measures could be attributed to genetic factors (Michalowicz *et al*. 1991). Another population-based twin study on 117 twin pairs (Michalowicz *et al*. 2000) assessed the heritability of the genetic and environmental variation in chronic periodontitis and gingivitis. It showed that the investigated MZ twins (64 pairs) were more similar than the DZ twins (53 pairs) for attachment loss and probing depth, and showed statistically significant genetic variance for the severity and extent of the disease. The heritability was estimated to be ~50%, which was unaltered following co-variate adjustments for smoking, dental hygiene, age, and gender (Table 15-3). It is noteworthy that this study showed no evidence of heritability for gingivitis and attributed this disease phenotype entirely to disease-related behaviors such as oral hygiene and smoking. This study also examined whether the concordance of the twins varied according to gender. It is conceivable that gender differences determine differential physiologic factors, caused by different hormonal, metabolic, and immunologic environments, as well as lifestyle, and possibly influence disease susceptibility and progression. Nevertheless, MZ twin

correlations did not significantly differ between the genders, indicating that potential gender-specific genetic effects may not contribute to the heritability of periodontitis (Fig. 15-4).

Gene mutation of major effect on human disease and its association with periodontitis

Complex diseases such as periodontitis are caused by an intricate interplay of many genetic and non-genetic factors. In contrast, monogenic diseases such as Huntington's disease and cystic fibrosis are fully heritable. People who carry a causative allele in a single specific gene will inevitably develop the disease. The Papillon–Lefèvre syndrome (PLS) is relatively unique in the group of monogenic diseases, in that severe aggressive periodontitis forms a significant component of the phenotype and is a defining clinical feature (Toomes *et al*. 1999). Both the deciduous and permanent dentitions are affected, resulting in prepubertal periodontitis and premature tooth loss. Additionally, palmoplantar keratosis, varying from mild psoriasiform scaly skin to overt hyperkeratosis, typically develops within the first 3 years of life. Keratosis also affects other sites such as the elbows and knees. Most PLS patients display both periodontitis and hyperkeratosis. Some patients have only one or the other, and rarely the periodontitis is mild or of late onset.

The causative mutations of PLS are located in the *CTSC* (cathepsin C) gene on chromosome 11; over 50 mutations in the gene are now recognized. The protein encoded by this gene is cathepsin C, a lysosomal cysteine proteinase, that appears to be a central coordinator for activation of various serine proteinases. It is expressed at high levels in polymorphonuclear leukocytes (PMNs) and alveolar macrophages and their precursors (Rao *et al*. 1997). It was proposed that minimal cathepsin C activity (~13%) was necessary to prevent the clinical features of PLS, but the exact mechanism by which an altered function of cathepsin C plays a role in the pathogenesis of PLS-associated prepubertal periodontitis is unknown (Hewitt *et al*. 2004). It is speculated that cathepsin C is essential for activation of many serine proteinases in immune-inflammatory cells, including cathepsin G, neutrophil serine proteases, proteinase 3, and elastase (Dalgic *et al*. 2011). The inactive forms of these neutrophil serine proteases result in dysregulation of the host immune response. Increased susceptibility to infections has been attributed to impaired neutrophil and T- and B-cell functions (Ryu *et al*. 2005). The impaired localized PMN response in inflamed periodontal tissues leads to aggressive periodontitis, most likely due to improper phagocytosis and digestion of Gram-negative periodontal pathogens. Likewise, the mutation in the *CTSC* gene seems to result in the incapacity of PMNs to kill *A. actinomycetemcomitans* in an anaerobic environment (de Haar *et al*. 2006).

Identification of genetic risk factors of periodontitis

What are the common genetic risk factors of periodontitis? Interestingly, despite tremendous efforts in the field of genetic association studies over the last decade, the causative gene polymorphisms of periodontitis and their pathophysiologic effects have remained mostly controversial. In this section, we will describe the focus and the limitations of recent studies that have been performed to identify the genetic risk factors underlying periodontitis. Additionally, we will summarize and discuss the current state of genetic research in periodontitis. To begin with, we will briefly look at what has been learned from research into other complex human diseases.

Similarly to periodontitis, many genetic risk factors were proposed for other complex diseases and also were controversial (Morgan *et al*. 2007). These genes were implicated as potential risk factors, but few of these candidate genes, if any, have definitively been established as such (Casas *et al*. 2006; Morgan *et al*. 2007). Several factors have undermined the validity of published reports, including inappropriately small sample sizes, multiple subgroup comparisons, and publication bias. Apparently, publication bias is a crucial stratification factor in the short-term advancement of research. It is explained by the simple fact that positive results are much easier to get published than negative findings, which results in publications biased towards the accumulation of false-positive findings in the scientific literature and under-representation of true negative findings. However, over time the true results usually achieve acceptance. These shortcomings have resulted in significant doubts about the collective panel of putative genetic risk factors for most complex diseases.

In 2007 there was an important turning point in the genetics of complex diseases. The era of genome-wide association studies (GWAS; Box 15-2) was ushered in by the milestone publication of the Wellcome Trust Case Control Consortium (WTCCC 2007). To begin this era, two paradigm shifts were necessary. First, it was realized that the literature-based hypotheses on candidate genes do not usually reflect the situation in nature, while technical advances allow the hypothesis-free approach of simultaneously testing 500 000 to several million polymorphisms spread across the genome in GWAS. Second, it was recognized that large case–control populations are an indispensable prerequisite to overcoming the inherent heterogeneity in populations, and that potential genetic risk factors have to be replicated in large, well-characterized patient populations to rule out stochastic chance observations (see Box 15-2) (Ioannidis *et al*. 2001). True positive as well as true negative associations can only reliably be identified if the statistical power of the population that is clinically analyzed is sufficient. The statistical power is determined, among other factors,

Box 15-2 Genetic association studies.

Studies designed to localize chromosomal regions (loci) that contribute to a disease susceptibility analyze the allele frequencies of variants in a study population and test their co-occurrence with the disease, in comparison to a study population not having the disease (control group). The intention of such *genetic association studies* (or association mapping) is to determine whether an individual carrying one or two copies of a high-risk variant is at increased risk of developing a disease. The principle of the commonly used case–control association study is illustrated in Fig. 15-5. This study is a powerful method to detect associations of certain alleles with a disease phenotype, and it has frequently been employed for the identification of the genetic risk factors in periodontitis.

An important prerequisite of case–control studies is to ensure a good match between the genetic background of cases and controls, so that any genetic difference between them is related to the disease under study and not to biased sampling. Therefore, cases and controls should have similar ethnical descent. A further prerequisite is a *case selection strategy* that is designed to enrich specific disease-predisposing alleles. This includes efforts to minimize phenotypic heterogeneity by stringent diagnosis criteria, and should focus on extreme cases, defined, for example, by a particularly early age of disease onset or severe disease or both.

In most circumstances, and particularly when the total sample size has financial or operational constraints, efforts to enrich case selection with the most severe phenotypes are very likely to improve the *statistical power* of a study due to an increase in the frequency of the risk genotype (McCarthy *et al*. 2008). Related to this and compulsory for the identification of a true genetic risk factor, are case–control analysis populations, which are large enough to provide the necessary statistical power for the initial explorative association study and the necessary subsequent replication of the finding. The statistical power increases with sample size and correlates with allele frequency and the genetic effect of the respective variant (Kathiresan *et al*. 2004). This is why common variants or variants with a high odds ratio (OR) are more likely to be detected in

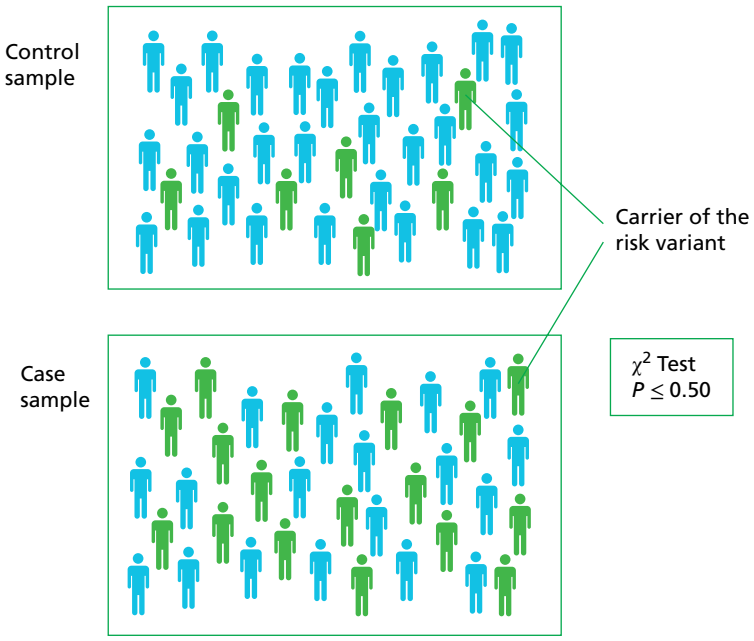

Fig 15-5 Case–control studies compare the frequency of single nucleotide polymorphism (SNP) alleles in two well-defined groups of non-related individuals: controls, who are either known to be unaffected or who have been randomly selected from the population, and cases who have been diagnosed with the disease under study. An increased frequency of an SNP allele or genotype in cases compared with controls indicates that the presence of the SNP allele may increase the disease risk. The potential association is a mere statistical association and always requires a replication in an independent sample. Significance can be assessed with various methods, but most often the χ^2 statistic is used in contingency table analyses, which provide an assessment of the departure from equal SNP allele frequencies in cases and controls (P value). Association studies can also be used to estimate the disease risk conferred by the SNP allele, which is expressed by the odds ratio (OR). The OR is the ratio of allele carriers to non-carriers in cases compared with that in controls, which gives the increase in disease risk for carriers compared to non-carriers (Lewis 2002).

Box 15-2 *Continued.*

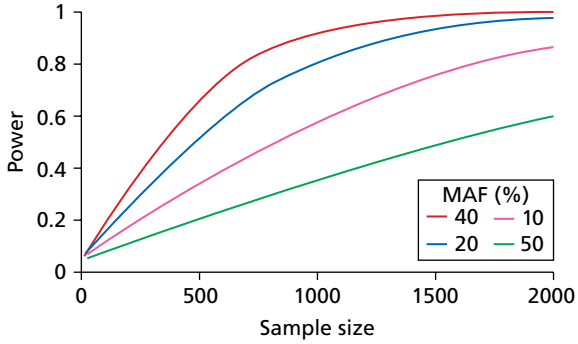

Fig 15-6 Statistical power in relation to the sample size, allele frequency, and odds ratio (OR). To identify a genetic risk variant with a minor allele frequency (MAF) of, for example, 20% in the general population, ≈1000 cases and 2000 controls are required to achieve the necessary statistical power of 0.8. [The statistical power was calculated as described by Dupont & Plummer (1998) for an average OR of 1.3, and twice as many controls as cases were considered. A power of 0.8 is regarded as statistically significant.]

genome-wide association studies (GWAS) than rare variants or variants with a small effect (Fig. 15-6). However, most disease-associated variants increase the susceptibility rather modestly and to identify a common variant with a modest genetic effect, often >1000 well-defined cases and at least the same number of controls are necessary to reach a sufficient statistical power.

The findings of case–control studies are mere statistical associations, which describe differences of allele frequencies between two independent samples; importantly, they should not be regarded as causative associations. By a preassigned significance threshold of 0.05, one in every 20 allelic variants tested will pass the commonly preassigned significance threshold of a *P* value of <0.05 by chance alone. Allele frequencies between independently sampled populations are also liable to stochastic fluctuations (random allele drifts across and between populations, without selection pressure). For these reasons, *replication* of the initial findings is the gold standard for genetic association studies. Notably, the replication needs to be performed in an independent case–control sample of the same phenotype (diagnosis criteria) and the same ethnic background. A repetition of the study with samples from different ethnic groups, with different diagnostic criteria or with independent cases but the same controls, cannot be considered as a replication and does not test the initial finding properly. Only after confirmation by replication is it useful to validate the initial finding of an association study in different sub-phenotypes or in different ethnicities.

As genes are usually patchworks of different haplotypes, being mostly in poor-to-moderate linkage disequilibrium (LD), the information on the potential association of one haplotype provides little to no information on the association or non-association with another haplotype within that gene (Slatkin 2008). Thus, association studies should capture the complete haplotype information of the gene of interest before drawing an unambiguous conclusion of the association findings for that gene, positive or negative (Slatkin 2008).

Candidate gene association studies

Until the middle of the last decade, investigations of selected candidate genes based on literature reviews and perceived pathophysiologic pathways was the most important strategy for the identification of risk genes that contribute to a disease. A major disadvantage of candidate gene studies is the requirement for an *a priori* hypothesis on the involvement of the gene in disease risk and on the presence of a functional variant within this particular gene (Wilkening *et al.* 2009). Essentially, there are two different selection strategies for a candidate gene, which depend on the question addressed. When it is of interest to ask whether or not specific loci within a regulatory signaling pathway are involved in the increase of the genetic risk of periodontitis, or there is functional evidence of the effect of a variant from the study of other diseases, it is reasonable to select genes from this pathway or the specific variants. This approach will determine whether or not the selected genes carry genetic variants which increase the risk of the disease.

Another question which addresses the classical objective of molecular genetics is more difficult to answer: which specific genes and pathways influence the disease risk? As the formulation of the hypothesis for the selection of the candidate gene is entirely dependent on the current knowledge of the molecular biologic mechanisms of the disease, hundreds of loci and/or genes which can have an influence on the disease will not be selected because their function might be unknown or their function lies within pathways that have not yet been implicated in the disease. As the knowledge on these genes is very incomplete, selection of candidate genes is necessarily arbitrary. Accordingly, most associations observed in these studies cannot be successfully replicated. Obviously, this does not rule out the finding of a true positive association if the correct candidate gene was selected *a priori*, but with this approach it is not possible to identify hitherto unknown genes that are disease relevant.

Genome-wide association studies

In contrast, GWAS provide an unbiased and hypothesis-free approach. A large number of SNPs (currently 500 000 to >1 000 000 markers) distributed

(*Continued*)

Box 15-2 *Continued.*

across the whole genome serve as proxies for multiple other SNPs in LD. Nevertheless, genome-wide testing of polymorphisms also entails problems. First, if by chance alone, one in every 20 markers tested gives a P value of <0.05, the probability of statistical errors rises with increasing number of single SNP association tests, so-called type 1 errors (false-positive association findings). If 500 000 markers or more are independently tested, the P value obtained from the χ^2 statistics must be corrected for multiple testing. This is addressed by setting a genome-wide significance threshold by correcting for the number of tests performed (Balding 2006). The current standard for declaring statistical significance at genome-wide level is a combined P value (including "initial discovery" GWAS and replication cohorts) of $<5 \times 10^{-8}$ (Manolio 2010). However, the sample sizes that are required to achieve such significance thresholds may be unrealistic for the study of less common diseases. The resulting lack of statistical power is the major factor that leads to type 1 and type 2 errors (false positive and false negatives), that is the failure to detect a true association.

Table 15-4 Number of identified risk diseases for a selection of inflammatory diseases. The total population size included in the explorative study and the replication is given for the largest of the current studies, which validated previous findings and reported new genetic susceptibility loci.

Disease	Number of risk genes	Population size	Reference
Atherosclerosis	46	64 000 cases	Deloukas *et al.* (2013)
		131 000 controls	
Type 2 diabetes	66	>35 000 cases	
		115 000 controls	Morris *et al.* (2012)
Rheumatoid arthritis	46	12 000 cases	Eyre *et al.* (2012)
		16 000 controls	
Systemic lupus erythematosis (SLE)	51	>8000 cases [e.g. Lessard *et al.* (2012)]	Various individual studies summarized in Boackle (2013)
		>8000 controls [e.g. Lessard *et al.* (2012)]	
Crohn's disease	163	38 000 cases	Jostins *et al.* (2012)
		38 000 controls	

to a large extent by the size of the population analyzed (see Box 15-2). Thus, thousands of well-defined cases and many more controls are needed to detect a genetic variant with a small effect that is observed commonly for complex diseases. This realization eventually resulted in the formation of extensive international consortia for the recruitment of the appropriate case and control numbers.

In a first wave of GWAS during 2007–2010, an era often referred to as the genetic gold rush of human genetics, many of the common genetic risk factors of complex human diseases (i.e. those genetic variants with a ≥5% prevalence in a given population) were identified. Although these studies proved highly successful in identifying the most common genetic susceptibility variants, they could explain only a fraction of the underlying genetic heritability (Maher 2008; Manolio *et al.* 2009). It turned out that the power of an individual study encompassing >1000 cases was still limited in terms of detecting small or modest effects of disease-associated variants. To detect such variants of moderate effect, but also rare variants with a large effect at the individual level, much larger analysis populations were required. To this end, the investigators of the first GWAS joined forces and combined data for GWAS meta-analysis, which eventually included over tens of thousands of cases and controls. Since then, it is considered that most of the common genetic risk factors for co-morbidities of periodontitis, like type 2 diabetes, coronary artery disease, or rheumatoid arthritis, have been unveiled. Table 15-4 gives a snapshot of the findings of recent years in terms of the numbers of identified genetic risk loci of the major complex inflammatory diseases, some of which are co-morbidities of periodontitis, and the numbers of cases and controls employed in these studies. Although the numbers of the identified risk loci for the various diseases are high, it is expected

that they will continue to rise in the coming years. Interestingly, most of the identified genes had not been thought of as likely candidate genes before. These findings confirm the polygenic character of complex diseases, and the pathogenic contribution of single nucleotide polymorphisms (SNPs) in individual genes to be low. We propose this is similarly valid for periodontitis.

Most of the genetic association studies which were designed for the elucidation of the genetic risk factors of periodontitis focused on a range of various candidate genes selected for their roles in the immune system (e.g. genes of the interleukin and Toll-like receptor families), tissue destructive processes (e.g. matrix metalloproteinases), or various metabolism mechanisms (Loos *et al*. 2005; Laine *et al*. 2010, 2012,). For reasons similar to those described for other complex diseases in the pre-GWAS era, despite many efforts in the field of genetic association studies, the genetic risk factors of periodontitis and their pathophysiologic effects had largely remained controversial. Few genes were established as conclusive. Significant doubts about the collective panel of the putative genetic risk factors were raised. In order to clarify the putative role of a comprehensive set of genes that had been the focus of recent genetic research in periodontitis, a large-scale replication study analyzed 23 genes in detail (*ABO, CCR5, FCGR2A, FCGR2C, FCGR3A, FCGR2B, FCGR3B, IL-1B, IL-2, IL-6, IL-10, LTA, MMP-9, NOD2, TLR-2, TLR-4, VDR, CD14, IL-1A, IL-1RN, TNFRSF11B, IFNGR1, L-selectin*) in 600 German patients with aggressive periodontitis and 1440 German population representative controls with an average SNP coverage of <5000 base pairs (bp) (Schäfer *et al*. 2013). Except for *IL-10*, this study showed no strong association between the tested genes and their regulatory regions with aggressive periodontitis, and the authors suggested that the positive associations with periodontitis that had previously been reported for these genes were most likely caused by type I errors. This non-validation of the classical candidate genes of periodontitis further emphasized the need for caution in the interpretation of genetic associations and for extensive validation of reported genetic risk factors.

Some genes can still be considered as true genetic susceptibility factors for periodontitis if evidence for this is replicated in repeated independent, reasonably large case–control populations.

ANRIL, CAMTA1/VAMP3, GLT6D1, COX-2, and *NPY* (Box 15-3)

ANRIL

The best-replicated evidence for conferring risk of periodontitis to date has been for the gene *ANRIL* ["antisense non-coding RNA in the *INK4* locus" (Pasmant *et al*. 2007); Genbank accession no.

Box 15-3 Genomic locations of genetic risk variants.

The recent discussion in genetic research on complex diseases, including periodontitis, suggests that common genetic risk variants are likely not to be found within the coding regions of the classical candidate genes, but rather within regulatory elements of unforeseen genes and chromosomal regions. Figure 15-7 shows that a majority of common human genomic variants that are strongly associated with over 400 common diseases and traits lie within regulatory active regions. This is also true for the location of the genetic risk variants of periodontitis, which is intronic for both *ANRIL* and *GLT6D1*, lying several kilobases up- and down-stream of the protein-coding regions of *COX-2* and *NPY*. Generally, disease- and trait-associated variants are significantly enriched within the sites of physiologically or pathogenetically relevant regulatory regions. Interestingly, they also cluster within known regulatory pathways and expose functional networks that are centered on specific transcriptional regulators. The results of recent GWAS point to the widespread involvement of regulatory DNA variation in common human diseases, and implicate numerous transcriptional regulators in disease susceptibility and pathogenesis.

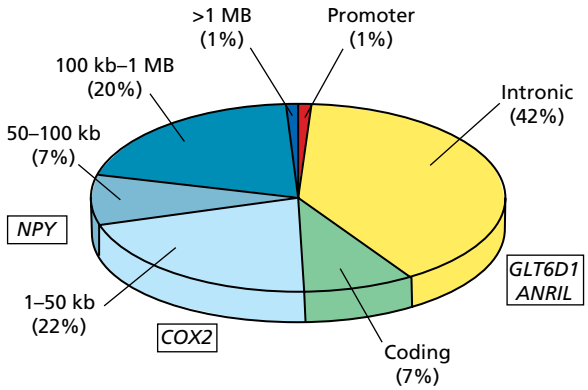

Fig 15-7 Chromosomal location of disease-associated single nucleotide polymorphisms (SNPs) of genome-wide significance from genome-wide association studies (GWAS) of various complex diseases. On average, 64% of disease-associated variants are located within the introns and 1–50 kb up- or down-stream of a gene. The location of the validated periodontitis-associated variants is in accordance with this observation (depicted in orange). (Courtesy of J. Stamatoyannopoulos, adapted from original.)

DQ485453; alias *CDKN2B-AS1* (*CDKN2B* antisense RNA 1) on chromosome 9p21.3], as shown in three independent North-West European populations with aggressive periodontitis (Schäfer *et al*. 2009; Ernst *et al*. 2010) and one Turkish population with aggressive periodontitis (Schäfer *et al*. 2013), as well as in one population with chronic periodontitis (Schäfer *et al*. 2011). Interestingly, *ANRIL* is also considered to be the most important genetic risk factor of myocardial infarction, as identified in various early GWAS on coronary artery disease (CAD) (McPherson *et al*. 2007; Samani *et al*. 2007; WTCCC 2007). This gene encodes a large antisense non-protein coding RNA molecule, a 126.6-kb full length transcript of 19 differentially spliced exons, yielding different RNA molecules of various lengths. Despite extensive research within the last few years, the molecular function of *ANRIL* has remained very poorly understood and the nature of the causative variants has not been clearly identified. It is still unknown how the genetic susceptibility for various diseases associated with this locus is transcribed into specific (patho)physiologic functions. It is agreed that *ANRIL* has a negative regulatory effect on the expression of the adjacent cycline-dependent kinase inhibitor genes *CDKN2A* and *CDKN2B* (Visel *et al*. 2010; Yap *et al*. 2010).

CAMTA1/VAMP3

In accordance with observations that lncRNAs often play a role in the transregulation of gene expression (Pandey *et al.* 2008; Mercer *et al.* 2009), it was shown that decreased expression of *ANRIL* is correlated with decreased expression levels of the distant genes *ADIPOR1* (adiponectin receptor 1; chromosome 1), *VAMP3* (vesicle-associated membrane protein 3; chromosome 1), and *C11ORF10* (chromosome 11 open reading frame 10; chromosome 11) (Bochenek *et al.* 2013). The protein VAMP3 belongs to the VAMP/synaptobrevin family and plays a role in phagocytosis, where VAMP3 mediates, for example, the delivery of tumor necrosis factor-alpha (TNF-α) to the cell surface (Murray *et al.* 2005). Located 2 kb upstream of *VAMP3* is the extremely large gene *CAMTA1* (calmodulin-binding transcription activator 1), spanning >1 Mb. In a GWAS on periodontal pathogen colonization, a large stretch of the *CAMTA1/VAMP3* region was reported to be strongly associated with increased quantities of pathogenic oral bacteria (Divaris *et al.* 2012). A search for potential periodontitis-associated variants within *CAMTA1/VAMP3* identified several SNP located at this pathogen-associated region to be significantly associated with aggressive periodontitis (Bochenek *et al.* 2013). Interestingly, this region was also shown to strongly increase the risk of CAD, a finding that was subsequently validated in a meta-analysis of 13 GWAS of CAD comprising 21 033 individuals with CAD and 44 065 controls of European descent (Bochenek *et al.* 2013). This makes the *CAMTA1/VAMP3* region the second validated shared genetic risk locus of periodontitis and CAD.

Further borderline associations with aggressive periodontitis were found at *C11ORF10* and the adjacent genes *FADS1* and *FADS2* (fatty acid desaturases 1 and 2). These alleles were identical to previously identified associations of genome-wide significance with the metabolic syndrome (Zabaneh & Balding 2010), type 2 diabetes (Dupuis *et al.* 2010), and the inflammatory bowel disease, Crohn's disease (Franke *et al.* 2010), indicating some genetic overlap between periodontitis and these conditions.

GLT6D1

Another risk gene of aggressive periodontitis, *GLT6D1*, also mapped to chromosome 9, at 9q34.3, was identified in the first GWAS on periodontitis (Schäfer *et al*. 2010b). It encodes an unknown protein belonging to a family of proteins that is characterized by a glycosyltransferase domain-1. *GLT6D1* was found to be predominantly expressed in the gingiva and T cells. The molecular function of this gene is still unknown, but sequencing and subsequent molecular biologic characterization of the main associated genetic polymorphisms suggest an impaired GATA3-transcription factor binding site as the causative variant for increased disease risk.

COX-2

The metabolic protein COX-2 converts arachidonic acid into prostaglandin H_2 (PGH_2), the precursor of prostaglandin E_2 (PGE_2). Prostaglandins (PGs) are a group of key inflammatory mediators of the immune response to infection. PGE_2 plays an important role in periodontitis by mediating pro-inflammatory reactions in the periodontal tissues, and is partly responsible for the resorption of the alveolar bone in the course of periodontal pathogenesis. *COX-2* (located on chromosome 1 at 1q24-25) expression is specifically induced by cytokines and specific *COX-2* expression has been reported for gingival tissues in periodontitis. In accordance with the central position of *COX-2* in the regulation of PGH_2 levels and the specificity of activation by cytokines, *COX-2* was subjected to various candidate–SNP association studies for different complex diseases, and polymorphisms within the *COX-2* gene were related to increased susceptibility to various inflammatory diseases. In Taiwanese and Chinese periodontitis case–control populations, the same genetic region was independently shown to be associated with severe periodontitis (Ho *et al*. 2008; Xie *et al*. 2009), and this association was subsequently validated in a European population with aggressive periodontitis (Schäfer *et al*. 2010a).

Therefore, these studies have provided strong evidence for a confined chromosomal region upstream to *COX-2* that possibly carries one or more risk variants of severe periodontitis in populations of different ethnic backgrounds.

NPY

NPY (neuropeptide Y) has immunomodulatory effects that are thought to alter the pro-inflammatory T-helper type 1 (Th1)-to-anti-inflammatory T-helper type 2 (Th2) balance. Binding of NPY to Y1 receptors on a variety of immune cells is thought to be responsible for promoting the anti-inflammatory Th2 response (Bedoui *et al*. 2003). NPY is therefore potentially important in the coordination of inflammation and bone metabolism, both of which are central to the pathogenesis of periodontitis (Lundy *et al*. 2009). Accordingly, the presence of NPY Y1 receptors was verified in human gingival tissue and of NPY in human gingival crevicular fluid (GCF), with significantly higher NPY levels in GCF in healthy compared with periodontitis-affected sites (Lundy *et al*. 2009). A GWAS first described an association with severe chronic periodontitis downstream of the coding region of *NPY* (chromosome 7) in a large sample of European–American individuals (Divaris *et al*. 2013). A second GWAS that systematically analyzed gene–sex interactions in German cases of aggressive periodontitis and controls observed that a sexually dimorphic role of genetic variants upstream of *NPY* was associated with aggressive periodontitis (Freitag-Wolf *et al*. 2014). Interestingly, sex-dependent effects of NPY had previously been described in mice. *NPY* loss-of-function mice showed different anxiogenic responses in behavioral tests in males and females, indicating a sexually dimorphic role of NPY in behavioral stress responses. Also, gastrointestinal inflammation, known to enhance anxiety in a sex-dependent manner, produced different behavioral responses to stress challenges in female and male *NPY* knockout mice (Painsipp *et al*. 2011). NPY activates the hypothalamic–pituitary–adrenal (HPA) axis and modulates the visceral stress responses mediated through corticotrophin-releasing hormone (CRH) pathways (Dimitrov *et al*. 2007). Additionally, NPY is potently anxiolytic (Karl *et al*. 2008), acting through NPY Y1 receptors in the amygdala to inhibit CRH signaling and terminate the behavioral stress and anxiety responses.

The genes *ANRIL*, *GLT6D1*, *COX-2*, and *NPY* are conclusive risk genes of periodontitis, (*ANRIL*, *COX-2*, and *NPY* for both aggressive and chronic periodontitis; *GLT6D1* for aggressive periodontitis only), because of repeated replication of evidence in independent large analysis populations. Obviously, they do not explain the complete heritability of periodontitis, and many more other genes, genetic elements, and variants are yet to be discovered (Boxes 15-4, 15-5).

Box 15-4 Current and future strategies for identifying the full range of genetic variance in periodontitis.

The basic paradigm used in the recently completed phase of genome-wide association studies (GWAS) into the genetics of frequently occurring inflammatory diseases was to catalog the common risk variants. These GWAS successfully represented variants with a frequency well above 5% in the general population. For the detection of less common variants, an extension of GWAS with a much increased coverage of rare variants is appropriate. This line of thought underlined the international consortium-driven "1000 Genomes Project" (www.1000genomes.org), which extended the catalog of known human variants with a frequency near 1%. A new wave of GWAS will catalog less common variants with allele frequencies of 1–5%, and will identify some new associations of rare variants. However, to capture rare variants with allele frequencies of <1%, entire genomes or the whole exome (see Box 15-1) of cases will have to be sequenced to provide sufficient coverage to read all DNA variations, including common and rare variants implicated in monogenic and complex diseases. Eventually, studies of the role of inherited variation in diseases will involve whole-genome sequencing of all enrolled subjects. Such studies will eventually be carried out in a manner similar to GWAS, with very large sample sizes that will provide sufficient statistical evidence to implicate variants on the basis of association evidence alone (Cirulli & Goldstein 2010; Janssens & van Duijn 2010). Several studies have already shown that whole exome sequencing can identify disease-causing variants (Choi *et al*. 2009; Ng *et al*. 2010a, b). However, until complete genomic sequencing is cheap enough to be generally used in large samples, various designs are likely to be the primary engines of discovery and will likely identify many common and rare causative variants:

1. Selecting families that have multiple affected individuals (family-based sequencing) and selecting individuals who are at the extreme ends of a trait distribution (extreme-trait designs)
2. Whole-exome sequencing or whole-exome genotyping arrays, which bundle the almost complete spectrum of known coding variants in the human exome (Cirulli & Goldstein 2010).

Epigenetic signatures

The above-described strategies for identifying genetic risk factors of periodontitis explore changes within the nucleotide sequence in the DNA. However, it is now becoming clear that a full understanding of the interactions of the environment and lifestyle factors with the genome will also require the consideration of epigenetic mechanisms. Epigenetics can be defined as the structural (mitotically or meiotically) heritable or reversible adaptation of chromosomal regions so as to register, signal or perpetuate altered gene activity states (Bird 2007), which refers to changes in gene expression that do not involve a change in the DNA nucleotide sequence, but encompass an array of molecular modifications to both DNA and chromatin (Li 2002; Klose & Bird 2006; Talbert & Henikoff, 2006). These modifications are conferred by methylation of cytosines in CpG dinucleotides, changes to chromatin and packaging of DNA by post-translational histone modifications, mechanisms that control the higher level organizations of chromatin within the nucleus, which have a range of effects on gene expression. In this context, the low concordance rates in MZ twins, who do not always show the same disease susceptibility, also raised the possibility of epigenetic differences arising during early development as well as with aging (Wong *et al*. 2005). Accordingly, it has been reported that young twins have similar amounts of DNA methylation, whereas older twins differ considerably in the amounts and patterns of this modification (Fraga *et al*. 2005). It is a subject of speculation whether the amounts and patterns of epigenetic alterations could give rise to the divergent disease predispositions of some MZ twins. However, unambiguous, reliable epigenetic data for twins and unrelated humans are scarce (Eckhardt *et al*. 2006), and generalizations and interpretations should be handled with prudence. Data from model organisms have suggested long-term and possibly even transgenerational epigenetic effects on gene expression (Morgan *et al*. 1999; Rakyan *et al*. 2003; Anway *et al*. 2005). Increasing evidence for potential mechanisms that modify the epigenome and link environmental and lifestyle influences to disease phenotypes (Jirtle & Skinner 2007) was reported for nutritional supplements (Wolff *et al*. 1998; Waterland & Jirtle 2003), xenobiotic chemicals (Li *et al*. 2003b; Anway *et al*. 2005; Ho *et al*. 2006), and even behaviors (Weaver *et al*. 2004).

Epigenetics has particularly caught the imagination because it is principally stable and inheritable, but is affected by the environment and lifestyle factors. The possibility that an acquired imprint can be kept through long periods of the lifetime or even passed from parents to children has drawn extensive public attention as it is perceived to be an alternative to genetic determinism (Bird 2007). How insights into epigenetics obtained from animal models can be extended to determine the importance of environmental influences on human disease susceptibility will be an exciting challenge in future research (Rakyan *et al*. 2011).

It has been speculated that epigenetic modifications can play a role in periodontitis (Barros & Offenbacher 2009). However, only a very few studies

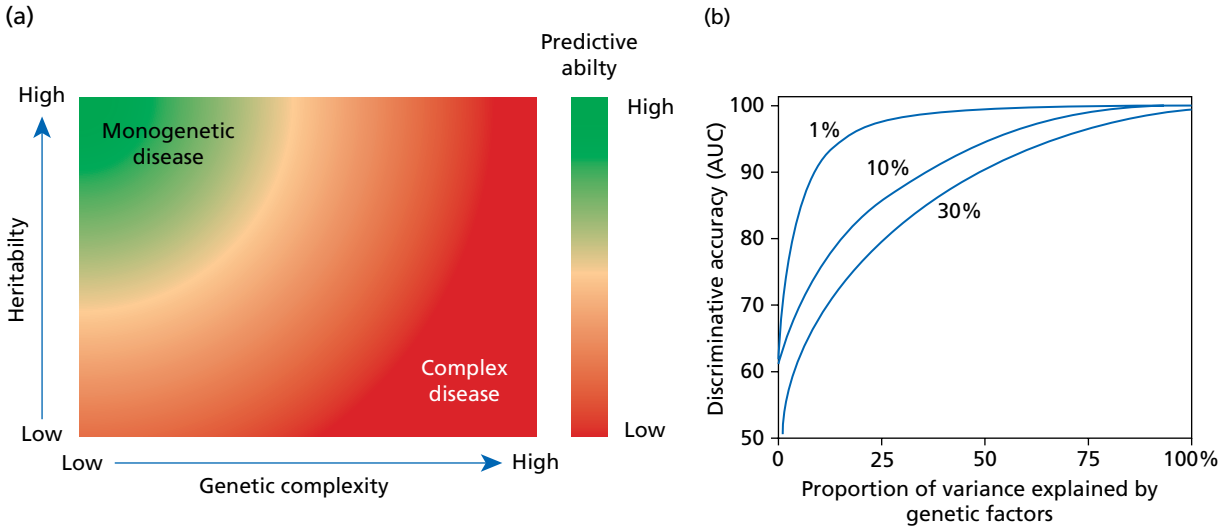

Fig 15-8 (a, b) Relationship between the heritability, genetic complexity, and predictive ability in personal genome testing. The predictive ability is highest if the heritability is high and the genetic complexity is low. The discriminative accuracy, assessed as the area under the operating characteristic curve (AUC), is the extent to which predicted risks can discriminate between individuals who will develop a disease of interest, like periodontitis, and those who will not. The AUC is the probability that the test correctly identifies the person who will develop the disease from a pair of whom one will be affected and one will remain unaffected, and ranges from 50% (complete lack of discrimination) to 100% (perfect discrimination). The percentages on the graph refer to the risk of disease prevalence in the population. Underlying this is the assumption that the total heritability can be explained, but whether or not this is realistic depends on the complexity of the genetic etiology. The discriminative accuracy for chronic periodontitis will always be low; however, for aggressive periodontitis the discriminative accuracy is expected to be higher. Box 15-5 Future perspectives.

Recent genome-wide association studies (GWAS) have provided valuable insight into the genetic basis of complex diseases and identified many genetic susceptibility genes. In 2014, the GWAS catalog of the US National Human Genome Resource Institute (NHGRI; http://www.genome.gov/gwastudies) included 14 769 SNPs with genome-wide associations in >600 traits (Welter *et al*. 2014). However, these variants only explain a small proportion of the heritability of these traits (Frazer *et al*. 2009). This is in part due to statistical limitations, which are inherent to GWAS and generally allow only the detection of common risk variants (see Box 15-2). Where the missing heritability is likely to lie and how research strategies might best be developed to uncover the missing genetic risk factors is currently debated (Eichler *et al*. 2010). When GWAS began some years ago, it was widely believed that complex disease is largely attributable to a moderate number of common variants, each of which explains several percent of the risk in a population (this was called the common disease–common variant hypothesis) (Pritchard & Cox 2002). This model is challenged by the so-called "missing heritability problem", which describes the observation that loci detected by GWAS almost without exception have only limited contribution to the disease (Maher 2008). In this context, Gibson (2011) stated that, "it was simply not the case, that a few dozen loci of moderate effect and intermediate frequency each explained several percent of disease risk in a population, as was typically observed in crosses or pedigrees". Therefore, the genetic variance has largely been attributed to one of two causal models of disease:

1. A large number of small-effect common variants across the entire allele frequency spectrum cause the genetic disease susceptibility. Underlying this hypothesis is the proposition that common genetic variants are among the major sources of genetic variance (see Box 15-1) or disease susceptibility, and hundreds or even thousands of different loci contribute to each case. The loci detected by GWAS are merely the largest effect sizes drawn from a Poisson or similar distribution (Gibson 2011). If ten common variants explain 10% of risk in a population, the remainder is attributable to a myriad of variants that each explain considerably <1% of risk and have a genotype relative risk of <1.1 (Gibson 2011). The disease is expressed as the subsequent combination of genetic, environmental, and lifestyle interactions (Feldman & Lewontin 1975; Eichler *et al*. 2010). Accordingly, this model is referred to as the "infinitesimal model" (Visscher *et al*. 2008).
2. Alternatively, in the "rare allele model", most of the genetic variance is due to highly penetrant variants with allele frequencies of <1%, but that strongly elevate the genetic risk. Many different rare variants have large effects on the phenotypic variation (Cirulli & Goldstein 2010). Each of these variants explains most of the risk in a subset of cases, but does not explain enough of the

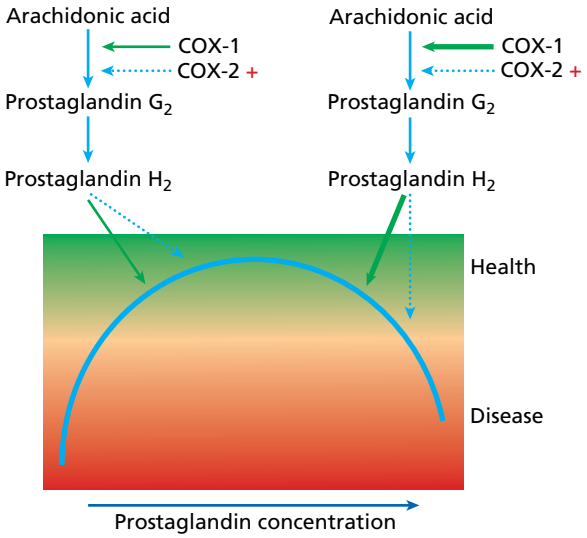

Fig 15-9 It is hypothesized that common variants influence the expression and activity of genes in pathways establishing the background susceptibility to disease that is then further modified by less common variants with larger effects. Prostaglandins are produced by a cascade of biochemical reactions following the sequential oxidation of arachidonic acid by the cyclooxygenases COX-1 and COX-2 and terminal prostaglandin synthases. Whereas COX-1 is responsible for the baseline levels of prostaglandins, COX-2 produces prostaglandins by specific stimulation in scenarios of periodontal inflammation. The half circle represents a range of prostaglandin concentrations in the lesion of a given population. The prostaglandin concentration is influenced by the interplay of the individual genetic constitutions, and the individual physiologic and environmental states. Prostaglandin concentrations at the low and high ends are associated with disease, while an intermediate concentration is physiologic and compatible with health. In this hypothetical illustration, genetic variation somewhere within the prostaglandin synthesis pathway results in some individuals having lower prostaglandin levels (left, normal COX-1 activity, indicated by the green horizontal arrow from COX-1) than others (right, genetic variation in COX-1 that establishes the background susceptibility to disease; indicated by the thick green horizontal arrow from COX-1). The variation in individuals with a background susceptibility is still within the healthy range. The effect of an additional variant that increases COX-2 synthesis (indicated by the "+" sign and blue dashed arrows) upon inflammatory stimulation is conditional on this liability, pushing those with a high concentration of prostaglandin that is genetically determined by the background susceptibility (those on the right) beyond the disease threshold and towards the development of periodontitis (into the red danger zone), whereas those with a low concentration of prostaglandin on the left can accommodate the genetic variation and remain in the green safe zone. (Adapted from Gibson 2011, from Macmillan Publishing.)

Box 15-5 *Continued.*

variance in the total population. Thus, they cannot be detected by standard GWAS. Although the severity of the disease is largely caused by the rare susceptibility genotype, it may be modified by the environment (which can lead to a change in penetrance of the genetic effects of rare as well as of common variants), epistasis or epigenetics (Bodmer & Bonilla 2008). However, a recent large-scale study showed that rare coding-region variants at known risk loci of autoimmune diseases have a negligible role in common autoimmune disease susceptibility (Hunt *et al*. 2013). An alternative study that used yeast as a model to study the missing heritability of complex traits, showed that interactions of known common genetic variants could explain almost the entire additive contribution to heritable variation (Bloom *et al*. 2013). These results are currently not in support of the rare-variant synthetic genome-wide association hypothesis.

In all likelihood, each of these genetic architectures contribute in various degrees to different diseases, but there is as yet insufficient data to resolve the debate, despite the many strong arguments in favor or against each of these two models (Gibson 2011). The debate on the contribution of genetic variation to disease over the coming years will center on how common and rare variants interact (Schork *et al*. 2009). A straightforward hypothesis states that common variation influences the expression and activity of genes in molecular pathways, establishing the background susceptibility to the disease that is then further modified by rare variants with larger effects (Fig. 15-9).

Figure 15-9 illustrates that disease is generally a threshold-dependent response that is superimposed on a continuous physiologic characteristic.

As only a proportion of the genetically predisposed and/or pathogen-exposed individuals develop a disease, simple genetic explanations for individual susceptibility to chronic inflammatory diseases such as periodontitis have not been forthcoming. The challenge for future research will be, apart from identifying as many true susceptibility factors as possible, to discern the relevant patterns within the generated data, in other words to model the effects of SNP–SNP interactions (Renz *et al*. 2011).

on epigenetic effects have been performed to date. Some have investigated epigenetic modifications in candidate genes that play a role in the pathophysiology of periodontitis or had been investigated in other diseases with reported positive results, and several studies suggest that bacteria or bacterial components are responsible for the epigenetic modifications. Similar to the earlier genetic association studies in periodontitis, these studies employed low sample sizes and were not replicated, so the reported epigenetic effects in periodontitis should be interpreted with caution. Modifications in *COX-2* were independently investigated in two studies (Loo *et al*. 2010; Zhang *et al*. 2010), with both showing increased hypermethylation of CpG dinucleotide sites in *COX-2* DNA extracted from periodontal inflamed gingival biopsies when compared with non-inflamed samples, but lacking clear functional evidence for the observations. Large-scale systematic studies of periodontitis-associated epigenetic variation will surely elucidate the role of epigenetic changes in the pathophysiology of periodontitis in the future.

From genetic disease susceptibility to improved oral care

Despite great breakthroughs in human genetics in recent years in a substantial number of inflammatory diseases, few direct improvements in clinical care have resulted to date. This is largely due to the complexity of most heritable diseases, as described earlier. Most of the identified common risk factors have only moderate effects and in most cases, the true causative variants that mediate the effect at the molecular biologic level, as well as the underlying mechanism, still await elucidation. Furthermore, only a relatively limited number of low-risk variants have been discovered so far. In this context it is of interest to look at the present potential of genetic health tests, which are offered in increasing numbers. Over time, these tests have evolved from testing a few variants for the prediction of a single disease, to testing hundreds of thousands of genetic variants genome-wide for multiple diseases simultaneously (Janssens & van Duijn 2010). The prediction ability of these tests is very imprecise and differs considerably between monogenic and complex diseases, which is explained by the different genetic complexities of these diseases (Hunter *et al*. 2008). Monogenic diseases such as cystic fibrosis or Huntington's disease are fully heritable and a mutation in a single specific gene is sufficient to cause these diseases. Testing for the absence or presence of these mutations gives an accurate estimate of future disease development. The effect of heritability and genetic complexity on the predictive ability of genetic tests for disease development is shown in Fig. 15-8a (Box 15-5). When diseases have a high heritability and a low genetic complexity, such as monogenetic disorders, genetic tests will be very accurate. In contrast, the predictive ability of tests for complex diseases is determined by the combined effect of all genetic, environmental, and lifestyle factors tested (Janssens & van Duijn 2010). Only when

diseases have a high heritability is the maximum discriminative accuracy reliable, assuming all variants are identified. Figure 15-8b (Wray *et al*. 2010) shows that a good predictive ability of a genetic test will theoretically be possible for a disease with a very high heritability and a low genetic complexity. Such diseases are commonly severe and have an early age of onset and a low frequency (<1%) in the population. Thus, accurate genetic testing may become possible for the juvenile and post-adolescent (early-onset) forms of aggressive periodontitis, which are the most severe phenotypes and have a particularly early age of onset, particularly if the genetic susceptibility factors are fully be identified. In contrast, late-onset diseases such as chronic periodontitis, with moderate and variable phenotypes and a high risk in the population, have many underlying low-risk variants, which may interact with each other and with other non-genetic risk factors in many different ways. Increased and decreased risks due to such very complex multidimensional interactions are still beyond our statistical and computational scope in predictive testing models (Janssens & van Duijn 2010). Nevertheless, the vision remains that, on the basis of comprehensive data that encompass the complete DNA sequence, biochemical data, and information on environmental and behavioral factors over a large time period in the life of a patient, this information can be turned into computational models that represent the patient and his/her health status and will enable the physician to devise a personalized therapy for the consenting patient. In order to make this information accessible, international pilot projects have begun, to assess the feasibility in scientific, technical, and financial terms, and to establish structures for integrating personal analytical and clinical data into an individualized model of the patient.

Part 5: Trauma from Occlusion

Chapter 16

Trauma from Occlusion: Periodontal Tissues

Jan Lindhe[1] and Ingvar Ericsson[2]

[1] Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden
[2] Department of Prosthodontic Dentistry, Faculty of Odontology, Malmo University, Malmo, Sweden

Definition and terminology

Trauma from occlusion is a term used to describe pathologic alterations or adaptive changes which develop in the periodontium as a result of undue force produced by the masticatory muscles. It is only one of many terms that have been used to describe such alterations in the periodontium. Other terms often used are: *traumatizing occlusion*, *occlusal trauma*, *traumatogenic occlusion*, *periodontal traumatism*, and *overload*. In addition to damaging the periodontal tissues, excessive occlusal force may also injure, for example, the temporomandibular joint, the masticatory muscles, and the pulp tissue. This chapter deals exclusively with the effects of trauma from occlusion on the periodontal tissues.

Trauma from occlusion was defined by Stillman (1917) as "a condition where injury results to the supporting structures of the teeth by the act of bringing the jaws into a closed position". The World Health Organization (WHO) in 1978 defined trauma from occlusion as "damage in the periodontium caused by stress on the teeth produced directly or indirectly by teeth of the opposing jaw". Occlusal trauma is an injury to the attachment apparatus that results from excessive occlusal force(s).

Traumatizing forces may act on an individual tooth or on groups of teeth in premature contact relationship; they may occur in conjunction with parafunctions such as clenching and bruxism, or in conjunction with loss or migration of premolar and molar teeth with an accompanying, gradual spread of the anterior teeth of the maxilla, etc.

In the literature, the tissue injury associated with trauma from occlusion is often divided into *primary* and *secondary*. The *primary* form includes tissue reactions (damage) elicited around a tooth with normal periodontium height, while the *secondary* form is related to situations in which occlusal forces cause injury to a periodontium of reduced height. The distinction between a primary and a secondary form of injury – primary and secondary occlusal trauma – serves no meaningful purpose, since the alterations which occur in the periodontium as a consequence of trauma from occlusion are similar and independent of the height of the target tissue, that is the periodontium. It is, however, important to understand that symptoms of trauma from occlusion may develop only in situations when the magnitude of the load elicited by occlusion is so high that the periodontium around the exposed tooth cannot properly withstand and distribute the resulting force without altering the position and stability of the tooth involved. This means that in cases of severely reduced height of the periodontium, even comparatively small forces may produce traumatic lesions or cause adaptive changes in the periodontium.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Trauma from occlusion and plaque-associated periodontal disease

Ever since Karolyi (1901) postulated that an interaction may exist between "*trauma from occlusion*" and "*alveolar pyrrohea*", different opinions have been expressed regarding the validity of this claim. In the 1930s, Box (1935) and Stones (1938) reported experiments in sheep and monkeys, the results of which seemed to indicate that "trauma from occlusion is an etiologic factor in the production of that variety of periodontal disease in which there is vertical pocket formation associated with one or a varying number of teeth" (Stones 1938). The experiments by Box and Stones, however, have been criticized because they lacked proper controls and because their design did not justify the conclusions drawn.

The interaction between trauma from occlusion and plaque-associated periodontal disease in humans was frequently discussed in the period 1955–1970 in connection with "case reports", "in my opinion" statements, etc. Even if such anecdotal data may have some value in clinical dentistry, it is obvious that conclusions drawn from research findings are much more pertinent. The research-based conclusions are not always indisputable but they invite the reader to critique them, which anecdotal data do not. In this chapter, therefore, the presentation will be limited to findings from research endeavors involving (1) human autopsy material, (2) clinical trials, and (3) animal experiments.

Analysis of human autopsy material

Research data derived from studies of human autopsy material are not always easy to interpret. Histologic sections of the site involved may have been examined regarding (1) the dimension the lesions in the periodontium, as well as (2) the presence and apical extension of microbial deposits at adjacent root surfaces. In addition, comments may have been made regarding (3) the anticipated mobility of the teeth examined, and (4) "the occlusion" of the sites under scrutiny. It is obvious that assessments made of specimens from cadavers have a limited to questionable value when "cause–effect" relationships between occlusion, plaque, and periodontal lesions are to be described. It is not surprising, therefore, that *conclusions* drawn from this type of research are controversial. This can best be illustrated by comparing "Glickman's concept" with "Waerhaug's concept" of what autopsy studies may document regarding the role of trauma from occlusion in the pathogenesis of periodontal disease.

Glickman's concept

Glickman (1965, 1967) claimed that the pathway of the spread of a plaque-associated gingival lesion can be changed if forces of an abnormal magnitude are acting on the contaminated tooth. This implies that the character of the progressive tissue destruction of the periodontium at a "traumatized tooth" may be different from that characterizing a "non-traumatized" tooth. Instead of an even destruction of the periodontium and the alveolar bone (suprabony pockets and horizontal bone loss), which, according to Glickman, occurs at sites with uncomplicated plaque-associated lesions, sites which are also exposed to abnormal occlusal force will develop angular bony defects and infrabony pockets.

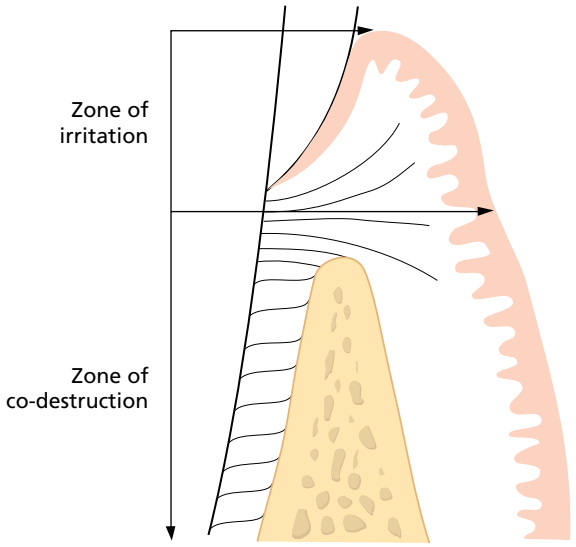

Fig. 16-1 Schematic drawing of the zone of irritation and the zone of co-destruction according to Glickman.

Since Glickman's concept regarding the effect of trauma from occlusion on the spread of the plaque-associated lesion is often cited, a more detailed presentation of his theory seems pertinent. The periodontal structures can be divided into two zones (Fig. 16-1):

1. Zone of irritation
2. Zone of co-destruction.

The *zone of irritation* includes the marginal and interdental gingiva. The soft tissue of this zone is bordered by hard tissue (the tooth) only on one side and cannot therefore be affected by forces of occlusion. Thus, the gingival lesion is the tissue response to products from microbial plaque. This gingival lesion at a "non-traumatized" tooth propagates, according to Glickman, in the apical direction by first involving the alveolar bone and only later the periodontal ligament area. The progression of this lesion results in an even (horizontal) bone destruction.

The *zone of co-destruction* includes the root cementum (mineralized tissue), the periodontal ligament, and the alveolar bone (mineralized tissue), and is coronally demarcated by the trans-septal (interdental) and the dentoalveolar collagen fiber bundles (Fig. 16-1). The tissues in this zone may become the seat of a lesion caused by trauma from occlusion.

It was claimed that the fiber bundles which separate the zone of co-destruction from the zone of irritation can be affected from two different directions:

1. From the inflammatory gingival lesion maintained in the *zone of irritation*
2. From trauma-induced changes in the *zone of co-destruction*.

Through this exposure from two different directions, the fiber bundles may become dissolved and/or orientated in a direction parallel to the root surface. The gingival lesion in the *zone of irritation* will spread directly into the "trauma-exposed" periodontal ligament (i.e. not via the bone) (Fig. 16-2). This alteration of the "normal" pathway of spread of the plaque-associated inflammatory lesion results in the development of angular bony defects. Glickman (1967) stated in a review paper that *trauma from occlusion* is an etiologic factor (co-destructive factor) of importance in situations where angular bony defects combined with infrabony pockets are found at one or several teeth (Fig. 16-3).

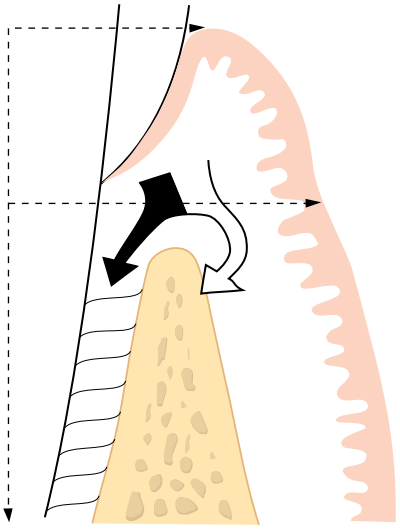

Fig. 16-2 Inflammatory lesion in the zone of irritation can, in teeth not subjected to trauma, propagate into the alveolar bone (open arrow), while in teeth also subjected to trauma from occlusion, the inflammatory infiltrate spreads directly into the periodontal ligament (filled arrow).

Waerhaug's concept

Waerhaug (1979) examined autopsy specimens (Fig. 16-4) similarly to Glickman, but in addition measured the distance between the microbial plaque and (1) the periphery of the associated inflammatory cell infiltrate and (2) the surface of the adjacent alveolar bone. He concluded from his measurements that angular bony defects and infrabony pockets occur equally, often at teeth which are not affected by trauma from occlusion. In other words, he refuted the hypothesis that trauma from occlusion plays a role in the spread of a gingival lesion into the zone of co-destruction.

The loss of connective attachment and bone around teeth is, according to Waerhaug, exclusively the result of inflammatory lesions associated with subgingival plaque. Waerhaug concluded that angular bony defects and infrabony pockets occur when the subgingival plaque of one tooth has reached a more apical level than the plaque on the neighboring tooth, and when the volume of the alveolar bone surrounding the roots is comparatively large. Waerhaug's observations support findings presented by Prichard (1965) and Manson (1976), which imply that the pattern of loss of supporting structures is the result of an interplay between the form and volume of the alveolar bone and the apical extension of the microbial plaque on the adjacent root surfaces.

Conclusion: It is obvious that examinations of autopsy material have a limited value when determining "cause–effect" relationships with respect to trauma

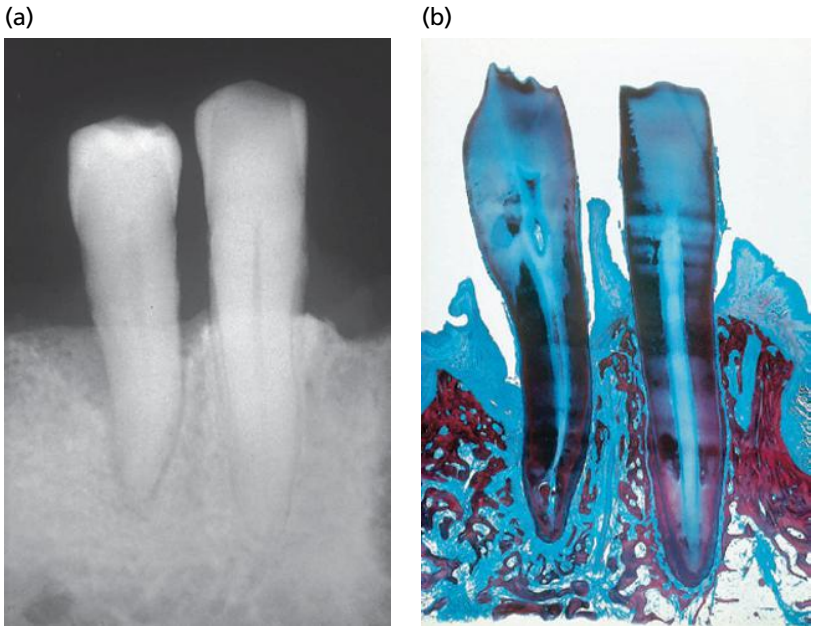

Fig. 16-3 (a) Radiograph of a mandibular premolar–canine region. Note the angular bony defect at the distal aspect of the premolar. (b) Histologic mesiodistal section of the specimen shown in (a). Note the infrabony pocket at the distal aspect of the premolar. (Source: Glickman & Smulow 1965. Reproduced from the American Academy of Periodontology.)

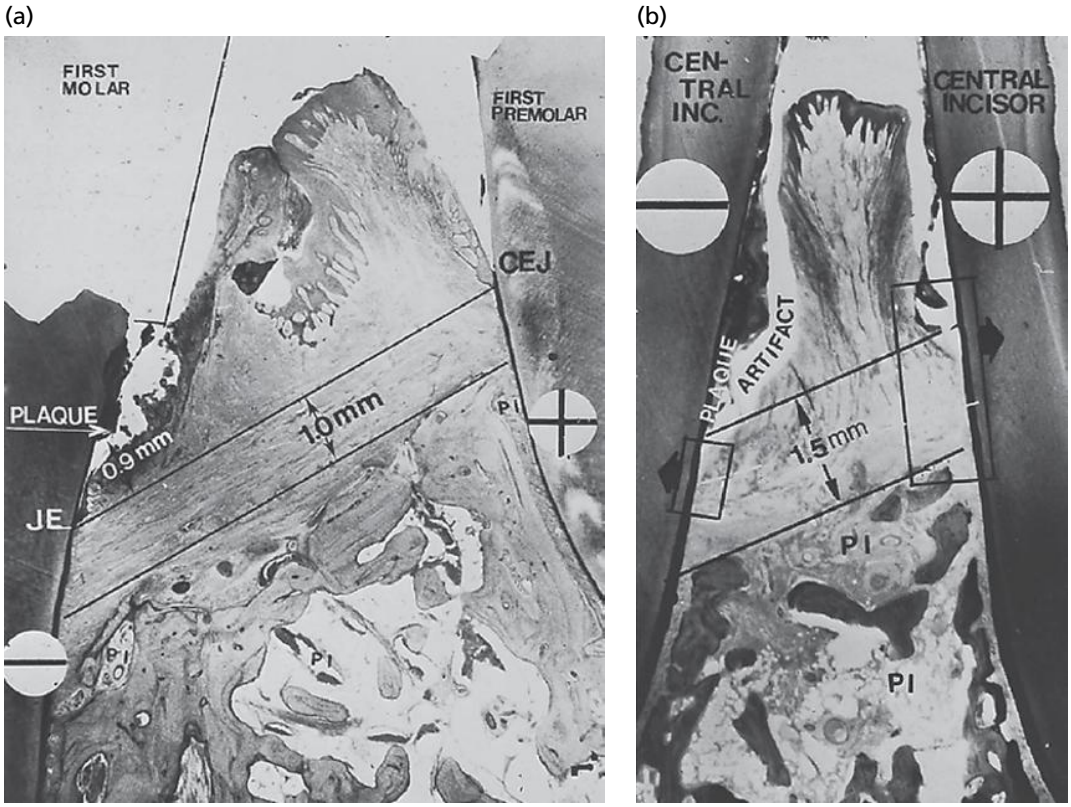

Fig. 16-4 (a, b) Microphotographs illustrating two interproximal areas with angular bony defects. "–" denotes a tooth not subjected and "+" denotes a tooth subjected to trauma from occlusion. In categories "–" and "+", the distance between the apical cells of the junctional epithelium (JE) and the supporting alveolar bone is about 1–1.5 mm, and the distance between the apical extension of plaque and the apical cells of the JE is about 1 mm. Since the apical cells of the JE and the subgingival plaque are located at different levels on the two adjacent teeth, the outline of the bone crest becomes oblique. A radiograph from such a site would disclose the presence of an angular bony defect at a non-traumatized ("–") tooth.

and progressive periodontitis. As a consequence, the conclusions drawn from this field of research have not been generally accepted. Some clinicians have tended to accept Glickman's conclusions that trauma from occlusion is an aggravating factor in periodontal disease (e.g. Macapanpan & Weinmann 1954; Posselt & Emslie 1959; Glickman & Smulow 1962, 1965), while others accept Waerhaug's concept that there is no relationship between occlusal trauma and the degree of periodontal tissue breakdown (e.g. Lovdahl *et al*. 1959; Belting & Gupta 1961; Baer *et al*. 1963; Waerhaug 1979).

Clinical trials

In addition to the presence of angular bony defects and infrabony pockets, *increased tooth mobility* is frequently listed as an important sign of occlusal trauma. For details regarding tooth mobility, see Chapter 52. Conflicting data have been reported regarding the periodontal condition of mobile teeth. In one clinical study by Rosling *et al*. (1976), patients with advanced periodontal disease associated with multiple angular bony defects and mobile teeth were exposed to antimicrobial therapy (i.e. subgingival scaling after flap elevation). Healing was evaluated by probing attachment level measurements and radiographic monitoring. The authors reported that "the infrabony pocket located at hypermobile teeth exhibited the same degree of healing as those adjacent to firm teeth". In another study, however, Fleszar *et al*. (1980) reported on the influence of tooth mobility on healing following periodontal therapy, including both antimicrobial therapy and occlusal adjustment. They concluded that "pockets of clinically mobile teeth do not respond as well to periodontal treatment" (including tooth debridement) "as do those of firm teeth exhibiting the same disease severity".

Pihlstrom *et al*. (1986) studied the association between trauma from occlusion and periodontitis by assessing a series of clinical and radiographic features at maxillary first molars: probing depth, probing attachment level, tooth mobility, wear facets, plaque and calculus, bone height, and widened periodontal space. The authors concluded from their examinations that teeth with increased mobility and widened periodontal ligament space had deeper pockets, more attachment loss, and less bone support than teeth without these symptoms.

In another clinical trial, Burgett *et al*. (1992) studied the effect of occlusal adjustment in the treatment of periodontitis. Fifty patients with periodontitis were examined at baseline and subsequently treated for their periodontal condition with root debridement ± flap surgery. Twenty-two of the 50 patients additionally received comprehensive occlusal adjustment. Re-examinations

performed 2 years later disclosed that probing attachment gain was on average about 0.5 mm greater in patients who received the combined treatment, that is debridement and occlusal adjustment, than in patients who did not receive occlusal adjustment.

Nunn and Harrel (2001) and Harrel and Nunn (2001) examined the relationship between occlusal discrepancies and periodontitis in two studies. Their sample included about 90 patients who had been referred for treatment of periodontal disease and who had at least two (≥1 year apart) complete periodontal records, including an analysis of their occlusion. The patients were examined with respect to probing pocket depth, tooth mobility, and furcation involvement (at multirooted teeth). In addition, occlusal contact relationships were studied, such as (1) discrepancies in centric relation and centric occlusion and (2) premature occlusal contacts in protrusive movements (lateral and frontal) of the mandible in working and non-working quadrants. A treatment plan, including both periodontal and occlusal measures, was subsequently designed for each patient. About one-third of the patients decided to abstain from treatment, about 20 accepted only a non-surgical approach to periodontal therapy (SRP), and about 50% accepted and received comprehensive treatment that included surgical pocket elimination (tooth debridement; SRP + surgery) as well as occlusal adjustment (if indicated). Some teeth in the SRP group received occlusal therapy, while other teeth with occlusal discrepancies were left untreated. It was observed that teeth with occlusal discrepancies had significantly deeper pocket depth values and higher mobility scores than teeth without occlusal "trauma", and also that teeth exposed to occlusal adjustment responded better (reduction in pocket depth) to SRP than teeth with remaining occlusal discrepancies.

The findings in some of the clinical studies referred to above lend some support to the concept that trauma from occlusion (and increased tooth mobility) may have a detrimental effect on the periodontium. Neiderud *et al*. (1992), however, in a Beagle dog study demonstrated that tissue alterations which occur at mobile teeth with clinically healthy gingivae (and normal height of the tissue attachment) may reduce the resistance offered by the periodontal tissues to probing. In other words, if the probing depth at two otherwise similar teeth – one non-mobile and one hypermobile – is recorded, the tip of the probe will penetrate 0.5 mm deeper at the mobile than at the non-mobile tooth. This finding must be taken into consideration when the above clinical data are interpreted.

Since neither analysis of autopsy material nor data from clinical trials can be used to properly determine the role trauma from occlusion may play in periodontal pathology, it was considered necessary to describe also the contributions from animal research in this particular field.

Animal experiments

Orthodontic-type trauma

In early experiments, the reaction of the periodontium was studied following the application of forces applied to teeth in one direction only. Biopsy specimens, including tooth and periodontium, were harvested after varying intervals and prepared for histologic examinations. Analysis of the sections (Häupl & Psansky 1938; Reitan 1951; Mühlemann & Herzog 1961; Ewen & Stahl 1962; Waerhaug & Hansen 1966; Karring *et al*. 1982) revealed that when a tooth is exposed to unilateral forces of a magnitude, frequency or duration that its periodontal tissues are unable to withstand and distribute while maintaining the stability of the tooth, certain well-defined reactions develop in the periodontal ligament, eventually resulting in an adaptation of the periodontal structures to the altered functional demand. If the crown of a tooth is affected by such horizontally directed forces, the tooth tends to tilt (tip) in the direction of the force (Fig. 16-5). The forces result in the development of *pressure* and *tension zones* within the marginal and apical parts of the periodontium. The tissue reactions which develop in the *pressure zone* are characteristic of a mild inflammation (increased number of vessels, increased vascular permeability, vascular thrombosis, and disorganization of cells and collagen fiber bundles). If the magnitude of forces is within certain limits, the vitality of the periodontal ligament cells is maintained and bone-resorbing osteoclasts soon appear on

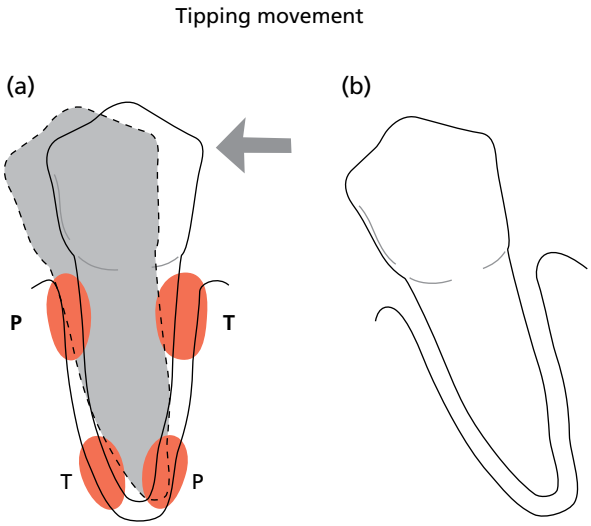

Fig. 16-5 (a) If the crown of a tooth is exposed to excessive, horizontally directed forces (arrow), pressure (P) and tension (T) zones will develop within the marginal and apical parts of the periodontium. The supra-alveolar connective tissue remains unaffected by force application. Within the pressure and tension zones, tissue alterations take place and eventually allow the tooth to tilt in the direction of the force. (b) When the tooth is no longer subjected to the trauma, complete regeneration of the periodontal tissues takes place. There is no apical down-growth of the dentogingival epithelium.

the bone surface of the alveolus in the *pressure zone*. A process of *direct bone resorption* is initiated.

If the force applied is of higher magnitude, the periodontal ligament tissue in the *pressure zone* may become necrotic and undergo *hyalinization*. "Direct bone resorption" therefore cannot occur. Instead, osteoclasts appear in marrow spaces within the adjacent bone tissue where the stress concentration is lower and a process of undermining or "*indirect bone resorption*" is initiated. Through this reaction the surrounding bone is resorbed until there is a breakthrough to the hyalinized tissue within the *pressure zone*. This breakthrough results in a reduction of the stress in this area, and cells from the neighboring bone or adjacent areas of the periodontal ligament can proliferate into the *pressure zone* and replace the previously hyalinized tissue, thereby re-establishing the prerequisites for "direct bone resorption". Irrespective of whether the bone resorption is of a direct or an indirect nature, the tooth moves (tilts) further in the direction of the force.

Concomitant with the tissue alterations in the *pressure zone*, apposition of bone occurs in the *tension zone* in order to maintain the normal width of the periodontal ligament in this area. Because of the tissue reactions in the *pressure* and *tension* zones, the tooth becomes hypermobile. When the tooth has moved (tilted) to a position where the effect of the forces is nullified, healing of the periodontal tissues takes place in both the *pressure* and the *tension zones*, and the tooth becomes stable in its new position. In orthodontic tilting (tipping) movements, neither gingival inflammation nor loss of connective tissue attachment will occur at teeth with a healthy periodontium.

These tissue reactions do not differ fundamentally from those which occur as a consequence of *bodily tooth movement* in orthodontic therapy (Reitan 1951). The main difference is that the *pressure* and *tension zones*, depending on the direction of the force, are more extended in an apicocoronal direction along the root surface than in conjunction with the tipping movement (Fig. 16-6). The supra-alveolar connective tissue is not affected by the force, either in conjunction with tipping or in conjunction with bodily movements of the tooth. Unilateral forces exerted on the crowns of teeth, therefore, will not induce inflammatory reactions in the gingiva or cause loss of connective tissue attachment.

Studies have demonstrated, however, that orthodontic forces producing bodily (or tipping) movement of teeth may result in gingival recession and loss of connective tissue attachment (Steiner *et al*. 1981; Wennström *et al*. 1987). This breakdown of the attachment apparatus occurred at sites with gingivitis when, in addition, the tooth was moved through the envelope of the alveolar process. At such sites bone dehiscence became established and, if the covering soft tissue was thin (in the direction of the movement of the tooth), recession (attachment loss) occurred.

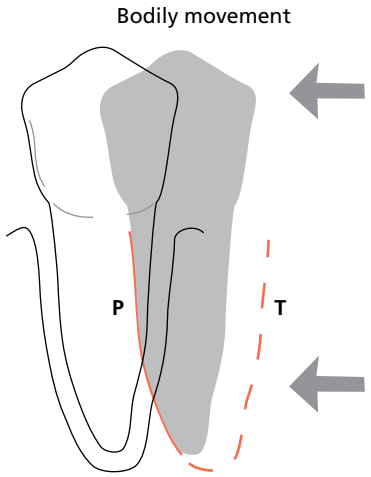

Fig. 16-6 When a tooth is exposed to forces which produce "bodily tooth movement", for example in orthodontic therapy, the pressure (P) and tension (T) zones, depending on the direction of the force, are extended over the entire tooth surface. The supra-alveolar connective tissue is not affected in conjunction either with tipping or with bodily movements of teeth. Forces of this kind, therefore, will not induce inflammatory reactions in the gingiva. No apical down-growth of the dentogingival epithelium occurs.

Criticism has been directed at experiments in which only unilateral trauma is exerted on teeth (Wentz *et al*. 1958). It has been suggested that in humans, unlike in the animal experiments described above, the occlusal forces act alternately in one and then in the opposite direction. Such forces have been termed *jiggling forces*.

Jiggling-type trauma

Healthy periodontium with normal height

Experiments have been reported in which traumatic forces were exerted on the crowns of the teeth, alternately in the buccal/lingual or mesial/distal directions, and the teeth were not allowed to move away from the force (e.g. Wentz *et al*. 1958; Glickman & Smulow 1968; Svanberg & Lindhe 1973; Meitner 1975; Ericsson & Lindhe 1982). In conjunction with "*jiggling-type trauma*" no clear-cut *pressure* and *tension zones* can be identified, but rather there is a combination of pressure and tension on both sides of the jiggled tooth (Fig. 16-7).

The tissue reactions in the periodontal ligament provoked by the combined *jiggling* forces were found to be rather similar to those reported to occur in the pressure zone at orthodontically moved teeth, but with one important difference. The periodontal ligament space at jiggled teeth gradually increased in width on both sides of the tooth. During the phase when the periodontal ligament gradually increased in width, (1) inflammatory changes were present in the ligament tissue, (2) active bone resorption

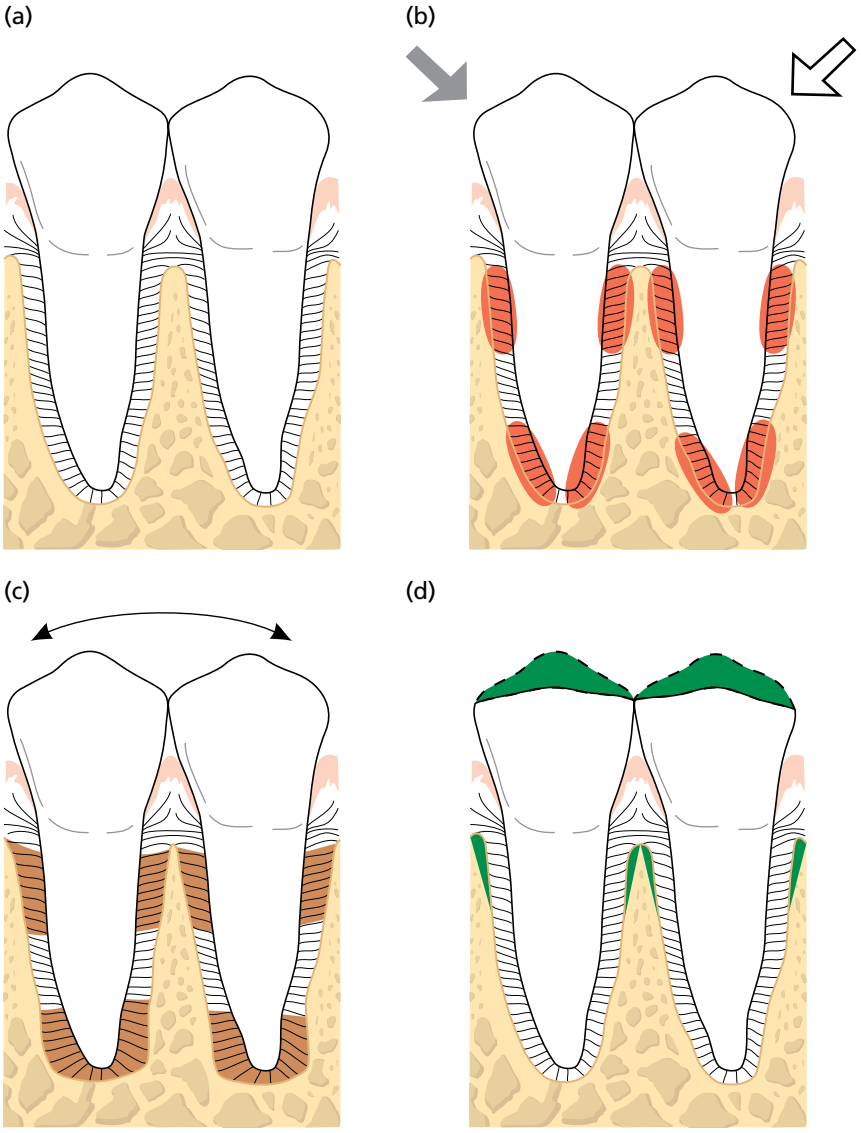

Fig. 16-7 Two mandibular premolars with normal periodontal tissues (a) are exposed to jiggling forces (b), as illustrated by the two arrows. The combined tension and pressure zones (encircled areas) are characterized by signs of acute inflammation, including collagen resorption, bone resorption, and cementum resorption. As a result of bone resorption, the periodontal ligament space gradually increases in size on both sides of the teeth as well as in the periapical region. (c) When the effect of the force applied has been compensated for by the increased width of the periodontal ligament space, the ligament tissue shows no signs of inflammation. The supra-alveolar connective tissue is not affected by the jiggling forces and there is no apical down-growth of the dentogingival epithelium. (d) After occlusal adjustment the width of the periodontal ligament becomes normalized and the teeth are stabilized.

occurred, and (3) the tooth displayed signs of gradually increasing (*progressive*) mobility. When the effect of the forces applied had been compensated for by the increased width of the periodontal ligament space, the ligament tissue showed no signs of increased vascularity or exudation. The tooth was hypermobile but the mobility was no longer *progressive* in character. Distinction should thus be made between *progressive* and *increased* tooth mobility.

In *jiggling-type trauma* experiments performed in animals with a normal periodontium, the supra-alveolar connective tissue was not influenced by the occlusal forces. This means that a gingiva which was healthy at the start of the experiment remained healthy. It was also observed that an overt gingival lesion was not aggravated by the jiggling forces.

Healthy periodontium with reduced height

Progressive periodontal disease is characterized by gingival inflammation and a gradually developing loss of connective tissue attachment and alveolar bone. Treatment of periodontal disease, that is removal of plaque and calculus and elimination of pathologically deepened pockets, will result in the re-establishment of a healthy periodontium but with reduced height. The question is whether a healthy periodontium with reduced height has a capacity similar to that of the normal periodontium to adapt

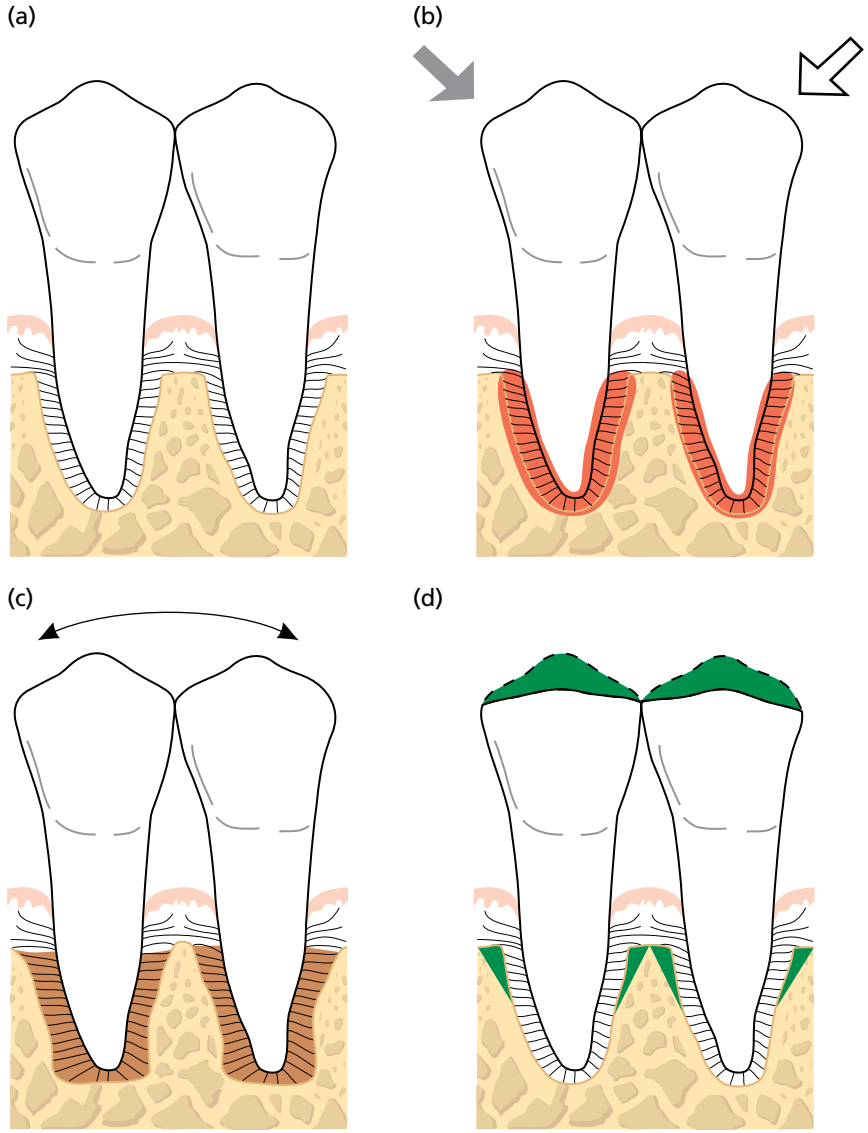

Fig. 16-8 (a) Two mandibular premolars are surrounded by a healthy periodontium with reduced height. (b) If such premolars are subjected to traumatizing forces of the jiggling type, a series of alterations occurs in the periodontal ligament tissue. (c) These alterations result in a widened periodontal ligament space and increased tooth mobility, but do not lead to further loss of connective tissue attachment. (d) After occlusal adjustment, the width of the periodontal ligament is normalized and the teeth are stabilized.

to traumatizing occlusal forces (secondary occlusal trauma).

This problem has also been examined in animal experiments (Ericsson & Lindhe 1977). Destructive periodontal disease was initiated in premolars of dogs by allowing the animals to accumulate plaque and calculus. When around 50% of the periodontal tissue support had been lost, the involved teeth were exposed to debridement and surgical pocket elimination. Following healing, these teeth had a reduced but healthy periodontium (Fig. 16-8a). During the subsequent months of continued plaque control, certain premolars were exposed to traumatizing jiggling forces (Fig. 16-8b). The periodontal tissues in the combined *pressure* and *tension zones* reacted to the application of forces with inflammation as well as by bone resorption. In the initial phase, the traumatized teeth displayed signs of *progressive* tooth mobility and a progressive increase of the size of the periodontal ligament. After several weeks of jiggling, there was no further increase in the mobility (Fig. 16-8c). The active bone resorption had ceased and the markedly widened periodontal ligament tissue had regained its normal composition. The teeth were hypermobile at this stage, but surrounded by a periodontal ligament which had adapted to the altered functional demands.

During the entire experimental period the supraalveolar connective tissue remained unaffected by the jiggling forces. There was no further loss of connective tissue attachment and no further downgrowth of dentogingival epithelium. The results from this study clearly revealed that, within certain limits, a healthy periodontium with reduced height has a capacity similar to that of a periodontium with

normal height to adapt to altered functional demands. Removal of the jiggling forces ("occlusal adjustment") will in this situation result in a normalization of the width of the periodontal ligament (Fig. 16-8d).

Plaque-associated periodontal disease

Experiments carried out on humans and animals have demonstrated that *trauma from occlusion* cannot induce pathologic alterations in the supra-alveolar connective tissue, in other words cannot produce inflammatory lesions in a normal gingiva or aggravate a gingival lesion and cannot induce loss of connective tissue attachment. The question remains whether or not abnormal occlusal forces can influence the spread of the plaque-associated lesion and enhance the rate of tissue destruction in periodontal disease. This has been studied in animal experiments (Lindhe & Svanberg 1974; Meitner 1975; Nyman *et al*. 1978; Ericsson & Lindhe 1982; Polson & Zander 1983) in which progressive and destructive periodontal disease was first initiated in dogs or monkeys by allowing the animals to accumulate plaque and calculus. Some of the premolars that were involved in a progressive periodontal disease process (periodontally involved) were also subjected to trauma from occlusion.

"Traumatizing" jiggling forces (Lindhe & Svanberg 1974) were exerted on periodontally involved premolars and were found to induce certain tissue reactions in the combined *pressure/tension zones*. Within a few days of the onset of the jiggling forces, the periodontal ligament tissue in these zones displayed signs of inflammation. On the adjacent bone surfaces a large number of osteoclasts were present. Since the teeth could not orthodontically move away from the jiggling forces, the periodontal ligament on both sides of the tooth gradually increased in width, the teeth became hypermobile (*progressive* tooth mobility), and angular bony defects could be detected on the radiographs. The effect of the forces were eventually nullified by the increased width of the periodontal ligament.

If the forces applied were of a magnitude to which the periodontal structures could adapt, the *progressive* increase of the tooth mobility terminated within a few weeks. The active bone resorption ceased, but the angular bone destruction persisted as well as the increased tooth mobility. The periodontal ligament had an increased width, but a normal tissue composition. Biopsy specimens including the periodontally involved teeth revealed that this process of adaptation had occurred with no further attachment loss (Fig. 16-9) (Meitner 1975). This means that occlusal forces which allow adaptive alterations to occur in

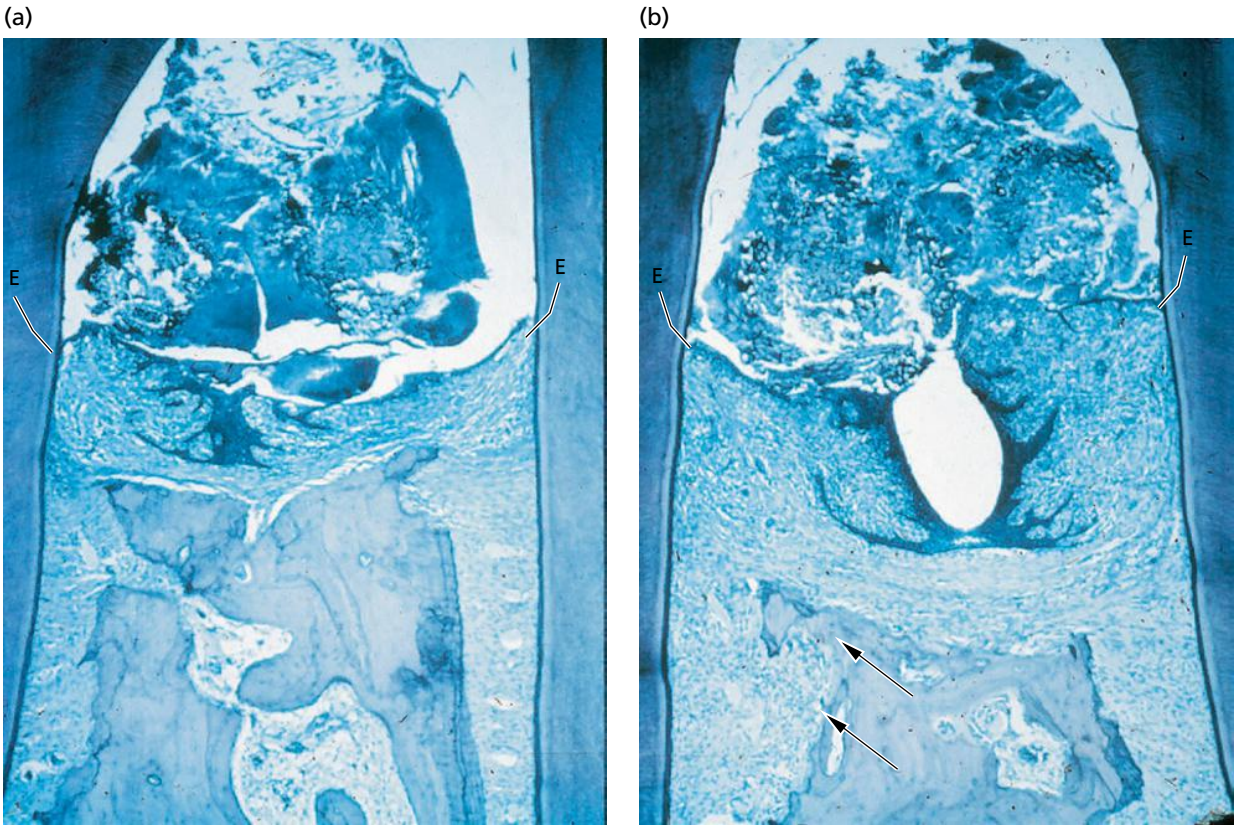

Fig. 16-9 (a) A composite photomicrograph illustrating the interdental space between two pairs of teeth. The teeth have been subjected to experimental, ligature-induced periodontitis and in (b) also to repetitive mechanical injury. In (b), there is considerable loss of alveolar bone and an angular widening of the periodontal ligament space (arrows). However, the apical down-growth of the dentogingival epithelium in the two areas in (a) and (b) is similar. E indicates the apical level of the dentogingival epithelium. (Courtesy of S.W. Meitner.)

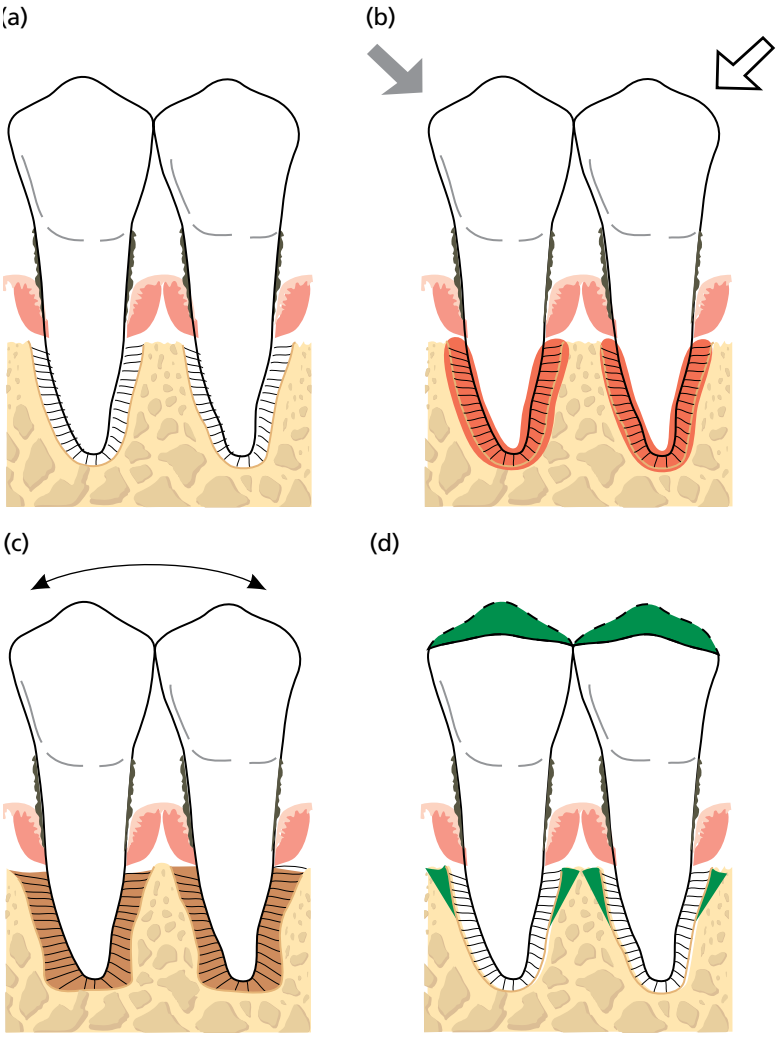

Fig. 16-10 (a) Two mandibular premolars with supra- and sub-gingival plaque, advanced bone loss, and periodontal pockets of a suprabony character. Note the connective tissue infiltrate (shadowed areas) and the uninflamed connective tissue between the alveolar bone and the apical portion of the infiltrate. (b) If these teeth are subjected to traumatizing forces of the jiggling type, pathologic and adaptive alterations occur within the periodontal ligament space. (c) These tissue alterations, which include bone resorption, result in a widened periodontal ligament space and increased tooth mobility, but no further loss of connective tissue attachment. (d) Occlusal adjustment results in a reduction of the width of the periodontal ligament and in less mobile teeth.

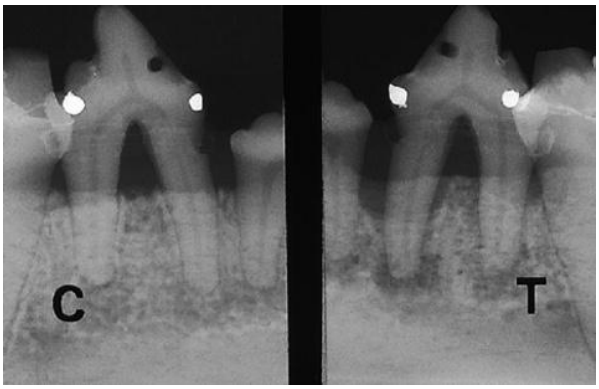

Fig. 16-11 Radiographic appearance of one test tooth (T) and one control tooth (C) at the termination of an experiment in which periodontitis was induced by ligature placement and plaque accumulation, and in which trauma of the jiggling type was induced. Note the angular bone loss particularly around the mesial root of the mandibular premolar (T) and the absence of such a defect at the mandibular premolar (C). (Source: Lindhe & Svanberg 1974. Reproduced with permission from John Wiley & Sons.)

the *pressure/tension* zones of the periodontal ligament will not aggravate a plaque-associated periodontal disease (Fig. 16-10).

If, however, the magnitude and direction of the jiggling forces were such that, during the course of the study, the tissues in the pressure/tension zones could not adapt, the injury in the *zones of co-destruction* had a more permanent character. For several months the periodontal ligament in the pressure/tension zones displayed signs of inflammation and osteoclastic bone resorption. This resulted in a gradual widening of the periodontal ligament (Fig. 16-11). As a consequence, the resulting angular bone destruction was continuous and the mobility of the teeth remained progressive. The plaque-associated lesion in the "zone of irritation" and the inflammatory lesion in the "zone of co-destruction" merged. In this dog model experiment, additional portions of the connective tissue attachment were lost and periodontal tissue destruction became more severe (Figs. 16-12, 16-13) (Lindhe & Svanberg 1974).

On the other hand, findings from more short-term experiments using a monkey model (Polson & Zander 1983), failed to support the observations of Lindhe and Svanberg (1974) and Ericsson and Lindhe (1982). Polson and Zander (1983) reported that trauma superimposed on periodontal lesions associated with angular bony defects caused increased loss of alveolar bone, but failed to produce additional loss of connective tissue attachment.

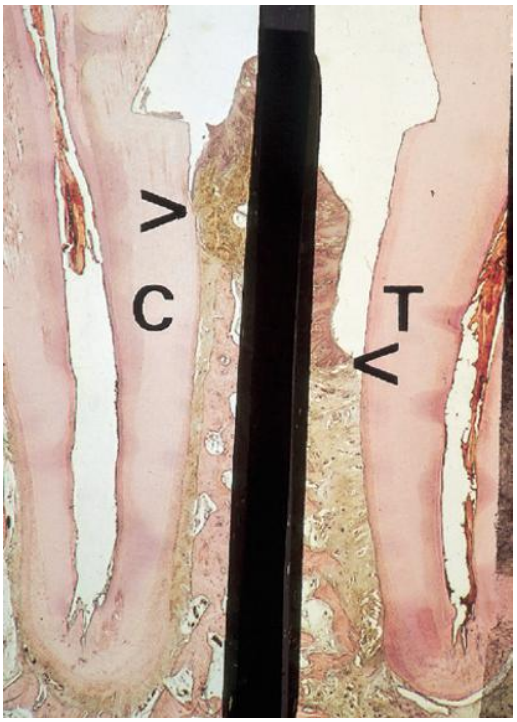

Fig. 16-12 Microphotographs from one control (C) and one test (T) tooth after 240 days of experimental periodontal tissue breakdown and 180 days of trauma from occlusion of the jiggling type (T). The arrowheads denote the apical position of the dentogingival epithelium. The attachment loss is more pronounced in T than in C. (Source: Lindhe & Svanberg 1974. Reproduced with permission from John Wiley & Sons.)

Conclusion

Experiments carried out in humans as well as in animals have produced convincing evidence that neither unilateral forces nor jiggling forces, applied to teeth with a healthy periodontium, result in pocket formation or in loss of connective tissue attachment. *Trauma from occlusion cannot induce periodontal tissue breakdown*. Trauma from occlusion does, however, result in resorption of alveolar bone, leading to an increased tooth mobility which can be of a transient or permanent character. This bone resorption with resulting increased tooth mobility should be regarded as a physiologic adaptation of the periodontal ligament and surrounding alveolar bone to the traumatizing forces, that is to altered functional demands.

In teeth involved in progressive, plaque-associated periodontal disease, trauma from occlusion may, under certain conditions, enhance the rate of progression of the disease, in other words act as a co-factor in the destructive process. It is important to realize that in such cases, treatment directed towards the trauma alone, that is occlusal adjustment or splinting, may reduce the mobility of the traumatized teeth and result in some regrowth of bone, but it will not influence the features of the plaque-associated lesion.

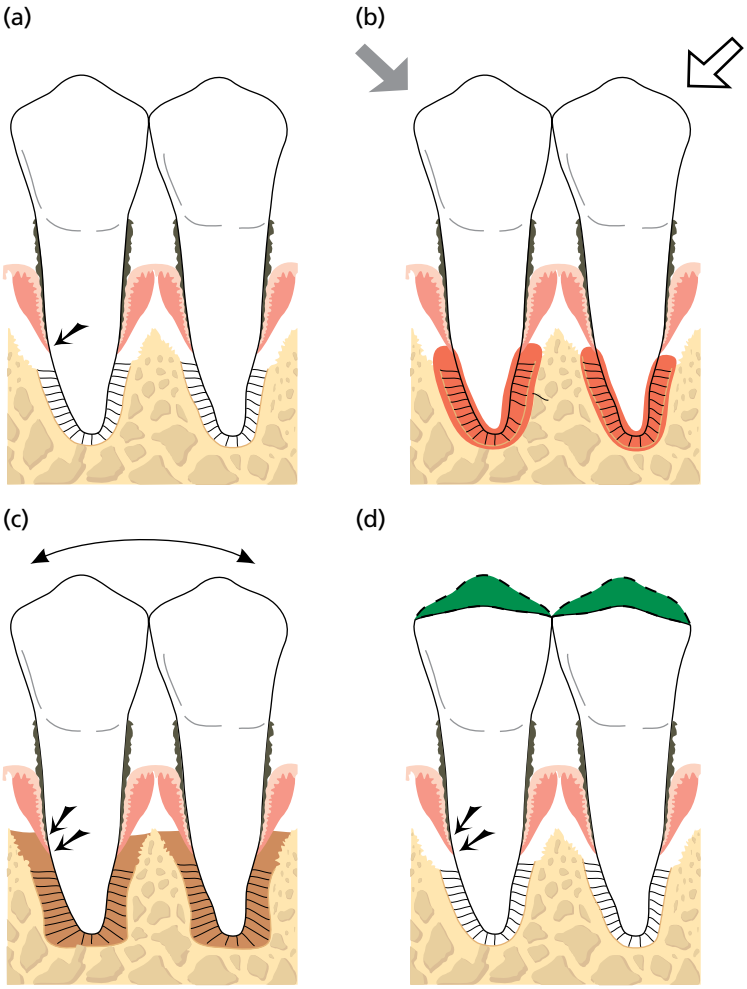

Fig. 16-13 (a) A tooth where subgingival plaque has mediated the development of an infiltrated soft tissue (shadowed area) and an infrabony pocket. (b) When trauma from occlusion of the jiggling type is inflicted (arrows) on the crown of this tooth, the associated pathologic alterations occur within a zone of the periodontium which is also occupied by the inflammatory cell infiltrate (shadowed area). In this situation, the increasing tooth mobility may also be associated with an enhanced loss of connective tissue attachment and further downgrowth of dentogingival epithelium; compare arrows in (c) and (d). Occlusal adjustment will result in a narrowing of the periodontal ligament, less tooth mobility, but no improvement of the attachment level (d). (Source: Lindhe & Ericsson 1982. Introduction

Endosseous osseointegrated oral implants have been suggested to serve as anchorage for orthodontic appliances where the existing dentition does not provide sufficient anchorage (see Chapter 59). Both clinical (Turley *et al*. 1988; Ödman *et al*. 1988; Haanaes *et al*. 1991; Ödman *et al*. 1994) and experimental (Wehrbein & Diedrich 1993; Wehrbein *et al*. 1996) studies have demonstrated that osseointegrated implants were able to provide sufficient and stable anchorage for tooth movement during the time period of orthodontic therapy, thereby eliminating the need to observe Newton's third law according to which an applied force can be divided into an *action* component and an equal and opposite *reaction* moment.

In long-term clinical studies of various two-stage submerged implant systems, however, implant losses have been attributed to *overloading* or *excessive loading*. In patients with edentulous (Adell *et al*. 1981; Lindquist *et al*. 1988) and partially edentulous jaws (Jemt *et al*. 1989; Quirynen *et al*. 1992), most of the implants losses were considered to be the result of excessive occlusal loading. While it has been shown that early loading of oral implants may impede successful osseointegration (Sagara *et al*. 1993), the effect of excessive occlusal functional forces following successful osseointegration has not been documented so far. However, studies by Isidor (1996, 1997) have demonstrated that loading of implants through the creation of a massive supraocclusion, leading to excessive – and most likely non-physiologic – laterally directed occlusal forces, established a high risk for the loss of osseointegration. Nevertheless, in one of four experimental animals, even such excessive loading forces were unable to jeopardize the interfacial union of the alveolar bone with the implant surface.

The forces applied in the studies mentioned were characterized as being very high and of short duration. However, they could not be quantified. None of the experimental studies analyzed the direct relationship between changes in the stress and strain applied to oral implants during functional loading and the tissue reactions of the surrounding alveolar bone. For the evaluation of the etiology and pathogenesis of implant losses due to overload, such information would appear to be of crucial importance.

Orthodontic loading and alveolar bone

In order to evaluate the tissue reactions adjacent to oral implants following loading with well-defined forces and to relate these to the strain values applied on the trabecular surface of the alveolar bone, an animal study was performed using finite element analysis (FEA) to determine the cellular activity (Melsen & Lang 2001). In six adult monkeys, the lower first

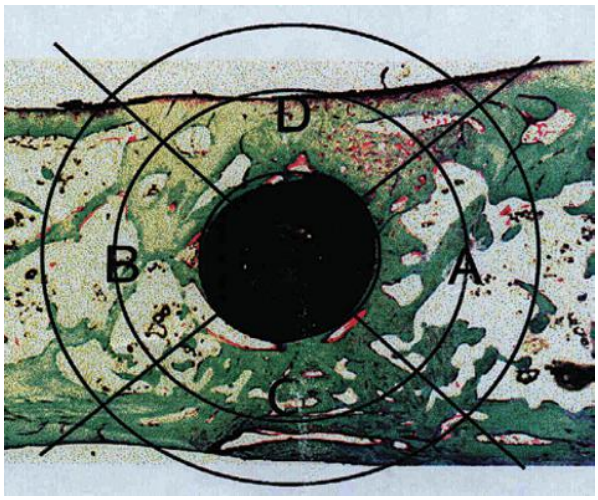

Fig. 17-2 Horizontal section of the implant with the projected grid used for the histomorphometric evaluation of different regions surrounding the implant. Region A is submitted to compression, region B to tension, and regions C and D to shearing forces.

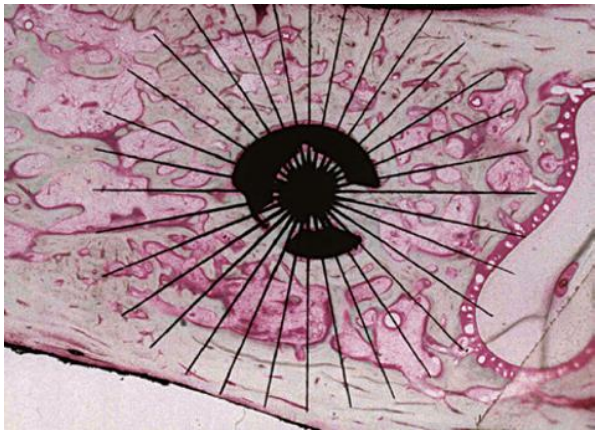

Fig. 17-3 Horizontal section of the implant onto which a grid with 32 radial lines was projected. The evaluation of the osseointegration included the determination of the percentage of direct bone–implant contact (×160).

and the second premolars as well as the second molars were removed. After 6 months, two specially designed screw implants were inserted in the region of the lower left second premolar and second molar. After a further 3 months, a square rod with three notches at different levels was inserted and tightened to the top of the implants. The notches served as a reference for the measurements of the implant displacement. A flat disk was placed between the implant and the rod. To this disk two extensions were welded buccally and lingually in a way that allowed a coil spring to be placed as close as possible to the estimated level of the center of resistance (Fig. 17-1). Immediately before the buccal and lingual springs were inserted, the extensions were placed on the occlusal surface of the implants. Impressions of each segment were taken. Subsequently, two measurements were performed with an electronic strain gauge-based measuring device. For anchorage of the device, a cast splint was fitted to the anterior segment of the dentition and each of the implant screws. One measurement was taken between the notches close to the implant connection, and another between the notches close to the top of the square rod extensions. These were repeated after 11 weeks, in other words at the termination of the orthodontic loading period. The direction and magnitude of the displacement of the implant as a result of loading could thus be calculated in the sagittal plane.

Following the baseline recordings, springs extending from the anterior to the posterior implant were attached to the power arms buccally and lingually (Fig. 17-1). Total load applied to each implant varied from 100 to 300 cN. One monkey served as a control with the implants in this animal not subjected to any loading.

At the end of the experiment, the monkeys were sacrificed. Subsequently, parallel horizontal tissue sections from the coronal to the apical end of the implants were cut and stained with fast green. A grid consisting of three concentric circular lines was projected onto the sections, with each of these lines intersected by four equidistant radial lines starting at the center of the grid and coinciding with the central axis of the implants. The four radial lines divided the circle into eight areas, two in the direction of the force (A: compression zone), two in the opposite direction (B: tension zone), and four lateral to the implants (C and D: shear zone) (Fig. 17-2).

At a magnification of ×160, the extent of resorption lacunae and the extent of the trabecular bone surfaces covered by osteoid as a fraction of the total were assessed. Also, using morphometry, bone density was evaluated within each quadrant. Furthermore, to measure the amount of osseointegration, the proportion of direct bone–implant contact was calculated by projecting a grid consisting of 32 radial lines extending from the center of the implants onto the section to be analyzed (Fig. 17-3).

None of the implants had lost osseointegration after 11 weeks of orthodontic loading, but loading significantly influenced the turnover of the alveolar bone in the vicinity of the implants. Bone apposition was most frequently found when the calculated strain varied between 3400 and 6600 μstrain. On the

other hand, when the strain exceeded 6700 μstrain, the remodeling of the bone resulted in a net loss of bone.

This study clearly supports the theory that apposition of bone around an oral implant is the biologic response to a mechanical stress below a certain threshold, whereas loss of marginal bone or complete loss of osseointegration may be the result of mechanical stress beyond this threshold. Hence, occlusal forces would have to substantially exceed the physiologic range before occlusal contacts could jeopardize the tissue integrity of an implant.

Several other studies of applied orthodontic forces have confirmed that the apposition or increase in bone density surrounding an oral implant, rather than loss of bone (Roberts *et al*. 1984; Wehrbein & Diedrich 1993; Asikainen *et al*. 1997; Akin-Nergiz *et al*. 1998).

Bone reactions to functional loading

A study addressed the reaction of peri-implant bone after longstanding functional loading compared to non-loaded controls (Berglundh *et al*. 2005). After extraction of all mandibular premolars, four AstraTech® implants were placed in one side of the mandible, and four Brånemark System® fixtures were installed in the contralateral side. Three months after abutment connection, fixed dental prostheses (FDPs) were fabricated in gold and cemented onto the maxillary canines and premolars (Fig. 17-4). FDPs were also installed onto three of the four mandibular implants in both sides. The fourth implant remained unloaded and served as a control (Fig. 17-5). Radiographs were obtained from each site following implant installation, abutment connection, and FDP placement. All radiographs were repeated after 10 months of functional loading. At this time, biopsies were obtained and analyzed histologically.

Radiographic analysis revealed that the largest amount of bone loss occurred following implant installation and abutment connection. This bone loss was more pronounced at the Brånemark® than at the AstraTech® implants. However, as a result of functional loading, bone loss was small and did not differ significantly from the unloaded control sites (Fig. 17-6).

Histologic analysis showed that implants subjected to 10 months of functional loading had more direct bone–implant contact than their unloaded counterparts. This was observed for both implant systems (Fig. 17-7).

Based on the radiographic and histologic results, this study demonstrated that *functional loading of implants may enhance osseointegration* (direct bone–implant contact) rather than induce marginal bone loss and hence, any bone loss should not be attributed to loading of implants. Whenever marginal bone loss is observed around implants in function, the most likely etiologic factor is bacterial in nature (see Chapter 26).

Excessive occlusal load on implants

The effect of *excessive occlusal load* following placement of titanium implants in the presence of healthy peri-implant mucosal tissues was evaluated in an experimental dog study (Heitz-Mayfield *et al*. 2004). In six Labrador dogs, two titanium plasma-sprayed (TPS) implants and two sandblasted, large grit, acid-etched (SLA) implants were placed on each side of the mandible (Fig.17-8a). A total of 45 implants were evaluated. Following 6 months of healing (Fig. 17-8b), gold crowns were placed on implants on the test side of the mandible. The crowns were in supraocclusal contact with the opposing teeth in order to create an

excessive occlusal load (Fig. 17-8c). Implants on the control side were not loaded. Plaque control was performed throughout the experimental period. Clinical measurements and standardized radiographs (Fig. 17-8d) were obtained at baseline and 1, 3, and 8 months after loading. At 8 months, all implants were osseointegrated, the dogs were sacrificed, and histologic analyses were performed.

The mean probing depth was 2.5 ± 0.3 and 2.6 ± 0.3 mm at the unloaded and loaded implants, respectively. Radiographically, the mean distance from the implant shoulder to the marginal bone level was 3.6 ± 0.4 mm in the control group and 3.7 ± 0.2 mm in the test group. There were no statistically significant changes in any of the parameters from baseline to 8 months in the loaded and unloaded implants.

Histologic evaluation (Fig. 17-9) showed a mean mineralized bone–implant contact of 73% in the control implants and 74% in the test implants, with no statistically significant difference between test and control implants.

Table 17-1 shows the level of osseointegration in relation to the total length of the implant after 8 months of excessive loading or non-loading. These values were generally slightly below those of the alveolar bone height (Table 17-2) for all sites and surfaces in both test and control implants. The differences varied between 1.1% and 3.7% and were not statistically significant.

Likewise, there were no statistically significant differences between the excessively loaded and the unloaded implants in terms of peri-implant bone density either at the implant–bone interface or at 1 mm from the implant surface (Fig. 17-9) after 8 months.

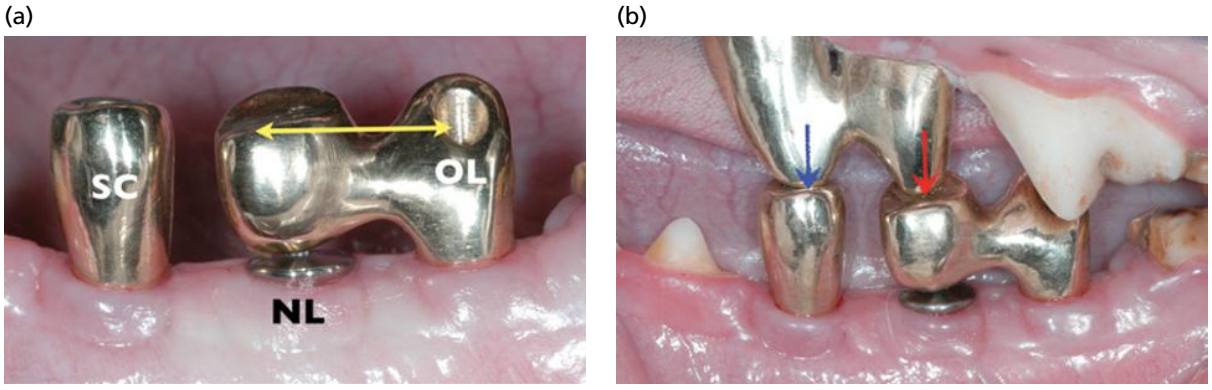

Fig. 17-10 Osseointegrated implants (a) not in occlusal contact and (b) in occlusal contact: a single crown unit with normal occlusal contacts and stable occlusion (SC) (blue arrow); a single non-loaded implant (NL) protected by a cantilever beam of 13.5 mm in length (yellow arrow); and an overloaded abutment (OL) with overt occlusal contacts through the cantilever beam (red arrow).

Since none of the clinical, radiographic, or histologic parameters yielded statistically significant differences between non-loaded and excessively loaded implants, the study clearly demonstrates that, in the presence of peri-implant mucosal health, a period of 8 months of *excessive occlusal load* on titanium implants does *not* result in loss of osseointegration or marginal bone loss when compared with non-loaded implants.

More recently, implants with both SLA and SLActive implant surfaces restored and overloaded by means of cantilever reconstructions were evaluated for implant stability over a period of 6 months using resonance frequency analysis (RFA) (Lima *et al*. 2010). In five Beagle dogs, all mandibular premolars were extracted bilaterally. After 3 months, full thickness flaps were raised, and six implants (Straumann®, length 8 mm, diameter 3.3 mm, three SLA and three SLActive) were installed in a block-randomized split-mouth design (d0). After 4 weeks, implants were restored on each side of the mandible as follows: one single crown with stable occlusal contacts (SC); one crown and a 13.5-mm cantilever unit with overt occlusal contacts (OL); and one non-loaded implant (NL) protected by the cantilever unit (Fig. 17-10). The vertical dimension was increased by 3 mm. RFA was evaluated on day 0 and weekly for 2–10 weeks after surgery, and at 12 weeks and 24 weeks after loading. Repeated measure MANOVA was used to test the significance of the interaction between three within-subject effects (i.e. implant surface, type of treatment, and follow-up) and their interaction with RFA values.

Mean implant stability quotient (ISQ) values (RFA) from 61 to 66 for SLA implants and 58–67 for SLActive implants immediately after placement, and then significantly increased to 74–77 and 76–78, respectively, 4 weeks later (P <0.001). Six months after loading, ISQ values were significantly greater for both SLA and SLActive implants, reaching levels of 77.90 (SLA/OL), 76.80 (SLA/NL), 77.75 (SLA/SC), 76.40 (SLActive/OL), 79.80 (SLActive/NL), and 74.30 (SLActive/SC), with no significant differences between units ($P = 0.30$).

It was evident that the application of early and excessive occlusal load on clinically stable implants restored with cantilever reconstructions did not cause significant changes in implant stability. Consequently, this study, again, provides evidence that *occlusal overload* does *not* result in loss of implant stability and hence, does not jeopardize the integrity of the implants even when under heavy function.

Static and cyclic loads on implants

While the study by Berglundh *et al.* (2005) addressed the possible influence of functional loading on the marginal bone levels of implants by applying a flat occlusal plane scheme and physiologic forces, many authors have studied the influence of loading forces exceeding physiologic functional conditions and impacting on the implants in a non-axial direction (Barbier & Schepers 1997; Gotfredsen *et al*. 2001a–c, 2002; Heitz-Mayfield *et al*. 2004).

The bone tissue reaction to axial loading was evaluated using conventional three-unit FDPs in the mandible of Beagle dogs, and compared with that to non-axial loading provoked by installing a distal cantilever of two implants (Barbier & Scheppers 1977). Bone remodeling was modest at the implant sites supporting conventional FDPs, while the non-axial load induced by the cantilever FDPs yielded a more pronounced bone response, including a higher activity of osteoclasts in the peri-implant bone. However, bone levels were not affected. This was interpreted as an adaptive phenomenon within the peri-implant bone as a result of non-axial loading.

The bone reactions around osseointegrated implants to static load were analyzed in three studies in dogs (Gotfredsen *et al*. 2001a–c, 2002). In the

first study (Gotfredsen *et al*. 2001a), a lateral static load was induced by an orthodontic expansion screw at eight ITI® TPS hollow-screw implants in each dog. After a loading period of 24 weeks, during which time the screws were activated every 4 weeks from 0.0, 0.2, 0.4, to 0.6 mm, histologic and histometric analysis revealed no marginal bone loss at loaded and unloaded implant sites. Peri-implant bone density and mineralized bone–implant contact was higher at the loaded than the unloaded implant sites. This, again, was interpreted as lateral static load resulting in an *adaptive remodeling of the peri-implant bone*.

In the second study (Gotfredsen *et al*. 2001b), two TPS and two turned ITI® hollow-screw implants were subjected to the 24-week loading period in each dog using orthodontic expansion screws. These were activated by 0.6 mm every 4 weeks. The histologic and histometric analysis showed higher marginal bone levels around TPS implants than around turned implants. Likewise, the peri-implant bone density and mineralized bone–implant contact was higher around the roughened TPS than the turned implants. Hence, it was concluded that surface roughness influences the bone reactions to the applied load. This in turn indicates that surface roughness may also be a determining factor in the remodeling process triggered by load at the bone–implant interface.

The third study (Gotfredsen *et al*. 2001c) analyzed the dynamics of applying a static load for various durations to ITI® implants in three Beagle dogs. After 24 weeks, the static load was maximally activated onto the implants of the right mandibular side, giving a total loading period of 46 weeks at sacrifice. At 60 weeks, maximal activation of static load was set onto the implants of the left mandibular side, giving a total loading period of 10 weeks at sacrifice.

Fluorochrome labeling was performed at weeks 62, 64, 66, and 68. The dogs were sacrificed at week 70. A similar distribution of bone markers, bone density, and bone–implant contact was observed at 10 and 46 weeks of static lateral loading. However, higher fluorochrome proportions were seen at 10 weeks compared to 46 weeks of lateral loading, suggesting higher adaptive activity at 10 weeks. Nevertheless, the structural adaptation appeared to be similar at the two observation periods.

In all three studies, greater bone–implant contact was identified at implants subjected to lateral static load application compared to non-loaded implants. Moreover, lateral static load failed to induce peri-implant bone loss or to enhance peri-implant bone loss. Hence, *lateral static load* does *not* appear to be detrimental to implants exhibiting peri-implant mucositis or peri-implantitis (Gotfredsen *et al*. 2001a–c).

In contrast to these findings are those from a study in dogs by Hoshaw *et al*. (1994). In this study, excessive cyclic axial forces were applied to implants [high cyclic (500 cycles/day) axial tension (10–300 N) for 5 consecutive days) placed in the tibiae of ten animals. Bone loss was observed to occur around the neck of the Brånemark implants after 1 year. Similar results were reported for a rabbit model (Duyck *et al*. 2001) in which dynamic load on implants resulted in the establishment of marginal crater defects, while no effects on osseointegration could be identified in other parts of the implants.

Load and loss of osseointegration

It has been reported (Isidor 1996, 1997) that excessive occlusal load may – under certain circumstances – lead to loss of osseointegration along the entire length of the implant, resulting in implant mobility. In this study, four monkeys received 18 self-tapping screw implants in the mandible after the first molars (n = 7), premolars (n = 8), and incisors (n = 3) had been extracted. Using an opposing maxillary splint in heavy supraocclusal contacts, *excessive occlusal load*, predominantly in the non-axial (lateral) direction, was applied to eight implants. Furthermore, cotton ligatures for increased plaque retention were placed around another 10 implants, resulting first in mucositis and later in peri-implantitis (Lindhe *et al*. 1992; Lang *et al*. 1993). After 18 months of excessive occlusal loading, two of the eight implants subjected to excessive occlusal load were lost. Two of the ten implants with the cotton ligatures revealed partial loss of osseointegration as a result of plaque-induced peri-implantitis (Fig. 17.11a). Of the retained six implants subjected to excessive load, two showed complete loss of osseointegration with a connective tissue capsule formed around the entire outline of the implants (Fig. 17.11b). Radiographically, the two implants showing complete loss of osseointegration and clinical mobility showed a peri-implant radiolucency after 18 months of excessive occlusal load. However, no loss of marginal bone height was evident.

Another two excessively loaded implants (in one monkey) showed no loss of osseointegration whatsoever. Instead, an increase in bone density and the highest percentage of bone–implant contact area was seen at these implants compared to the remaining implants. This monkey also did not develop ligature-induced peri-implantitis (at three implants). Two implants under excessive occlusal load revealed a reduced bone–implant contact.

Thus, the study demonstrated that excessive occlusal load can, indeed, result in loss of osseointegration characterized by a fibrous connective tissue capsule around the implant, in contrast to the marginal bone loss encountered at implants with ligature-induced peri-implantitis. It must be noted, however, that the bone trabecular structure

around the implant loosing osseointegration as a result of excessive occlusal load (Fig. 17.11b) was much less dense than that of, for example, the implants subjected to experimental peri-implantitis (Fig. 17.11a). Thus, this study does not support the concept that occlusal overload may lead to implant losses. Rather, it supports the fact that marginal bone loss at implants is associated with peri-implant disease.

Masticatory occlusal forces on implants

Closing and occlusal functional force distributions have been studied using one- (Lundgren *et al*. 1987, 1989; Falk *et al*. 1989, 1990) or three-dimensional piezoelectric force transducers (Mericske-Stern *et al*. 1996; Mericske-Stern 1997, 1998; Mericske-Stern *et al*. 2000).

Eight strain gauge transducers were mounted bilaterally in a maxillary complete denture to occlude with a mandibular implant-supported fixed cantilever prosthesis (Fig. 17-12a) (Lundgren *et al*. 1989). The study demonstrated that closing and chewing forces *increased* distally along the cantilever beams when occluding with complete dentures. Moreover, on both the preferred and non-preferred chewing sides, significantly larger closing and chewing forces were measured over the cantilever segments than over the implant-supported area (Fig. 15-12b). Also, the distally increasing force distribution pattern could be changed to a distally *decreasing* force distribution pattern by infra-occluding the second cantilever unit by as little as 100 µm. Such slight reductions in posterior occlusal contacts on cantilevers may need to be considered whenever the opposing masticatory unit is a complete removable dental prosthesis. However, maximal biting and chewing forces *decreased* distally along the cantilever beams when occluding with tooth-supported FDPs (Fig. 17-13) (Lundgren *et al*. 1987).

From this series of experimental clinical studies it was concluded that forces directed onto the implants *per se* are difficult to evaluate using the transducer methodology. Nevertheless, maximal closing forces were always substantially greater than chewing forces. In addition, each subject in these studies developed a preferred chewing side that was associated

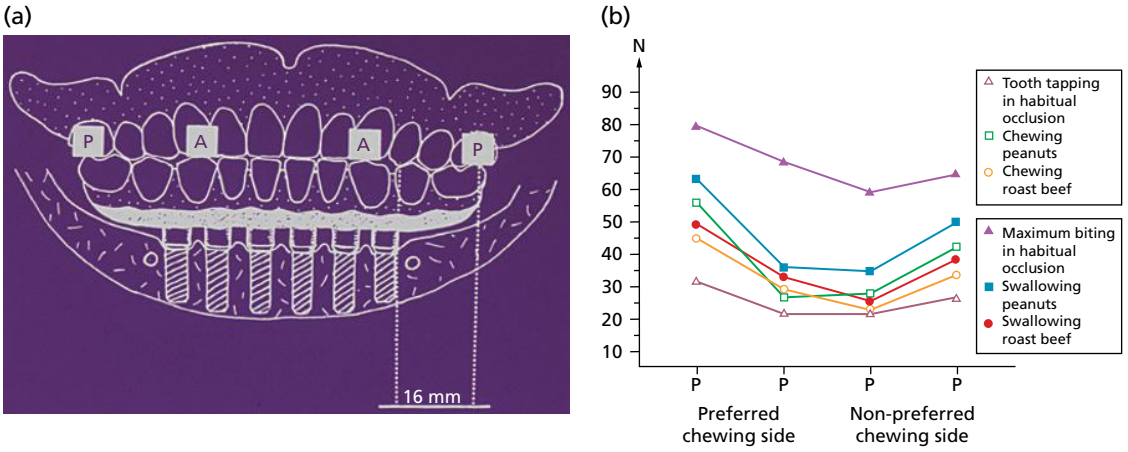

Fig. 17-12 (a) Eight strain gauge transducers placed into a maxillary completely removable prosthesis and occluding against an implant-supported fixed mandibular dental prosthesis with cantilever beams of 16 mm. (Source: Lundgren *et al*. 1989. Reproduced from Quintessence.) (b) Chewing forces amounting to a maximum biting force of 80 N on the preferred (right) chewing side and 64 N on the non-preferred (left) chewing side. While masticating, higher forces are applied to the cantilever beams than to the implant-supported part of the mandibular FDP. (Data from Lundgren *et al*. 1989. Courtesy of D. Lundgren, Gothenburg.)

with higher chewing forces than the non-preferred chewing side (Lundgren *et al*. 1987, 1989; Falk *et al*. 1989, 1990).

Occlusal force distribution patterns have been studied using three-dimensional piezoelectric transducers for mandibular overdentures that were mounted onto two mandibular implants in the canine region designed to support either a ball joint- or a bar-retained mandibular complete removable prosthesis. Rigid bars provided the best distribution of forces in a vertical direction onto the two mandibular implants (Mericske-Stern *et al*. 1996; Mericske-Stern 1998). Moreover, short distal bar extensions did not negatively influence the force pattern (Mericske-Stern 1997).

When ball joint anchors were used to retain the mandibular overdenture, rather low forces were measured on the implants, particularly in a vertical direction (Mericske-Stern 1998). Vertical forces amounted to 60–140 N, while horizontal forces were much smaller (15–60 N).

Tooth–implant supported reconstructions

In reconstructing patients with inadequate masticatory function, oral implants are often used to increase the patients' chewing comfort (see Chapter 53) and provide additional chewing units in an edentulous posterior region. Occasionally, reconstruction of a chewing side may be contemplated, with the reconstruction supported by both a tooth and an implant (Fig. 17-14). In this way, problems with the location of the mental nerve in an area of a planned implant installation or lack of an adequate bone volume may be overcome.

Combined tooth–implant reconstructions have been associated with numerous clinical problems, including root intrusion as a potential clinical hazard of non-rigid connection. Hence, it has been claimed that natural teeth should not be connected to implants beneath a fixed prosthesis.

However, experimental studies have clearly established that no detrimental effects on the periodontium of abutment teeth can be demonstrated despite the different biomechanical condition mediated by a periodontal ligament as opposed to the ankylotic anchorage of an implant (Biancu *et al*. 1995).

In vivo measurements of vertical forces and bending moments during biting and chewing were carried out on ten three-unit prostheses in the posterior mandibles of five patients. Each patient had two prostheses, one supported by two implants and the other supported by one implant and one tooth. The results demonstrated no major difference in functional load magnitudes between the support types. Obviously, functional loads were shared between the teeth and the implants (Gunne *et al*. 1997; Rangert *et al*. 1991, 1995).

Further studies using FEA showed no increased risk of stress concentrations at the neck of the implant (Gross & Laufer 1997; Laufer & Gross 1998).

Clinical studies reporting life table statistics in combined implant and tooth restorations do not show adverse effects of splinting teeth to implants. No increased risk of tooth intrusion was reported if the

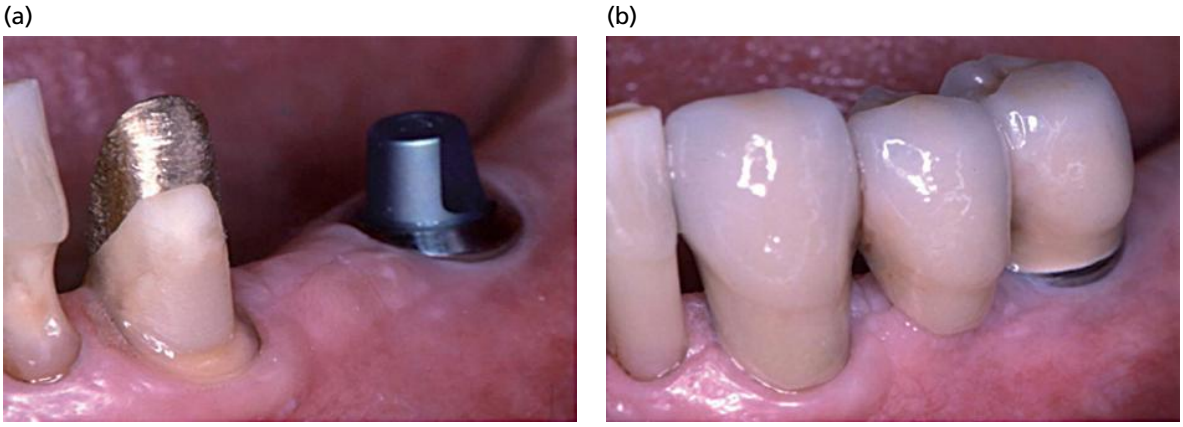

Fig. 17-14 Reconstruction of a chewing side in the left mandible using a fixed dental prosthesis (FDP). (a) Prepared abutment tooth 33 after having established adequate abutment height by the installation of a cast post and core prior to seating a three-unit FDP. (b) Tooth-implant supported three-unit FDP 10 years after placement.

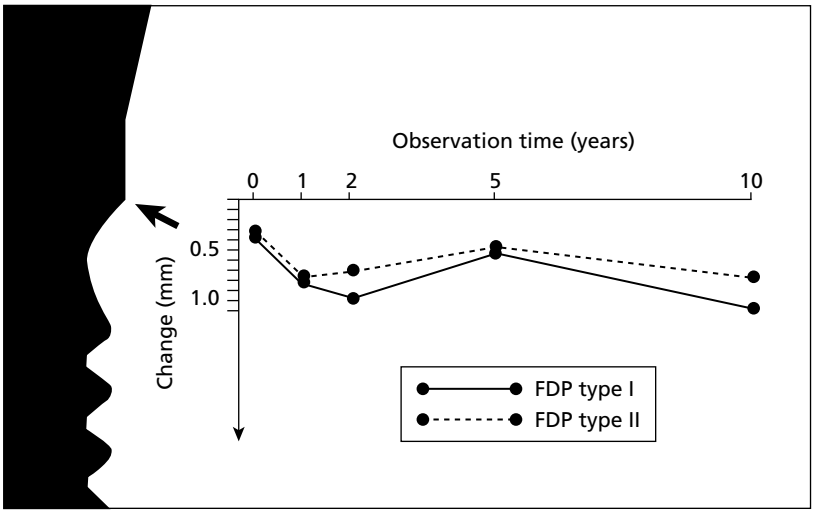

Fig. 17-15 Ten-year randomized controlled clinical trial of three-unit fixed dental prostheses, either implant–implant (type I) or tooth–implant (type II) supported. No differences in the crestal bone levels after 1, 2, 5, and 10 years in function. (Source: Lundgren *et al*. 1987. Reproduced with permission from Elsevier.)

implant was rigidly connected to the tooth (Fugazzotto *et al*. 1999; Lindh *et al*. 2001; Naert *et al*. 2001a, b).

For 843 consecutive patients treated in a private practice set-up (Fugazzotto *et al*. 1999) with 1206 natural tooth–implant supported prostheses utilizing 3096 screw-fixed attachments, after 3–14 years in function, only nine intrusion problems were noted. All problems were associated with fractured or lost screws.

Probably the most relevant clinical study is a 10-year randomized controlled prospective study of 23 patients with residual mandibular anterior teeth (Gunne *et al*. 1999). Each patient received two three-unit FDPs either supported by two implants or, on the contralateral side, by one implant and one tooth, thus permitting intraindividual comparison. The distribution of the two types of FPDs in each jaw was randomized. Implant success rates, marginal bone changes, and mechanical complications were studied. The tooth–implant connection did not demonstrate any negative influences on the overall success rates for the 10-year period when compared to the implant–implant supported FDPs (Fig. 17-15). Hence, it was suggested that a prosthetic construction supported by both a tooth and an implant may be recommended as a predictable and reliable treatment alternative in the posterior mandible (Gunne *et al*. 1999).

Based on the available evidence, it can be stated that a combination of implant and tooth support for FDP is acceptable (Belser *et al*. 2004).

While a systematic review (Lang *et al*. 2004) indicated that tooth–implant reconstructions have a 5-year survival rate of 94.1%, thus comparing very well with the 5-year survival rate of implant–implant reconstructions of 95.0% (Pjetursson *et al*. 2004), the 10-year survival rate of tooth–implant reconstructions (77.8%) appears to be significantly lower than the 10-year survival of implant–implant reconstructions (86.7%). However, owing to the fact that the former 10-year survival rate was based on only 60 (I–T) FDPs and the latter on only 219 (I–I) FDPs, the reliability of such 10-year survival rates has to be questioned.

The biomechanical aspects of implant–tooth-supported FDPs have been presented (Lundgren & Laurell 1994). As the implant is rigidly fixed within the alveolus and the tooth is surrounded by a periodontal ligament that allows minute movement, rigid FDP designs have been advocated.

The movement of the natural tooth abutment affects the load-bearing capacity of the FDP whenever a long-span FDP is constructed (e.g. a beam length of 24 mm or two premolar or molar pontics). Before the occlusal load is applied, the FDP acts as a cantilever construction. Upon loading, an angular deflection of the implant–crown unit of approximately 50 µm is noted. Along with bending of the long-span beam, an apical deflection of the tooth of approximately 50 µm is allowed, leading to bilateral (tooth and implant) support for the FDP.

If the tooth and implant only support a short-span FDP (e.g. a beam length of 12 mm or one premolar pontic only), however, the angular deflection of the implant–crown unit of approximately 50 µm and the bending of the short-span beam are insufficient to provide bilateral support for the bridge. Apical deflection of the tooth will not be achieved and the implant will bear the entire occlusal load applied to the FDP. As indicated above, there is no doubt that osseointegration will cope with such functional loads.

Part 6: Periodontal Pathology

Chapter 18

Non–Plaque-Induced Inflammatory Gingival Lesions

Palle Holmstrup[1] and Mats Jontell[2]

[1]Department of Periodontology, School of Dentistry, University of Copenhagen, Copenhagen, Denmark
[2]Oral Medicine and Pathology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Gingival inflammation, clinically presenting as gingivitis, is not always due to accumulation of plaque on the tooth surface, and non–plaque-induced inflammatory gingival reactions often present with characteristic clinical features (Holmstrup 1999). They may have several causes, such as specific bacterial, viral or fungal infection. Inherited gingival lesions are seen in hereditary gingival fibromatosis, and several mucocutaneous disorders manifest as gingival inflammation. Typical examples of such disorders are lichen planus, pemphigoid, pemphigus vulgaris, and erythema multiforme. Allergic and traumatic lesions are other examples of non–plaque-induced gingival inflammation. Dentists, and especially specialists in periodontology, are the key healthcare providers in the diagnostic unraveling and treatment of patients affected by such lesions.

This chapter focuses on the most relevant non–plaque-induced inflammatory lesions of the gingival tissues, either because they are common or because they are important examples for the understanding of the variety of tissue reactions that take place in the periodontium. For further information, the reader is referred to oral medicine textbooks. The modifying factors of plaque-related gingivitis such as smoking, sex hormones, and metabolic anomalies (diabetes) are dealt with in Chapters 12 and 14.

Gingival diseases of specific bacterial origin

Infective gingivitis and stomatitis may occur on rare occasions in both immunocompromised and non-immunocompromised individuals, when the homeostasis between innate host resistance and non–plaque-related pathogens is not maintained (Rivera-Hidalgo & Stanford 1999). The lesions may be due to bacteria and oral lesions may be the primary presentation of the infection. Typical examples of such lesions are due to infections with *Neisseria gonorrhea* (Scully 1995; Siegel 1996), *Treponema pallidum* (Scully 1995; Ramirez-Amador *et al*. 1996; Siegel 1996; Rivera-Hidalgo & Stanford 1999). streptococci, *Mycobacterium chelonae* (Pedersen & Reibel 1989) or other organisms (Blake & Trott 1959; Littner *et al*. 1982). Although oral manifestations of syphilis and gonorrhea are most likely to be observed during secondary disease, all stages of the disease can give rise to oral lesions. The gingival lesions manifest as fiery red edematous painful ulcerations,

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

as asymptomatic chancres or mucous patches, or as atypical non-ulcerated, highly inflamed gingivitis. Biopsy supplemented by microbiologic examination reveals the background of the lesions.

Gingival diseases of viral origin

Herpes virus infections

A number of viral infections are known to cause gingivitis (Scully *et al*. 1998b). The most important are the herpes viruses: herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2) and varicella zoster virus. These viruses usually enter the human body in childhood and may give rise to oral mucosal disease followed by periods of latency and sometimes reactivation. HSV-1 usually causes oral manifestations, whereas herpes HSV-2 is mainly involved in anogenital infections and only occasionally is involved in oral infection (Scully 1989).

Primary herpetic gingivostomatitis

HSV infections are among the most common viral infections. HSV is a DNA virus with low infectiosity, which after entering the oral mucosal epithelium, penetrates a neural ending and by retrograde transport through the smooth endoplasmatic reticulum (200–300 mm/day) travels to the trigeminal ganglion where it can remain latent for years. The virus has also been isolated in extraneural locations such as the gingiva (Amit *et al*. 1992). Sometimes HSV may also be involved in recurring erythema multiforme. It is presently unknown whether the virus plays a role in other oral diseases, but HSV has been found in gingivitis (Ehrlich *et al*. 1983), acute necrotizing gingivitis (Contreras *et al*. 1997), and periodontitis (Parra & Slots 1996).

When a newborn is infected, sometimes from the parent's recurrent herpes labialis, he/she is often wrongly diagnosed as "teething". With increased hygiene in industrialized societies, more and more primary infections occur at older ages, that is during adolescence and adulthood. It has been estimated in the US that there are about half a million cases of primary infection per year (Overall 1982). The primary herpetic infection may run an asymptomatic course in early childhood, but may also give rise to severe gingivostomatitis, which occurs mostly before adolescence (Fig. 18-1). This manifestation includes painful severe gingivitis with redness, ulcerations with serofibrinous exudate, and edema accompanied by stomatitis (Figs. 18-2, 18-3). The incubation period is 1 week. A characteristic feature is the formation of vesicles, which rupture, coalesce, and leave fibrin-coated ulcers (Scully *et al*. 1991; Miller & Redding 1992). Fever and lymphadenopathy are other classic features. Healing occurs spontaneously without scarring in 10–14 days (Fig. 18-4). During this period pain can render eating difficult.

Fig. 18-1 Herpetic gingivostomatitis in a 3-year-old child. Erythematous swelling of attached gingiva with serofibrinous exudate along the gingival margin.

Fig. 18-2 Herpetic gingivostomatitis affecting palatal gingiva. Numerous vesicles and small ulcerations.

The virus remains latent in the ganglion cell, probably through integration of its DNA in that of the chromosomal DNA (Overall 1982). Reactivation of the virus occurs in 20–40% of primary infected individuals (Greenberg 1996) and usually presents as herpes labialis, but recurrent intraoral herpes infections are also seen. Herpes labialis occurs in general more than once per year, usually at the same location on the vermilion border and/or the skin adjacent to it, where neural endings are known to cluster. A large variety of factors trigger reactivation of latent virus: trauma, ultraviolet light exposure, fever, menstruation, and others (Scully *et al*. 1998b).

While recurrences at the vermilion border are well recognized, recurrent intraoral herpes lesions often remain undiagnosed because they are considered aphthous ulcerations (Lennette & Magoffin 1973; Sciubba 2003), irrespective of the fact that aphthous ulcers do not affect keratinized mucosa. Recurrent intraoral herpes typically presents a less dramatic course than does the primary infection. A characteristic manifestation is a cluster of small painful ulcers in the attached gingiva and hard palate (Yura *et al*. 1986) (Fig. 18-5). The diagnosis can be made on the basis of the patient history and clinical findings supported by isolation of HSV from lesions. The polymerase chain reaction (PCR) has largely superseded most other methods and is a rapid and reliable diagnostic tool that provides subtype diagnosis. Laboratory diagnosis may also involve examination of a blood sample

Fig. 18-3 Herpetic gingivostomatitis in a 38-year-old woman. Widespread ulceration of the lower lip mucosa and gingiva.

Fig. 18-4 Same patient as shown in Fig. 18-3, 4 weeks later. Healing without loss of tissue or scar formation.

Fig. 18-5 Recurrent intraoral herpes infection. Ruptured vesicles of right palatal gingiva and mucosa.

for increased antibody titer against HSV. However, this is most relevant in cases of primary infection, because the antibody titer remains elevated for the rest of the individual's lifetime. The histopathologic features of cytologic smears from the gingival lesions are not specific, but the presence of giant cells and intranuclear inclusion bodies may indicate intracellular activity of the virus (Burns 1980).

Immunodeficient patients, such as human immunodeficiency virus (HIV)-infected individuals, are at increased risk of acquiring the infection (Holmstrup & Westergaard 1998). In the immunocompromised patient the recurrence of herpes infection, either gingival or elsewhere, may be severe and even life threatening.

The treatment of herpetic gingivostomatitis includes careful plaque removal to limit bacterial superinfection of the ulcerations, which delays their healing. In severe cases, including patients with immunodeficiency, the systemic use of antiviral drugs such as acyclovir, valacyclovir or famciclovir is recommended (O'Brien & Campoli-Richards 1989; Mindel 1991; Arduino & Porter 2006). Resistance to acyclovir, especially among immunodeficient patients on long-term therapy, is a growing concern (Westheim *et al*. 1987) and explains why other antiviral drugs may be relevant. Prophylactic antiviral treatment before dental treatment has been recommended for patients at risk of experiencing a recurrence, as well as to minimize transmission of the disease (Miller *et al*. 2004).

Herpes zoster

Varicella zoster virus causes varicella (chicken pox) as the primary self-limiting infection. It occurs mainly in children and later reactivation of the virus in adults causes herpes zoster (shingles). Both manifestations can involve the gingiva (Straus *et al*. 1988; Scully 1995). Chicken pox is associated with fever, malaise, and a skin rash. The intraoral lesions are small ulcers, usually on the tongue, palate, and gingiva (Miller 1996; Scully *et al*. 1998b). The virus remains latent in the dorsal root ganglion from where it can be reactivated years after the primary infection (Rentier *et al*. 1996). Later reactivation results in herpes zoster, with unilateral lesions following the infected nerve (Miller 1996). The reactivation normally affects the thoracic ganglia in elderly or immunocompromised patients. Reactivation of virus from the trigeminal ganglion occurs in 20% of reported cases (Hudson & Vickers 1971). If the second or third branch of the trigeminal nerve is involved, skin lesions may be associated with intraoral lesions, or intraoral lesions may occur alone (Eisenberg 1978), for instance affecting the palatal gingiva (Fig. 18-6). Initial symptoms are pain and paraesthesia, which may be present before lesions occur (Greenberg 1996). The associated pain is usually severe. The lesions, which often involve the gingiva, start as vesicles. They soon rupture to leave fibrin-coated ulcers, which often coalesce to irregular

Fig. 18-6 Herpes zoster of left palatal gingiva and mucosa. Irregular fibrin-coated ulcerations with severe pain.

Fig. 18-7 Pseudomembranous candidosis of maxillary gingiva and mucosa in an HIV-seropositive patient. The lesions can be scraped off, leaving a slightly bleeding surface.

forms (Millar & Traulis 1994) (Fig. 18-6). In immunocompromised patients, including those infected with HIV, the infection can result in severe tissue destruction with tooth exfoliation and necrosis of alveolar bone and high morbidity (Melbye *et al*. 1987; Schwartz *et al*. 1989). The diagnosis is usually obvious due to the unilateral occurrence of lesions associated with severe pain. Healing of the lesions usually takes place in 1–2 weeks.

Treatment consists of a soft or liquid diet, rest, atraumatic removal of plaque, and diluted chlorhexidine rinses. This may be supplemented by antiviral drug therapy.

Gingival diseases of fungal origin

Fungal infection of the oral mucosa includes a range of diseases such as aspergillosis, blastomycosis, candidosis, coccidioidomycosis, cryptococcosis, histoplasmosis, mucormycosis, and paracoccidioidomycosis infections (Scully *et al*. 1998b), but some of the infections are very uncommon and not all of them manifest as gingivitis. This section focuses on candidosis and histoplasmosis, both of which may cause gingival infection.

Candidosis

Various *Candida* species are recovered from the mouth of humans, including *C. albicans, C. glabrata, C. krusei, C. tropicalis, C. parapsilosis,* and *C. guillermondii* (Cannon *et al*. 1995). The most common fungal infection of the oral mucosa is candidosis mainly caused by the organism *C. albicans* (Scully *et al*. 1998b). *C. albicans* is a normal commensal of the oral cavity but also an opportunistic pathogen. The prevalence of oral carriage of *C. albicans* in healthy adults ranges from 3% to 48% (Scully *et al*. 1995), the large variation being due to differences in examined populations and the procedures used. The proportion of *C. albicans* in the total oral yeast population can reach about 50–80% (Wright *et al*. 1985). The proteinase-positive strains of *C. albicans* are associated with disease (Negi *et al*. 1984; Odds 1985) and invasion of keratinized epithelia such as that of the gingiva. Invasion and increased desquamation is due to hyaluronidase production. Infection by *C. albicans* usually occurs as a consequence of reduced host defense (Holmstrup & Johnson 1997), including immunodeficiency (Holmstrup & Samaranayake 1990) (Figs. 18-7, 18-8, 18-9), reduced saliva secretion, smoking, and treatment with corticosteroids, but may be due to a wide range of predisposing factors. The occurrence of oral candidosis may act as a predictor of immune and virologic failure in HIV-infected patients treated with antiviral drugs (Miziara & Weber 2006). Disturbances in the oral microbial flora, such as after therapy with broad-spectrum antibiotics, may also lead to oral candidosis. The predisposing factors are, however, often difficult to identify. Based on their site, infections may be defined as superficial or systemic. Candidal infection of the oral mucosa is usually a superficial infection, but systemic infections are not uncommon in debilitated patients.

In otherwise healthy individuals, oral candidosis rarely manifests in the gingiva. This is surprising when considering the fact that *C. albicans* is frequently isolated from the subgingival flora of patients with severe periodontitis (Slots *et al*. 1988). The most common clinical characteristic of gingival candidal infections is redness of the attached gingiva, often associated with a granular surface (Fig. 18-10).

Various types of oral mucosal manifestations are pseudomembranous candidosis (also known as thrush in neonates), erythematous candidosis, plaque-type candidosis, and nodular candidosis (Holmstrup & Axéll 1990). Pseudomembranous candidosis shows whitish patches (Fig. 18-7), which can be wiped off the mucosa with an instrument

Fig. 18-8 Erythematous candidosis of attached mandibular gingiva in an HIV-seropositive patient. The mucogingival junction is not visible.

Fig. 18-9 Same patient as shown in Fig. 18-8 after topical antimycotic therapy. The mucogingival junction is visible.

Fig. 18-10 Chronic erythematous candidosis of maxillary attached gingiva of the incisor region.

or gauze to leave a slightly bleeding surface. The pseudomembranous type usually has no major symptoms. Erythematous lesions can be found anywhere in the oral mucosa (Fig. 18-10). The intensely red lesions are usually associated with pain, which is sometimes severe. The plaque type of oral candidosis usually affects smokers and presents with a whitish plaque, which cannot be removed. There are usually no symptoms and the lesion is clinically indistinguishable from oral leukoplakia. Nodular candidal lesions are infrequent in the gingiva. Slightly elevated nodules of a white or reddish color characterize them (Holmstrup & Axéll 1990).

A diagnosis of candidal infection can be accomplished on the basis of culture, smear, and biopsy. A culture on Nickerson's medium at room temperature is easily handled in the dental premises. Microscopic examination of smears from suspected lesions is another easy diagnostic procedure, either performed as direct examination by phase-contrast microscopy or as light microscopic examination of periodic acid–Schiff-stained or Gram-stained smears. Mycelium-forming cells in the form of hyphae or pseudohyphae and blastospores are seen in great numbers among masses of desquamated cells. Since oral carriage of *C. albicans* is common among healthy individuals, positive culture and smear does not necessarily imply candidal infection (Rindum *et al*. 1994). Quantitative assessment of the mycologic findings and the presence of clinical changes compatible with the above types of lesions are necessary for a reliable diagnosis, which can also be obtained on the basis of identification of hyphae or pseudohyphae in biopsies from the lesions.

Topical treatment involves application of antifungals, such as nystatin, amphotericin B or miconazole. Nystatin may be used as an oral suspension. Since it is not resorbed, it can be used in pregnant or lactating women. Miconazole exists as an oral gel. It should not be given during pregnancy and it can interact with anticoagulants and phenytoin. The treatment of severe or generalized forms also involves systemic antifungals such as fluconazole.

Linear gingival erythema

Linear gingival erythema (LGE) is regarded as a gingival manifestation of immunosuppression characterized by a distinct linear erythematous band limited to the free gingiva (Holmstrup 1999) (Fig. 18-11). It is characterized by inflammation of disproportionate intensity for the amount of plaque present. There is no evidence of pocketing or attachment loss. A further characteristic of this type of lesion is that it does not respond well to improved oral hygiene or to scaling (EC Clearinghouse on Oral Problems 1993) and the diagnosis should be considered if the lesion persists after removal of plaque at the initial visit (Umadevi *et al*. 2006) . The extent of gingival banding measured at a number of affected sites has been shown to depend on tobacco usage (Swango *et al*. 1991). While 15% of affected sites were originally reported to bleed on probing and 11% exhibited spontaneous bleeding (Winkler *et al*. 1988), a key feature of LGE is now considered to be lack of bleeding on probing (Robinson *et al*. 1994).

Some studies of various groups of HIV-infected patients have revealed prevalences of gingivitis with band-shaped patterns of 0.5–49% (Klein *et al*. 1991;

Fig. 18-11 Linear gingival erythema of maxillary gingiva. Red banding along the gingival margin, which does not respond to conventional therapy.

Swango *et al*. 1991; Barr *et al*. 1992; Laskaris *et al*. 1992; Masouredis *et al*. 1992; Riley *et al*. 1992; Ceballos-Salobrena *et al*. 1996; Robinson *et al*. 1996). These prevalence values reflect some of the problems with non-standardized diagnosis and selection of study groups. A few studies of unbiased groups of patients have indicated that gingivitis with band-shaped or punctate marginal erythema may be relatively rare in HIV-infected patients, and is probably a clinical finding which is no more frequent than in the general population (Drinkard *et al*. 1991; Friedman *et al*. 1991).

It is interesting to note that, whereas there was no HIV-related preponderance of red banding, diffuse and punctate erythema was significantly more prevalent in HIV-infected than in non–HIV-infected individuals in a British study (Robinson *et al*. 1996). Red gingival banding as a clinical feature alone was, therefore, not strongly associated with HIV infection.

There are indications that candidal infection is the background of some cases of gingival inflammation including LGE (Winkler *et al*. 1988; Robinson *et al*. 1994), but studies have revealed a microflora comprising both *C. albicans* and a number of periopathogenic bacteria consistent with those seen in conventional periodontitis, that is *Porphyromonas gingivalis*, *Prevotella intermedia*, *Actinobacillus actinomycetemcomitans*, *Fusobacterium nucleatum*, and *Campylobacter rectus* (Murray *et al*. 1988, 1989, 1991). By DNA probe detection, the percentage of positive sites in HIV-associated gingivitis as compared with matched gingivitis sites of HIV-seronegative patients for *A. actinomycetemcomitans* was 23% and 7% respectively, for *P. gingivalis* 52% and 17%, for *P. intermedia* 63% and 29%, and for *C. rectus* 50% and 14% (Murray *et al*. 1988, 1989, 1991). *C. albicans* has been isolated by culture from about 50% of HIV-associated gingivitis sites, 26% of unaffected sites in HIV-seropositive patients, and 3% of healthy sites of HIV-seronegative patients. The frequent isolation and the pathogenic role of *C. albicans* may be related to the high levels of the yeasts in the saliva and oral mucosa of HIV-infected patients (Tylenda *et al*. 1989).

An interesting histopathologic study of biopsy specimens from the banding zone has revealed no inflammatory infiltrate but an increased number of blood vessels, which explains the red color of the lesions (Glick *et al*. 1990). The incomplete inflammatory reaction of the host tissue may be the background to the lack of response to conventional treatment.

A number of diseases present clinical features resembling those of LGE and which, accordingly, do not resolve after improved oral hygiene and debridement. Oral lichen planus is frequently associated with an inflammatory red band of the attached gingiva (Holmstrup *et al*. 1990), as sometimes is mucous membrane pemphigoid (Pindborg 1992) or erythematous lesions associated with renal insufficiency because of the salivary ammonia production associated with the high levels of urea.

There is little information about treatment based on controlled studies. Conventional therapy plus rinsing with 0.12% chlorhexidine gluconate twice daily has been shown to give significant improvement after 3 months (Grassi *et al*. 1989). It was mentioned above that LGE in some cases might be related to the presence of *Candida* strains. In accordance with this finding, clinical observations suggest that improvement is frequently dependent on successful eradication of intraoral *Candida* strains, which results in disappearance of the characteristic features (Winkler *et al*. 1988). Consequently, attempts to identify the presence of fungal infection either by culture or smear is recommended, followed by antimycotic therapy in *Candida*-positive cases.

Histoplasmosis

Histoplasmosis is a granulomatous disease caused by *Histoplasma capsulatum*, a soil saprophyte found mainly in feces from birds and cats. The infection occurs in the North-Eastern, South-Eastern, mid Atlantic, and central states of the US. It is also found in Central and South America, India, East Asia, and Australia. Histoplasmosis is the most frequent systemic mycosis in the US. Airborne spores from the mycelial form of the organism mediate it (Rajah & Essa 1993). In the normal host, the course of the infection is subclinical (Anaissie *et al*. 1986). The clinical manifestations include acute and chronic pulmonary histoplasmosis and a disseminated form, mainly occurring in immunocompromised patients (Cobb *et al*. 1989). Oral lesions have been seen in 30% of patients with pulmonary histoplasmosis and in 66% of patients with the disseminated form (Weed & Parkhill 1948; Loh *et al*. 1989). The oral lesions may affect any area of the oral mucosa (Chinn *et al*. 1995), including the gingiva, which appears to be one of the most frequent sites affected (Hernandez *et al*. 2004). The lesions start as nodular or papillary, and later may become ulcerative with loss of gingival tissue and pain (Figs. 18-12, 18-13). They are sometimes granulomatous and the clinical appearance may resemble a malignant tumor (Boutros *et al*. 1995). The diagnosis is based on clinical appearance and histopathology and/or culture, and the treatment consists of systemic antifungal therapy.

Gingival lesions of genetic origin

Hereditary gingival fibromatosis

Gingival hyperplasia (synonymous with gingival overgrowth, gingival fibromatosis) may occur as a side effect to systemic medications, including phenytoin, cyclosporine, and nifedipine (Coletta & Graner 2006). These lesions are to some extent plaque dependent and they are reviewed in Chapter 19. Gingival hyperplasia may also be of genetic origin. Such lesions are known as hereditary gingival fibromatosis (HGF), which is an uncommon condition characterized by diffuse gingival enlargement, sometimes covering major parts of or the entire tooth surfaces. The lesions develop irrespective of effective plaque removal.

HGF may be an isolated disease entity or part of a syndrome (Gorlin *et al*. 1990), associated with other clinical manifestations, such as hypertrichosis (Horning *et al*. 1985; Cuestas-Carneiro & Bornancini 1988), mental retardation (Araiche & Brode 1959), epilepsy (Ramon *et al*. 1967), hearing loss (Hartsfield *et al*. 1985), growth retardation (Bhowmick *et al*. 2001), and abnormalities of the extremities (Nevin *et al*. 1971; Skrinjaric & Basic 1989). Most cases are related to an autosomal dominant mode of inheritance, but cases have been described with an autosomal recessive background (Emerson 1965; Jorgensen & Cocker 1974; Singer *et al*. 1993). The most common syndrome of HGF includes hypertrichosis, epilepsy, and mental retardation; the latter two features, however, are not present in all cases (Gorlin *et al*. 1990).

Typically, HGF presents as large masses of firm, dense, resilient, insensitive fibrous tissue that covers

Fig. 18-14 Hereditary gingival fibromatosis. Facial aspect with partial coverage of teeth.

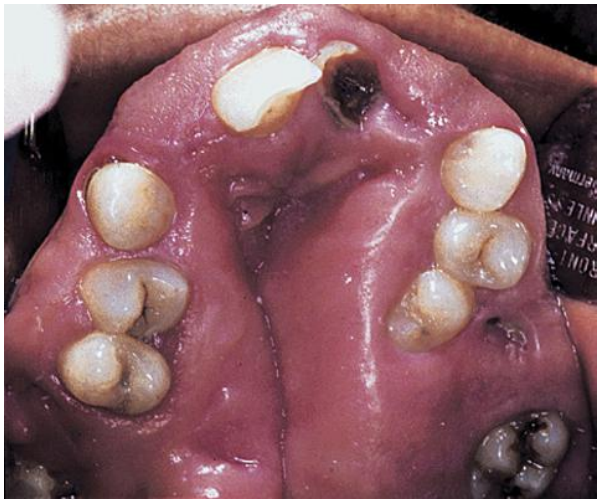

Fig. 18-15 Same patient as shown in Fig. 18-14. The maxillary gingival fibromatosis is severe and has resulted in total disfiguration of the dental arch.

the alveolar ridges and extends over the teeth, resulting in extensive pseudopockets. The color may be normal or erythematous if inflamed (Figs. 18-14, 18-15). Depending on the extent of the gingival enlargement, patients complain of functional and esthetic problems. The enlargement may result in protrusion of the lips and the patient may chew on a considerable hyperplasia of tissue covering the teeth. HGF is seldom present at birth but may be noted at an early age. If the enlargement is present before tooth eruption, the dense fibrous tissue may interfere with or prevent the eruption (Shafer *et al*. 1983).

Studies have suggested that an important pathogenic mechanism may be enhanced production of transforming growth factor-beta1 (TGF-β1) which reduces the proteolytic activities of HGF fibroblasts, which again favors the accumulation of extracellular matrix (Coletta *et al*. 1999). A locus for autosomal dominant HGF has been mapped to a region on chromosome 2 (Hart *et al*. 1998; Xiao *et al*. 2000), although at least two genetically distinct loci seem to be responsible for this type of HGF (Hart *et al*. 2000) and a novel locus for maternally inherited human gingival fibromatosis has been reported at human chromosome 11p15 (Zhu *et al*. 2006).

The histologic features of HGF include moderate hyperplasia of a slightly hyperkeratotic epithelium with extended rete pegs. The underlying stroma is almost entirely made up of dense collagen bundles with only a few fibroblasts. Local accumulation of inflammatory cells may be present (Shafer *et al*. 1983). Histologic examination may facilitate the differential diagnosis from other genetically determined gingival enlargements, such as Fabry's disease, characterized by telangiectasia.

The treatment is surgical removal, often in a series of gingivectomies, but relapses are not uncommon. If the volume of the overgrowth is extensive, a repositioned flap to avoid exposure of connective tissue by gingivectomy may better achieve elimination of pseudopockets.

Gingival diseases of systemic origin

Mucocutaneous disorders

A variety of mucocutaneous disorders present gingival manifestations, sometimes in the form of desquamative lesions or ulceration of the gingiva. The most important of these diseases are lichen planus, pemphigoid, pemphigus vulgaris, erythema multiforme, and lupus erythematosus.

Lichen planus

Lichen planus is the most common mucocutaneous disease manifesting on the gingiva. The disease may affect the skin and oral as well as other mucosal membranes in some patients, while others may present with either skin or oral mucosal involvement alone. Oral involvement alone is common and concomitant skin lesions in patients with oral lesions have been found in 5–44% of cases (Andreasen 1968; Axéll & Rundquist 1987). The disease may be associated with severe discomfort and since it has been shown to possess a premalignant potential (Holmstrup 1992), it is important to diagnose and treat the patients and to follow them at the regular oral examinations (Holmstrup *et al*. 1988; Mattson *et al*. 2002; Mignogna *et al*. 2007).

The prevalence of oral lichen planus (OLP) in various populations has been found to be 0.1–4% (Scully *et al*. 1998a). The disease may afflict patients at any age, although it is seldom observed in childhood (Scully *et al*. 1994).

Skin lesions are characterized by papules with white striae (Wickham striae) (Fig. 18-16). Itching is a common symptom, and the most frequent locations are the flexor aspects of the arms, thighs, and neck. In the vast majority of cases, the skin lesions disappear spontaneously after a few months, which is in sharp contrast to the oral lesions, which usually persist for many years (Thorn *et al*. 1988).

Fig. 18-16 Skin lesions of lichen planus. Papules with delicate white striations.

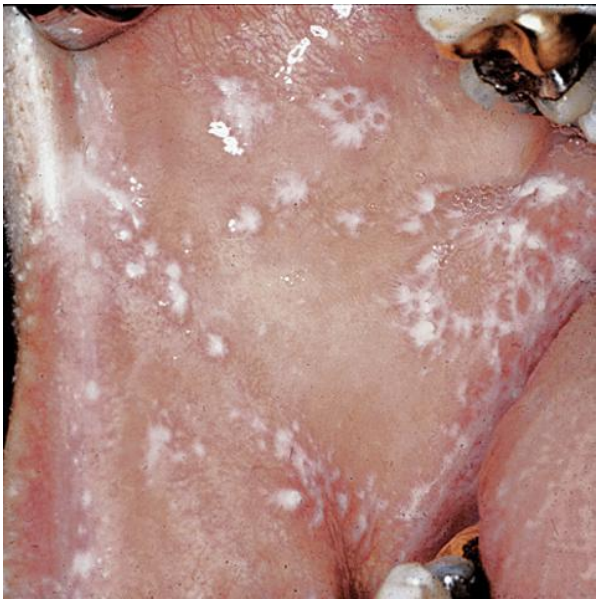

Fig. 18-17 Oral lichen planus. Papular lesion of right buccal mucosa.

A variety of clinical appearances is characteristic of OLP. These include:

- Papular (Fig. 18-17)
- Reticular (Figs. 18-18, 18-19)
- Plaque-like (Fig. 18-20)
- Erythematous (atrophic) (Figs. 18-21, 18-22, 18-23, 18-24, 18-25)
- Ulcerative (Figs. 18-22, 18-26)
- Bullous (Fig. 18-27).

The simultaneous presence of more than one type of lesion is common (Thorn *et al*. 1988). The most characteristic clinical manifestations of the disease and the basis of the clinical diagnosis are white papules (Fig. 18-17) and white striations (Figs. 18-18, 18-19,

Fig. 18-18 Oral lichen planus. Reticular lesion of lower lip mucosa. The white striations are denoted Wickham's striae.

Fig. 18-21 Oral lichen planus. Erythematous lesions of facial maxillary and mandibular gingiva. Such lesions were previously termed desquamative gingivitis. Note that the margin of the gingiva has a normal color in the upper incisor region, which distinguishes the lesions from plaque-induced gingivitis.

Fig. 18-28 Same patient as shown in Fig. 18-25 after modified toothbrushing procedure with no traumatic action on the marginal gingiva. There is no longer pain.

Fig. 18-29 Same patient as shown in Fig. 18-26 after periodontal treatment and extraction of teeth with deep pockets. An individual oral hygiene program, which ensured gentle, meticulous plaque removal, has been used by the patient for 3 months. The erythematous/ulcerative lesions are now healed and there are no more symptoms.

reticular, and plaque-type lesions usually do not give rise to significant symptoms, whereas erythematous and ulcerative lesions are associated with moderate-to-severe pain, especially in relation to oral hygiene procedures and eating. Any area of the oral mucosa may be affected by OLP, but the lesions often change in clinical type and extent over the years. Such changes

may imply the development of plaque-type lesions, which are clinically indistinguishable from oral leukoplakia. This may give rise to a diagnostic problem if other lesions more characteristic of OLP have disappeared (Thorn *et al*. 1988).

A characteristic histopathologic feature in OLP is a subepithelial, band-like accumulation of lymphocytes and macrophages characteristic of a type IV hypersensitivity reaction (Eversole *et al*. 1994). The epithelium shows hyperortho- or hyperparakeratinization and basal cell disruption with transmigration of lymphocytes into the basal and parabasal cell layers (Eversole 1995). The infiltrating lymphocytes have been identified as CD4- and CD8-positive cells (Buechner 1984; Walsh *et al*. 1990; Eversole *et al*. 1994). Other characteristic features are Civatte bodies, which are dyskeratotic basal cells. Common immunohistochemical findings of OLP lesions are fibrin in the basement membrane zone, and deposits of IgM, C3, C4, and C5 may also be found. None of these findings is specific for OLP (Schiødt *et al*. 1981; Kilpi *et al*. 1988; Eversole *et al*. 1994).

The subepithelial inflammatory reaction in OLP lesions is presumably due to an unidentified antigen in the junctional zone between the epithelium and connective tissue or to components of basal epithelial cells (Holmstrup & Dabelsteen 1979; Walsh *et al.* 1990; Sugerman *et al*. 1994). A lichen planus-specific antigen in the stratum spinosum of skin lesions has been described (Camisa *et al*. 1986), but does not appear to play a significant role in oral lesions since it is rarely identified there. It is still an open question whether OLP is a multivariate group of etiologically diverse diseases with common clinical and histopathologic features or a disease entity characterized by a type IV hypersensitivity reaction to an antigen in the basement membrane area. The clinical diagnosis is based on the presence of papular or reticular lesions. The diagnosis may be supported by histopathologic findings of hyperkeratosis, degenerative changes of basal cells, and subepithelial inflammation dominated by lymphocytes and macrophages (Holmstrup 1999).

The uncertain background of OLP results in several border zone cases of so-called oral lichenoid lesions (OLLs), a final diagnosis for which is difficult to establish (Thornhill *et al*. 2006). The most common OLLs are probably lesions in contact with dental restorations (Holmstrup 1991) (see later in this chapter). Other types of OLL are associated with various types of medications, including antimalarials, quinine, quinidine, non-steroidal anti-inflammatory drugs, thiazides, diuretics, gold salts, penicillamine, and beta-blockers (Scully *et al*. 1998a). Graft-versus-host reactions are also characterized by a lichenoid appearance (Fujii *et al*. 1988) and a group of OLLs is associated with systemic diseases including liver disease (Fortune & Buchanan 1993; Bagan *et al*. 1994; Carrozzo *et al*. 1996). This appears to be particularly evident in Southern Europe and Japan where hepatitis C has been found in 20–60% of OLL cases (Bagan *et al*. 1994; Gandolfo *et al*. 1994; Nagao *et al*. 1995).

Several follow-up studies have demonstrated that OLP is associated with increased development of oral cancer, the frequency of cancer development being in the range of 0.5–2% (Holmstrup *et al.* 1988; Mattson *et al*. 2002; Ingafou *et al*. 2006; Mignogna *et al*. 2007).

When gingiva is involved, the most important part of the therapeutic regimen is atraumatic meticulous plaque control, which results in significant improvement in many patients (Holmstrup *et al*. 1990) (Figs. 18-25, 18-26, 18-28, 18-29). Individual oral hygiene procedures with the purpose of effective plaque removal without traumatic influence on the gingival tissue should be established for all patients with symptoms. In cases of persistent pain, typically associated with atrophic and ulcerative lesions, antifungal treatment may be necessary if the lesions host yeast, which is the case in 37% of OLP cases (Krogh *et al*. 1987). In painful cases who have not responded to the treatment above, topical corticosteroids, preferably in a paste or an ointment, should be used three times daily for a number of weeks. However, in such cases, relapses are very common, which is why intermittent periods of treatment may be needed over an extended period of time.

Pemphigoid

Pemphigoid is a group of disorders in which autoanibodies towards components of the basement membrane result in detachment of the epithelium from the connective tissue. Bullous pemphigoid predominantly affects the skin, but oral mucosal involvement may occur (Brooke 1973; Hodge *et al*. 1981). If only mucous membranes are affected, the term benign mucous membrane pemphigoid (BMMP) is often used. The term cicatricial pemphigoid is also used to describe subepithelial bullous disease limited to the mouth or eyes and infrequently other mucosal areas. This term is problematic for the oral lesions, because usually oral lesions do not result in scarring, whereas this is an important concern for ocular lesions (Scully *et al*. 1998b). It is now evident that BMMP comprises a group of disease entities characterized by an immune reaction involving autoantibodies directed against various basement membrane zone antigens (Scully & Laskaris 1998). These antigens have been identified as hemidesmosome or lamina lucida components (Leonard *et al*. 1982, 1984; Manton & Scully 1988; Domloge-Hultsch *et al*. 1992, 1994), and sera from patients with oral lesions have been shown to recognize the alpha-6 integrin subunit (Rashid *et al*. 2006). In addition, complement-mediated cell destructive processes may be involved in the pathogenesis of the disease (Eversole 1994). The trigger mechanisms behind these reactions, however, have not yet been revealed.

The majority of affected patients are female with a mean age at onset of 50 years or over

Fig. 18-30 Benign mucous membrane pemphigoid affecting the attached gingiva of both jaws. The lesions are erythematous and resemble erythematous lichen planus lesions. They result in pain associated with oral procedures, including eating and oral hygiene procedures.

Fig. 18-31 Benign mucous membrane pemphigoid with intact and ruptured gingival bulla.

Fig. 18-32 Benign mucous membrane pemphigoid with hemorrhagic gingival bulla. The patient uses chlorhexidine for daily plaque reduction.

Fig. 18-33 Benign mucous membrane pemphigoid. Eye lesion with scar formation due to coalescence of palpebral and conjunctival mucosa.

(Shklar & McCarthy 1971). Oral involvement in BMMP is almost inevitable and usually the oral cavity is the first site of disease activity (Silverman *et al*. 1986; Gallagher & Shklar 1987). Any area of the oral mucosa may be involved in BMMP, but the main manifestation is desquamative lesions of the gingiva presenting as intensely erythematous attached gingiva (Laskaris *et al*. 1982; Silverman *et al*. 1986; Gallagher & Shklar 1987) (Fig. 18-30). The inflammatory changes, as always when not caused by plaque, may extend over the entire gingival width and even over the mucogingival junction. Rubbing the gingiva may precipitate bulla formation (Dahl & Cook 1979). This is denoted a positive Nicholsky sign and is caused by the destroyed adhesion of the epithelium to the connective tissue. The intact bullae are often clear to yellowish or they may be hemorrhagic (Figs. 18-31, 18-32). This, again, is due to the separation of epithelium from connective tissue at the junction, resulting in exposed vessels inside the bullae. Usually, the bullae rupture rapidly leaving fibrin-coated ulcers. Sometimes, tags of loose epithelium can be found due to rupture of bullae. Other mucosal surfaces may be involved in some patients. Ocular lesions are particularly important because scar formation can result in blindness (Williams *et al.* 1984) (Fig. 18-33).

The separation of epithelium from connective tissue at the basement membrane area is the main diagnostic feature of BMMP. A non-specific inflammatory reaction is a secondary histologic finding. In addition, immunohistochemical examination can help distinguish BMMP from other vesiculobullous diseases, in particular pemphigus, which is life threatening. Deposits of C3, IgG, and sometimes

Fig. 18-34 Pemphigus vulgaris. Initial lesion resembling recurrent aphthous stomatitis.

Fig. 18-35 Pemphigus vulgaris. Erosions of soft palatal mucosa. The erosive lesions are due to loss of the superficial part of the epithelium, leaving the connective tissue covered only by the basal cell layers.

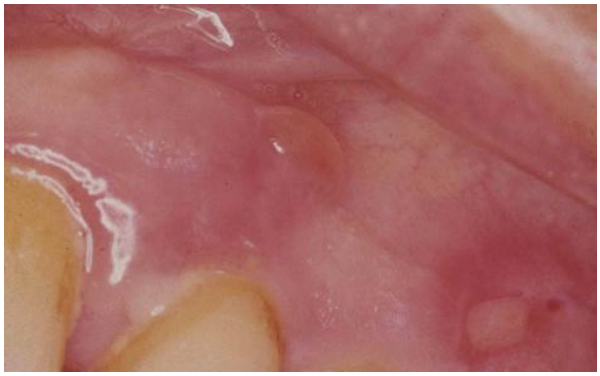

Fig. 18-36 Pemphigus vulgaris. Intact and ruptured gingival bullae.

other immunoglobulins as well as fibrin are found at the basement membrane zone in the vast majority of cases (Laskaris & Nicolis 1980; Daniels & Quadra-White 1981; Manton & Scully 1988). It is important to involve perilesional tissue in the biopsy because the characteristic features may have been lost within lesional tissue (Ullman 1988). Circulating immunoglobulins are not always found in BMMP by indirect immunofluorescence (Laskaris & Angelopoulos 1981). However, a study has shown that 75% of 20 patients with oral pemphigoid phenotype without scarring possessed circulating autoantibodies against the BP180 molecule, indicating a prominent role for this protein as a target antigen in this type of pemphigoid with only oral lesions (Calabresi *et al*. 2007).

Therapy consists of professional atraumatic plaque removal and individual instruction in gentle, but careful, daily plaque control, eventually supplemented with daily use of chlorhexidine and/or topical corticosteroid application if necessary. As for all the chronic inflammatory oral mucosal diseases, oral hygiene procedures are very important and controlling the infection from plaque bacteria may result in a considerable reduction of disease activity and symptoms. It is also important to prevent the development of attachment loss due to periodontitis in those patients with difficulties in maintaining oral hygiene (Tricamo *et al*. 2006). However, the disease is chronic in nature and formation of new bullae is inevitable in most patients. Topical corticosteroids, preferably applied as a paste at night, temper the inflammatory reaction.

Pemphigus vulgaris

Pemphigus is a group of autoimmune diseases characterized by formation of intraepithelial bullae in skin and mucous membranes. The group comprises several variants of which pemphigus vulgaris (PV) is the most common and most serious (Barth & Venning 1987).

Individuals of a Jewish or Mediterranean background are more often affected by PV than others. This is an indication of a strong genetic background to the disease (Pisanti *et al*. 1974). The disease may occur at any age, but is typically seen in the middle-aged or elderly. It presents with widespread bulla formation, often including large areas of skin, and if left untreated the disease is life threatening. Intraoral onset of the disease with bulla formation is very common and lesions of the oral mucosa, including the gingiva, are frequently seen. Early lesions may resemble aphthous ulcers (Fig. 18-34), but widespread erosions are common at later stages (Fig. 18-35). Gingival involvement may present as painful desquamative lesions or as erosions or ulcerations, which are the remains of ruptured bullae (Fig. 18-36). Such lesions may be indistinguishable from BMMP (Zegarelli & Zegarelli 1977; Sciubba 1996). Since the bulla formation is located in the spinous cell layer, the chance of seeing an intact bulla is even more reduced than in BMMP. Involvement of other mucous membranes is common (Laskaris *et al*. 1982). The ulcers heal slowly, usually without scar formation, and the disease runs a chronic course with recurring bulla formation (Zegarelli & Zegarelli 1977).

Diagnosis of PV is based on the characteristic histologic feature of intraepithelial bulla formation due to destruction of desmosomes resulting in acantholysis. The bullae contain non-adhering free epithelial cells, denoted Tzank cells, which have lost their intercellular bridges (Coscia-Porrazzi *et al*. 1985;

Nishikawa *et al*. 1996). Mononuclear cells and neutrophils dominate the associated inflammatory reaction. Immunohistochemistry reveals pericellular epithelial deposits of IgG and C3. Circulating autoantibodies against interepithelial adhesion molecules are detectable in serum samples of most patients, but at the initial stage of the intraoral disease, antiepithelial antibody may not be elevated (Melbye *et al*. 1987; Manton & Scully 1988; Lamey *et al*. 1992; Lever & Schaumburg-Lever 1997). The background to bulla formation in PV is damage to the intercellular adhesion caused by autoantibodies to cadherin-type epithelial cell adhesion molecules (desmoglein 1 and 3) (Nousari & Anhalt 1995; Nishikawa *et al*. 1996; Lanza *et al*. 2006). The mechanism by which these molecules trigger the formation of autoantibodies has not yet been established.

Immediate referral of patients with PV to a dermatologist or internal medicine specialist is important because when recognized late, the disease can be fatal, although systemic corticosteroid therapy can presently treat most cases. Supplementary local treatment consists of gentle plaque control and professional cleaning, as mentioned for the chronic inflammatory oral mucosal diseases earlier. Sometimes, additional topical corticosteroid application is needed to control the intraoral disease activity.

Fig. 18-37 Erythema multiforme with crust formation of the vermilion border of the lower lip.

Fig. 18-38 Erythema multiforme with ulceration covered by heavy fibrin exudate.

Erythema multiforme

Erythema multiforme (EM) is a reactive acute, sometimes recurrent, vesiculobullous disease affecting mucous membranes and skin. A general malaise often precedes the lesions. The spectrum of the disease is from a self-limited, mild, exanthematic, cutaneous variant with minimal oral involvement to a progressive, fulminating, severe variant with extensive mucocutaneous epithelial necrosis. The latter form of the disease has been described as Stevens–Johnson syndrome, with widespread mucous membrane lesions, that is oral, ocular, and genital, in addition to skin lesions (Lozada-Nur *et al*. 1989; Assier *et al*. 1995; Bystryn 1996; Ayangco & Rogers 2003). The multilocular entity has to be differentiated from other disorders such as Reiter's and Behçet's syndromes, which also affect the eyes, the oral mucosa, and often the genitalia. The pathogenesis of EM remains unknown, but the disease appears to be a cytotoxic immune reaction against keratinocytes (Ayangco & Rogers 2003) precipitated by a wide range of factors, including HSV (Lozada & Silverman 1978; Nesbit & Gobetti 1986; Ruokonen *et al*. 1988; Miura *et al*. 1992; Aurelian *et al*. 1998), *Mycoplasma pneumoniae* (McKellar & Reade 1986; Stutman 1987), and various drugs (Bottiger *et al*. 1975; Gebel & Hornstein 1984; Kauppinen & Stubb 1984).

EM may occur at any age but most frequently affects young individuals. It may or may not involve the oral mucosa, but oral involvement occurs in as many as 25–60% of cases (Huff *et al*. 1983); sometimes it is the only involved site. The characteristic oral lesions comprise swollen lips often with extensive crust formation of the vermilion border (Fig. 18-37). The basic lesions, however, are bullae that rupture and leave extensive ulcers, usually covered by heavy yellowish fibrinous exudates sometimes described as pseudomembranes (Figs. 18-38, 18-39). Such lesions

Fig. 18-39 Erythema multiforme. Fibrin-coated ulcerations of the ventral surface of the tongue and lower lip.

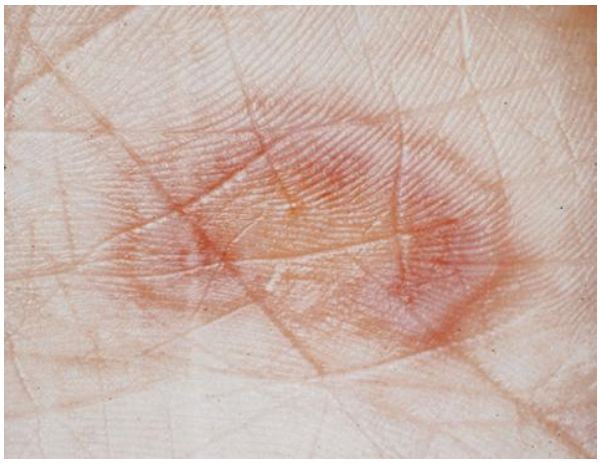

Fig. 18-40 Erythema multiforme. Skin lesion with characteristic iris appearance. A central bulla is surrounded by a blanched halo within an erythematous zone.

Fig. 18-41 Gingival discoid lupus erythematosus lesion. A central erythematous area with small white dots is surrounded by delicate white striae.

may also involve the buccal mucosa and gingiva (Huff *et al.* 1983; Lozada-Nur *et al*. 1989; Scully *et al*. 1991; Barrett *et al.* 1993). The skin lesions are characteristic due to the iris appearance with a central bulla surrounded by a blanched halo within an erythematous zone (Fig. 18-40). Similar intraoral lesions do occur but they are infrequent. The disease is usually self-limiting but recurrences are common. Healing of the lesions may take several weeks (Fabbri & Panconesi 1993).

The histopathology of EM shows intra- or subepithelial separation of the epithelium from connective tissue with perivascular inflammation (Reed 1985). Immunohistochemical findings are non-specific and in most instances the diagnosis relies on the clinical findings.

Although periodontal lesions are not the most frequent intraoral manifestation, they can sometimes pose a differential diagnostic problem. The typical crusty ulcerations of the vermilion border and the heavy fibrin exudates covering intraoral lesions are indicative of EM, and therefore are sometimes denoted erythema multiforme exudativum. The mucosal ulcerations may take weeks to heal and they are painful (Lozada-Nur *et al*. 1989).

As for any intraoral ulcerations, gentle plaque control and professional cleaning are mandatory. The treatment often involves systemic corticosteroids, but topical treatment may be effective in cases with minor lesions. Cases of recurrent EM caused by herpes infection may require prophylactic use of 400 mg acyclovir twice daily.

Lupus erythematosus

Lupus erythematosus (LE) is a group of autoimmune connective tissue disorders in which autoantibodies form to various cellular constituents, including nucleus and cytoplasmic membrane. All parts of the body may be affected, and the disease is much more prevalent among women than among men. The etiology of LE remains unknown, but deposits of antigen–antibody complexes appear to play a role in the tissue damage characteristic of the disease (Schrieber & Maini 1984). The prevalence of LE has been estimated at 0.05% (Condemi 1987).

There are two major traditional forms: discoid LE (DLE) and systemic LE (SLE), which may involve a range of organ systems, including the kidney, heart, central nervous system, vascular system, and bone marrow. Two new forms, acute and subacute cutaneous LE, have more recently been added to the classification, and represent different degrees of disease activity and increased risk of development of SLE (Wouters *et al*. 2004).

DLE is a mild chronic form, which involves skin and mucous membranes, sometimes including the gingiva as well as other parts of the oral mucosa (Schiødt 1984a, b). The typical lesion presents as a central atrophic area with small white dots surrounded by irradiating fine white striae with a periphery of telangiectasia (Fig. 18-41). The lesions can be ulcerated or clinically indistinguishable from leukoplakia or erythematous OLP (Fig. 18-42) (Schiødt 1984b). Sometimes patients present with brownish gingival lesions, which are a side effect of antimalarial drugs prescribed to these patients as part of their treatment (Fig. 18-43). Eight percent of patients with DLE develop SLE, and ulcerations may be a sign of SLE, which has a 25–40% prevalence of oral lesions (Schiødt 1984a; Pisetsky 1986; Jonsson *et al*. 1988). The characteristic Bordeaux-colored "butterfly" skin lesions are photosensitive, scaly, erythematous macules located on the bridge of the nose and the cheeks (Standefer & Mattox 1986). The systemic type, which can still be fatal because of nephrologic and hematologic complications, also shows skin lesions on the face, but they tend to spread over the entire body.

Diagnosis is based on clinical and histopathologic findings. The epithelial changes, characteristic of oral LE lesions, are hyperkeratosis, keratin plugging,

Fig. 18-42 Gingival plaque-type discoid lupus erythematosus lesion resembling frictional keratosis and leukoplakia.

Fig. 18-43 Antimalarial drugs may result in brownish gingival discoloration. This is a patient with discoid lupus erythematosus receiving an antimalarial drug, chloroquine, as part of the treatment regimen.

and variation in epithelial thickness, as well as liquefaction degeneration of basal cells and increased width of the basement membrane. The subepithelial connective tissue harbors inflammation, sometimes resembling OLP, but often with a less distinct band-shaped pattern (Schiødt & Pindborg 1984). Immunohistochemical investigation reveals deposits of various immunoglobulins, C3, and fibrin along the basement membrane (Reibel & Schiødt 1986).

Systemic corticosteroid and other anti-inflammatory treatment regimens are required for SLE. Additional topical treatment is sometimes needed for the resolution of symptomatic intraoral lesions.

Drug-induced mucocutaneous disorders

A number of drugs cause reverse effects in the oral mucosa. Best known in the periodontal field is gingival hyperplasia related to intake of phenytoin, cyclosporine, and nifedipine. Because these lesions to some extent are plaque dependent, they are reviewed in Chapter 19. Other types of drugs may give rise to EM, as mentioned above.

Fig. 18-44 Drug-induced stomatitis sometimes involves the gingiva. This is a mucosal lesion due to azathioprine, which is an antimetabolite used for immunosuppression.

Several other drugs may be associated with adverse effects that include lesions of the oral mucosa. An example is azathioprine, which is an antimetabolite used for immunosuppression in the treatment of autoimmune and other diseases, and to prevent rejection of transplants. Its mode of action is through inhibition of purine base synthesis, resulting in suppression of nucleic acid and protein synthesis, whereby the immune response is inhibited at various stages. Rapidly proliferating tissues such as the bone marrow, hair follicles, and gastrointestinal and oral mucosa may show side effects, for example oral ulceration, including of the gingiva. Other drugs frequently causing stomatitis are antineoplastic drugs used in cancer chemotherapy. Methotrexate is a cytostatic drug sometimes used in the treatment of leukemia and rheumatoid arthritis. Epithelial atrophy, superficial sloughing, intense erythema, and ulceration are characteristic findings in the oral mucosa of patients with adverse effects to chemotherapy (Pindborg 1992) (Fig. 18-44). The ulcerative lesions are frequent portals of entry for microorganisms from the mouth, and thereby are often sources of serious systemic infection in patients with suppression of the bone marrow and reduced defense systems against infection. Professional plaque removal, mouth rinsing with 0.1% chlorhexidine, and a prophylactic antibiotic regimen are important in such patients (Sonis 1998; Holmstrup & Glick 2002).

Allergic reactions

Allergic manifestations in the oral mucosa are uncommon. Several mechanisms may be involved in allergy, which is an exaggerated immune reaction. Oral mucosal reactions may be type I reactions (immediate type), which are mediated by IgE, or more often they are type IV reactions (delayed type) mediated by T cells. The rare intraoral occurrence may be due to the fact that much higher concentrations of allergen are required for an allergic reaction to occur in the oral mucosa than in skin and other surfaces (Amlot *et al*. 1985; Lüders 1987; Holmstrup 1999). This section

Fig. 18-45 Lichenoid contact lesion of the left buccal mucosa due to type IV hypersensitivity to mercury. The lesion is confined to the zone of contact with the amalgam fillings. These lesions usually recover after replacement of the mercury-containing fillings with composites or other materials devoid of allergy-provoking components.

Fig. 18-46 Diffuse gingivitis and cheilitis due to contact allergy to a flavor additive in dentifrice.

covers allergies to dental restorative materials, toothpastes, mouthwashes, chewing gum, and food.

Reactions to dental restorative materials

The clinical manifestation of type IV allergy (contact allergy) occurs after a period of 12–48 hours following contact with the allergen. The effects on oral mucosa have been denoted contact lesions and prior contact with the allergen resulting in sensitization is a prerequisite for these reactions to occur (Holmstrup 1991). Oral mucosal reactions to restorative materials include reactions to mercury, nickel, gold, zinc, chromium, palladium, and acrylics (Ovrutsky & Ulyanow 1976; Zaun 1977; Bergman *et al*. 1980; Council on Dental Materials, Instruments and Equipment Workshop 1984; Fisher 1987). The lesions, which may infrequently affect the gingiva have clinical similarities with those for OLP, which is why they are denoted OLLs (see earlier in this chapter) or oral leukoplakia (Fig. 18-45). They are reddish or whitish, sometimes ulcerated lesions, but one of the crucial diagnostic observations is that the lesions resolve after removal of the offending material. Additional patch testing to identify the exact allergen gives supplementary information, but for dental amalgam it has been shown that there is no obvious correlation between the result of an epicutaneous patch test and the clinical result after removal of the fillings (Skoglund 1994). A clinical manifestation confined to the area of contact with the offending restorative material and the result after replacing this material indicate the diagnosis (Holmstrup 1999).

Reactions to oral hygiene products, chewing gum, and food

Toothpastes, mouth washes, and chewing gum

Contact allergy rarely occurs after the use of toothpastes (Sainio & Kanerva 1995; Skaare *et al*. 1997) and mouth washes (Sainio & Kanerva 1995). The constituents responsible for the allergic reactions may be flavor additives, for instance carvone and cinnamon (Drake & Maibach 1976) or preservatives (Duffin & Cowan 1985). These flavoring additives may be used also in chewing gum and result in similar forms of gingivostomatitis (Kerr *et al*. 1971). The clinical manifestations of allergy include a diffuse, fiery red edematous gingivitis, sometimes with ulcerations or whitening (Fig. 18-46). The labial, buccal, and tongue mucosa may be similarly affected, and cheilitis may also be seen. These characteristic clinical manifestations form the basis of the diagnosis, which may be supported by resolution of the lesions after stopping use of the allergen-containing agent (Holmstrup 1999).

Foods

The gastrointestinal tract is the largest immunologic organ in the body. It is constantly bombarded by a myriad of dietary proteins. Despite the extent of protein exposure, very few patients develop food allergies due to development of oral tolerance to these antigens (Chehade & Mayer 2005). Allergic reactions attributable to food may manifest both as type I and type IV reactions. Type I reaction with severe swelling has been described after intake of food components such as peanuts and pumpkin seed. Birch pollen allergy is associated with some types of oral mucosa allergy, and >20% of patients with oral allergy may be hypersensitive to kiwi, peach, apple, chestnut, and salami (Yamamoto *et al*. 1995; Antico 1996; Asero et al. 1996; Liccardi *et al*. 1996; Rossi *et al*. 1996; Helbling 1997; Wutrich 1997). Another food allergen that can result in gingivitis or gingivostomatitis is red pepper (Serio *et al*. 1991; Hedin *et al*. 1994). Unless it has been demonstrated that the lesions resolve after removal of the allergen, the diagnosis is difficult to establish.

Other gingival manifestations of systemic conditions

Gastrointestinal diseases: Crohn's disease

Crohn's disease is characterized by chronic granulomatous infiltrates of the wall of the last ileal loops, but any part of the gastrointestinal tract can be affected. As the oral cavity is part of the gastrointestinal tract,

Fig. 18-47 A frequent oral finding in patients with Crohn´s disease is mucosal foldings, usually located in the buccal or labial sulcus. Such lesions may be the first clinical finding that leads to the diagnosis of the disease. Histopathologic examination of biopsies from these foldings reveals epitheloid cell granulomas. The foldings are characteristic for the other types of orofacial granulomatosis as well.

Fig. 18-48 Granulomatous gingival hyperplasia may be due to sarcoidosis, which is one of the orofacial granulomatoses; others are Crohn's disease and Melkersson–Rosenthal syndrome.

it is not surprising that Crohn's disease can occur from the rectum to the lips.

The number of reports of lesions involving the periodontium is limited (van Steenberghe *et al*. 1976), which is probably related to a tradition by many clinicians of using the term aphthous lesions for any ulcerative disease of the oral mucosa. The oral lesions have striking similarity to those of the intestinal tract, as revealed by rectoscopy, that is irregular long ulcerations with elevated borders with a cobblestone appearance. Usually, the periodontal lesions appear after the diagnosis has been established on the basis of the intestinal involvement, but sometimes the oral lesions are the first findings that lead to diagnosis. Characteristic clinical findings are mucosal foldings of the buccal or labial sulcus (Fig. 18-47). Exacerbations of the oral lesions appear in parallel with those of the intestine. An increased risk of periodontal destruction has been reported to be associated with a defective neutrophil function (Lamster *et al*. 1982).

The term orofacial granulomatosis has been used for a collective diagnosis of Crohn's disease, Melkersson–Rosenthal syndrome, and sarcoidosis, because these diseases show the same histopathologic features: non-caseating, epitheloid cell granulomas in the affected tissue. Rarely, all three diseases may present with gingival lesions, characterized by swellings (Pindborg 1992; Mignogna *et al*. 2001) and sarcoidosis, which is sometimes present as a fiery red granular gingival overgrowth (Fig. 18-48). Of 45 cases of oral sarcoidosis, 13% had gingival lesions (Blinder *et al*. 1997). A study of 35 patients with orofacial granulomatosis demonstrated ileal and colonic abnormalities in 54%, and granulomas were revealed in gut biopsies of 64% of the patients. Intestinal abnormality was significantly more likely if the age of onset was <30 years (Sanderson *et al*. 2005).

Local treatment consists of intralesional steroid injection (Mignogna *et al*. 2004; El-Hakim & Chauvin 2004) or paste application daily or twice daily during painful exacerbations, and meticulous oral hygiene to reduce additional inflammation of the oral cavity. Treatment of any inflammatory condition in the oral region, including periodontitis, periapical inflammation, and even mucosal lesions due to hypersensitivity to restorative dental materials, is important for resolution in some cases (Guttman-Yassky *et al*. 2003). An important differential diagnosis is a gingival lesion presumably associated with mouth breathing. This type of lesion, which may resemble those of orofacial granulomatosis, is confined to the area between the maxillary canine teeth. The erythematous surface has a dry and shiny appearance, and the lesion is primarily seen in patients with impaired lip closure. Deposition of bacteria on the facial side of the front teeth and the gingiva, facilitated by mouth breathing, may play a role in the development of this type of gingival lesion, which may also be seen in conjunction with lichenoid lesions of the mucosal side of the upper lip (Bäckman & Jontell 2007).

Hematologic disorders: Leukemia

Leukemia is a malignant hematologic disorder with abnormal proliferation and development of leukocytes and their precursors in blood and bone marrow. It can involve any of the subsets of leukocytes, polymorphonuclear leukocytes, lymphocytes or monocytes. Normal hematopoiesis is suppressed and, in most cases of leukemia, the white blood cells appear in the circulating blood in immature forms. The leukemic cell proliferation at the expense of normal hematopoietic cell lines causes bone marrow failure and a depressed blood cell count. As a consequence of the inability to produce sufficient functional white blood cells and platelets, death may result from infection or bleeding associated with neutropenia and thrombocytopenia, respectively.

The classification of leukemia is based on its course, acute or chronic, and origin of the cells involved. The basic forms are: acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML). Acute leukemias have an aggressive course, resulting in death within 6 months if untreated. They are rather rare and patients are usually either under 20 or over 60 years

Fig. 18-49 Acute myelogenous leukemia with extensive swelling of the gingiva.

Fig. 18-50 Acute lymphocytic leukemia with gingival ulceration in a child.

Fig. 18-51 Acute myelogenous leukemia with petechiae and swelling of the gingiva. This patient had several episodes of spontaneous bleeding from the gingiva, which prevented oral hygiene procedures from being undertaken.

of age. Chronic leukemias, of which the lymphocytic form is the most common, have less pronounced bone marrow failure and a more indolent course, usually lasting several years. They occur during adulthood and normally after the age of 40 years. Whereas the peripheral granulocyte count is markedly elevated in chronic leukemia, it may be elevated, decreased or normal in acute leukemia (McKenna 2000).

Gingival manifestations in leukemia, which include extensive swelling (Fig. 18-49), ulceration (Fig. 18-50), petecchia (Fig. 18-51), and erythema, are much more common in acute than in chronic forms. Sometimes, the manifestations lead to the diagnosis of leukemia; 69% of patients with acute leukemia had oral signs of leukemia on examination and 33% of the patients had gingival swelling (Pindborg 1992). In another study, gingival swelling was observed in 21% of AML patients, but in no patients with ALL (Meyer *et al*. 2000). In the latter group, on the other hand, 36% showed both gingival erythema and ulcers. In leukemic children, only 10–17% appear to have gingival swelling (Curtis 1971; Michaud *et al*. 1977). The pronounced gingival swelling seen in patients with leukemia is mostly due to plaque-induced inflammation, since stringent plaque control appears to resolve the swelling (Barrett 1984); it may also be due to the presence of leukemic infiltrates, although this has been reported to be an uncommon feature of patients with leukemia (Barrett 1984). Gingival bleeding due to secondary thrombocytopenia is a common sign in patients with leukemia. It has been reported as the initial sign in 17.7% of patients with acute leukemias and in 4.4% of patients with chronic forms (Lynch & Ship 1967).

In general, the periodontal treatment of patients with leukemia is important; it aims to reduce plaque as a source of bacteremia and damage to the periodontal tissues, both during the disease course and during periods of chemotherapy. In such periods, potentially pathogenic bacteria occur in plaque simultaneously with granulocytopenia (Peterson *et al*. 1990). The reduction of periodontal inflammation may also prevent episodes of gingival bleeding. As with many other patients, chemical plaque control in combination with mechanical debridement appears to be most effective and is the preferred method of periodontal therapy in patients with leukemia (Holmstrup & Glick 2002). However, the increased tendency to bleeding in many of these patients may necessitate the use of alternative methods to toothbrushing. A study of professional plaque removal preceding mouth rinsing with 0.1% chlorhexidine in patients with AML showed that the additional initial removal of plaque and calculus was more effective in reducing gingival inflammation than mouth rinsing with chlorhexidine alone (Bergman *et al*. 1992). A 1-day antibiotic prophylaxis regimen with a combination of piperacillin and netilmicin was given prior to and after the mechanical debridement. Periodontal treatment always involves a close cooperation with the medical department or specialist responsible for coordination of the patient's treatment.

Traumatic lesions

The background to traumatic lesions of the oral tissues may be self-inflicted, iatrogenic or accidental. Chemical as well as physical and thermal injuries may affect the periodontium (Armitage 1999).

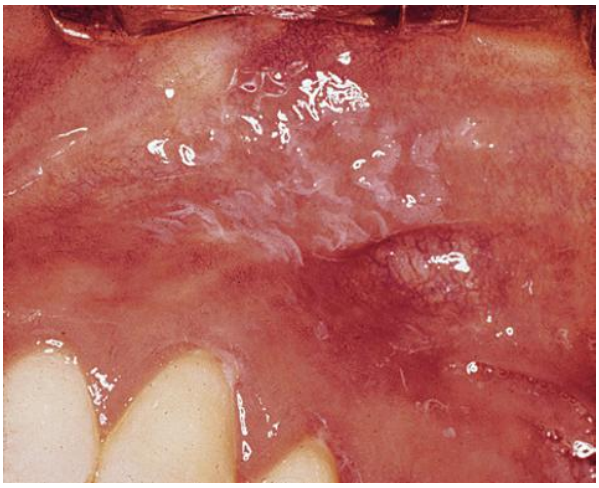

Fig. 18-52 Chlorhexidine-induced mucosal desquamation. This is a reversible type of lesion, which is completely normalized after stopping chlorhexidine use.

Fig. 18-53 Frictional keratosis due to violent toothbrushing. Note the cervical abrasion of adjacent teeth.

Fig. 18-54 Gingival wounding due to improper toothbrushing. Note the characteristic horizontal extension of the lesion, affecting the most prominent part of the tooth arch.

Fig. 18-55 Gingival wounding due to improper toothbrushing. Note the characteristic horizontal extension of the lesion and the uninflamed, unaffected interdental papillae.

Chemical injury

Surface etching by various chemical products with toxic properties may result in mucosal reactions, including reactions of the gingiva. Chlorhexidine-induced mucosal desquamation (Fløtra *et al*. 1971; Almquist & Luthman 1988) (Fig. 18-52), acetylsalicylic acid burn (Najjar 1977), cocaine burn (Dello Russo & Temple 1982), and slough due to dentifrice detergents are examples of such reactions (Muhler 1970). These lesions are reversible and resolve after quitting the toxic influence. Chemical injury to the gingival tissue may be caused by incorrect use of caustics by dentists. Paraformaldehyde used for pulp mummification may give rise to inflammation and necrosis of the gingival tissue if the cavity sealing is insufficient (Di Felice & Lombardi 1998). Usually, the diagnosis is obvious from the clinical findings and the patient history.

Physical injury

Oral hygiene agents and inexpedient procedures can be injurious to the gingival tissues. If physical trauma is limited, the gingival response is hyperkeratosis, resulting in a white leukoplakia-like, frictional keratosis (Fig. 18-53). In cases of more violent trauma, the damage varies from superficial gingival laceration to major loss of tissue resulting in gingival recession (Axéll & Koch 1982; Smukler & Landsberg 1984). Abrasiveness of dentifrice, strong brushing force, and horizontal movement of the toothbrush contribute to the gingival injury even in young patients. Characteristic findings in these patients are extremely good oral hygiene, cervical tooth abrasion, and unaffected tops of the interdental papillae at the site of injury (Figs. 18-54, 18-55, 18-56, 18-57). The condition has been termed traumatic ulcerative gingival lesion (Axéll & Koch 1982). Dental flossing may also cause gingival ulceration and inflammation

Fig. 18-56 Severe gingival recession and wounding due to improper toothbrushing. Note the unaffected interdental papillae.

Fig. 18-57 Healing of the lesion shown in Fig. 18-56. The damage to the periodontal tissues is severe, leaving extended gingival recession.

Fig. 18-58 Lesions after dental flossing are common and sometimes result in permanent fissuring of the gingival tissue.

primarily affecting the top of the interdental papillae (Fig. 18-58). The prevalence of such findings is unknown (Gillette & Van House 1980). Diagnosis of physical injuries is based on the clinical findings. An important differential diagnosis is necrotizing gingivitis (Blasberg *et al.* 1981) (see Chapter 22). The latter normally reveals itself as a necrotic gingival margin and interdental papillae, while brushing trauma leads to ulceration of a few millimeters of the gingival margin.

Self-inflicted physical injury to the gingival tissues can occur; sometimes these lesions are termed gingivitis artefacta. The lesions often show ulceration of

Fig. 18-59 Self-inflicted gingival recession with an ulcerated margin due to this 7-year-old boy's scratching with his fingernail.

Fig. 18-60 Self-inflicted gingival ulceration of the palatal gingiva of the upper right incisor region in the same boy as shown in Fig. 18-59. This lesion was also caused by fingernail scratching.

the gingival margin and this is often associated with recession. Such lesions are most common in children and young adults and two-thirds appear to occur in female patients. The lesions, which may be hemorrhagic, are usually produced by picking at or scratching the gingiva with a finger or a fingernail (Fig. 18-59, 18-60). Sometimes the lesions are made by instruments (Pattison 1983). The correct diagnosis is often difficult to establish based on clinical findings, and identification of the cause may be impossible.

Thermal injury

Extensive thermal burns of the oral mucosa are very rare, but minor burns particularly from hot beverages, are seen occasionally. Their site of predilection is the palatal and labial mucosa, but any part of the oral mucosa can be involved, including the gingiva (Colby *et al*. 1961). The area involved is painful and erythematous, and may slough a coagulated surface. Vesicles may also occur (Laskaris 1994) and sometimes the lesions present as ulceration, petechia or erosion (Fig. 18-61). Obviously, the history is important for reaching the correct diagnosis. Common causes are hot coffee, pizza, and melted cheese, but dental treatments involving improper handling of hot hydrocolloid impression material, hot wax or cautery instruments are other causes (Colby *et al*. 1961).

Fig. 18-61 Thermal burn with slight erosion and petechiae of palatal gingiva due to hot coffee intake.

Fig. 18-62 Amalgam tattoo of attached gingiva.

Foreign body reactions

Another type of tissue reaction is established through epithelial ulceration that allows entry of foreign material into the gingival connective tissue. This can happen via abrasion or cutting (Gordon & Daley 1997b), a route of tissue injury, which is best exemplified by the amalgam tattoo (Buchner & Hansen 1980) (Fig. 18-62). Gingival inflammation associated with foreign bodies has been termed foreign body gingivitis. A clinical study of this condition has shown that it often presents as a red or combined red–white painful chronic lesion which is frequently misdiagnosed as lichen planus (Gordon & Daley 1997a). An X-ray microanalysis of foreign body gingivitis showed that most of the identified foreign bodies were of dental material origin, usually abrasives (Gordon & Daley 1997b). Another way in which foreign substances can enter the tissues is self-inflicted injury, for instance due to chewing on sticks or self-induced tattooing (Gazi 1986). It is uncertain whether the inflammatory reaction in such cases is due to a toxic or an allergic reaction.

Chapter 19

Plaque-Induced Gingival Diseases

Angelo Mariotti

Division of Periodontology, Ohio State University, College of Dentistry, Columbus, OH, USA

For almost four millennia the clinical manifestations of gingival diseases have been noted by mankind. Throughout the centuries the notion of cause, effect, and management of these diseases was largely dormant, resulting in a dubious realm of remedies that were dominated by superstition, frequently were subjective, often palliative, sometimes painful, and rarely successful. It was not until the last half of the 20th century that our views about the nature of gingival diseases began to emerge, with pivotal human experiments showing the unmistakable role of dental biofilms in the initiation and progression of gingival inflammation (Löe *et al*. 1965). In the 21st century, we are living in a time of radical shifts of culture and science, one in which evidence-based dentistry increasingly plays a pervasive role in our knowledge regarding gingival diseases.

As more clinical evidence becomes available, the scope and nature of various forms of gingivitis become evident. More specifically, there has been growing acceptance that gingivitis does not represent a single disease but rather a spectrum of diseases that are the outcome of a variety of different processes. It is true that inflammation of the gingiva induced by bacteria is the most common form of gingivitis; however, this has created a bias toward naming all manifestations that affect the gingival tissues (e.g. atrophic, desquamative, neoplastic, etc.) as gingivitis. Although inflammation of the gingival tissues can be induced by a variety of methods (e.g. trauma, chemical agents, temperature extremes, ionizing radiation, viruses, fungi, immune defects, etc.), at this time gingival diseases are considered to be disease entities that are initiated by dental plaque and are restricted to gingival tissues. This chapter will focus on the commonly occurring and diverse family of complex and distinct pathologic entities found within the gingiva that are initiated by dental plaque and that can be influenced by systemic conditions, endogenous hormones, genetic factors, drugs, and malnutrition.

Classification criteria for gingival diseases

Categorization of diseases affecting the gingiva requires an evaluation of patient signs and symptoms, medical and dental histories, a clinical examination that includes the extent, distribution, duration, and physical description of lesions affecting the gingiva, clinical or relative attachment levels, and radiographs. The universal features of gingival diseases include clinical signs of inflammation, signs and symptoms

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Table 19-1 Universal features of gingival diseases.

- Signs and symptoms that are confined to the gingiva
- Presence of dental plaque to initiate and/or exacerbate the severity of the lesion
- Clinical signs of inflammation (enlarged gingival contours due to edema or fibrosis, color transition to a red and/or bluish-red hue, elevated sulcular temperature, bleeding upon stimulation, increased gingival exudate)
- Clinical signs and symptoms associated with stable attachment levels on a periodontium with no loss of attachment or on a stable but reduced periodontium (see Fig.19-8)
- Reversibility of the disease by removing the etiology(ies)
- Possible role as a precursor to attachment loss around teeth

Table 19-2 Common clinical changes from gingival health to gingivitis.

Parameter	Normal gingiva	Gingivitis
Color	Coral pink (correlated to mucocutaneous pigmentation)	Red/bluish-red hue
Contour	Scalloped outline that envelops teeth. Papillary gingiva fills interdental space while marginal gingival forms a knife-edged appearance with tooth surface	Edema blunts marginal tissues leading to loss of knife edge adaptation to tooth and produces bulbous papillary tissues resulting in minimization of tissue scalloping
Consistency	Firm and resilient	Tissue is soft and exhibits pitting edema
Bleeding on provocation	Negative	Positive
Gingival exudate	Minimal	Significantly increased
Sulcular temperature	~34 °C	Slight increase

Fig. 19-1 Changes in gingival color and contour associated with plaque-induced gingivitis.

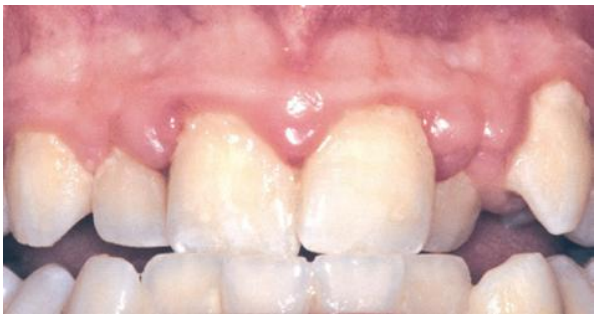

Fig. 19-2 Gingival inflammation as a result of tooth anatomic factors (malocclusion).

that are confined to the gingiva, reversibility of the diseases by removal of etiology(ies), the presence of bacteria-laden plaque to initiate and/or exacerbate the severity of the lesion, and a possible role as a precursor to attachment loss around teeth (Table 19-1).

Clinical signs of gingival inflammation involve enlarged gingival contours due to edema or fibrosis (Muhlemann & Son 1971; Polson & Goodson 1985), color transition to a red and/or bluish-red hue (Muhlemann & Son 1971; Polson & Goodson 1985), elevated sulcular temperature (Haffajee *et al*. 1992; Wolff *et al*. 1997), bleeding upon probing (Löe *et al*., 1965; Muhlemann & Son, 1971; Greenstein *et al*. 1981; Engelberger *et al*. 1983; Page & Eke, 2007), and increased gingival exudates (Löe & Holm-Pedersen 1965; Engelberg 1966; Oliver *et al*. 1969; Rudin *et al*. 1970; Goodson, 2003) (Table 19-2, Fig. 19-1). Clinical signs of gingival inflammation indicative of a gingival disease must be associated with stable (i.e. unchanging) attachment levels on a periodontium with no loss of attachment or alveolar bone or on a stable but reduced periodontium.

The classification of gingival diseases relies on the presence of dental plaque and factors that modify the inflammatory status of the gingiva. Local or systemic factors can modify plaque-induced gingivitis. Local factors include tooth anatomic factors (Fig. 19-2), dental restorations (Fig. 19-3) and appliances (Fig. 19-4), root fractures (Fig. 19-5), and cervical root resorption (Fig. 19-6) (Blieden 1999), whereas systemic factors involve the endocrine system, hematologic diseases, drugs, or malnutrition (Mariotti 1999). Table 19-3 presents a classification of plaque-induced gingival diseases (Mariotti 1999).

Fig. 19-3 Gingival inflammation associated with violation of the biologic width and overhanging restorations retaining plaque.

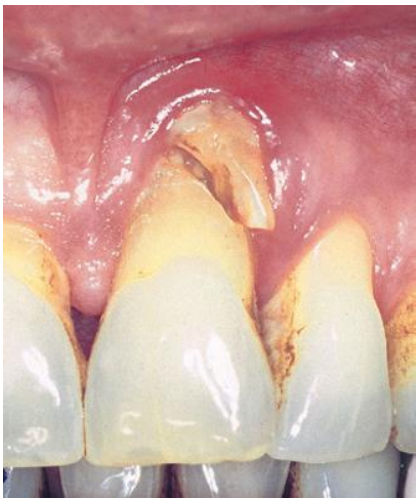

Fig. 19-5 Root fracture with associated periodontal destruction and gingival inflammation.

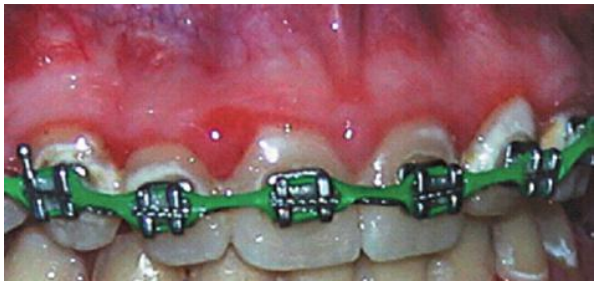

Fig. 19-4 Presence of appliances, such as braces, allows for the accumulation of plaque, resulting in gingival inflammation.

Fig. 19-6 Early cervical resorption and associated inflammation. The arrow indicates gingival inflammation resulting from cervical tooth resorption.

Table 19-3 Plaque-induced gingival diseases.

Associated with bacterial plaque only	Associated with a periodontium that exhibits no attachment loss Associated with a stable but reduced periodontium	Plaque-induced gingivitis
Associated with bacterial plaque and modified by systemic factors	Associated with endogenous sex steroid hormones	Puberty-associated gingivitis Menstrual cycle-associated gingivitis Pregnancy-associated gingivitis Pregnancy-associated pyogenic granuloma
	Associated with medications	Drug-influenced gingival enlargements Oral contraceptive-associated gingivitis
	Associated with systemic diseases	Diabetes mellitus-associated gingivitis Leukemia-associated gingivitis
	Associated with malnutrition	Ascorbic acid deficiency gingivitis

Adapted from Mariotti (1999). Reproduced from the American Academy of Periodontology.

Plaque-induced gingivitis

Plaque-induced gingivitis is inflammation of the gingiva resulting from bacteria located at the gingival margin. The relationship of plaque to gingival inflammation has often been postulated as the cause for gingivitis, but it was not until the elegant experimental human gingivitis studies that a plaque bacterial etiology was confirmed (Löe *et al*. 1965). Epidemiologic data have shown plaque-induced gingivitis to be prevalent at all ages of dentate populations (US Public Health Service 1965, 1972, 1987; Stamm 1986; Bhat 1991; Albandar 2002; Gjermo *et al*. 2002; Baelum & Schutz 2002; Corbet *et al*. 2002; Sheiham & Netuveli 2002; Hugoson & Norderyd, 2008) and this disease has been considered to be the most common form of periodontal disease (Page 1985; AAP 2000). In children, the prevalence of plaque-induced gingivitis continues to increase

Fig. 19-7 Typical generalized marginal and papillary gingivitis.

Fig. 19-8 Treated periodontitis case displaying gingival health on a reduced periodontium. If such a case developed inflammation and no further loss of attachment could be demonstrated, the diagnosis of plaque-induced gingivitis would be appropriate.

until it reaches a zenith at puberty (Parfitt 1957; Hugoson *et al*. 1981; Stamm 1986; Mombelli *et al*. 1989). The initial changes from health to plaque-induced gingivitis may not be detectable clinically (Page & Schroeder 1976), but as plaque-induced gingivitis progresses to more advanced forms of this disease, clinical signs and symptoms become more obvious.

Plaque-induced gingivitis begins at the gingival margin and can spread throughout the remaining gingival unit. Clinical signs of gingival inflammation involving changes to gingival contour, color, and consistency (Muhlemann & Son 1971; Polson & Goodson 1985) are associated with a stable periodontium which exhibits no loss of periodontal attachment or alveolar bone (Fig. 19-7). In children, gingivitis is not as intense as that found in young adults with similar amounts of dental plaque (Matsson 1978; Matsson & Goldberg 1985). This age-related difference in the development and severity of gingivitis may be associated with the quantity and/or quality of dental plaque, response of the immune system, and/or morphologic differences in the periodontium between children and adults (Bimstein & Matsson 1999). More specifically, dental plaque of children usually contains lower concentrations of putative periodontal pathogens and the thicker junctional epithelium is coupled with increased vascularity in the gingival connective tissues and a developing immune system (Bimstein & Matsson 1999). In contrast to children and young adults, gingival inflammation in senior adult populations is more pronounced even when similar amounts of dental plaque are present (Fransson *et al*. 1996). The reason for the difference in senior adults may be the result of age-related differences in cellular inflammatory response to plaque (Fransson *et al*. 1996, 1999).

The intensity of the clinical signs and symptoms of gingivitis will vary between individuals (Tatakis & Trombelli 2004; Trombelli *et al*. 2004), as well as between sites within a dentition. The common clinical findings of plaque-induced gingivitis include erythema, edema, bleeding, sensitivity, tenderness, and enlargement (Löe *et al*. 1965; Suzuki 1988). Radiographic analysis and/or probing attachment levels of individuals with plaque-induced gingivitis will not indicate loss of supporting structures. Histopathologic changes include proliferation of basal junctional epithelium leading to apical and lateral cell migration, vasculitis of blood vessels adjacent to the junctional epithelium, progressive destruction of the collagen fiber network with changes in collagen types, cytopathologic alteration of resident fibroblasts, and a progressive inflammatory/immune cellular infiltrate (Page & Schroeder 1976). Although the composition of bacterial flora associated with plaque-induced gingivitis differs from the flora associated with gingival health (Teles *et al*. 2007; Hojo *et al*. 2009), there are no specific bacterial flora that are pathognomonic for plaque-induced gingivitis (Ranney 1993; Socransky & Haffajee, 2005). Similar to the changes observed in the bacterial composition during plaque-induced gingivitis, the gingival transcriptome (i.e. the set of all RNA molecules) dramatically changes, with leukocyte transmigration, cell adhesion, and antigen processing/presentation being the leading differentially regulated pathways during the inflammatory process (Jönsson *et al*. 2011).

Plaque-induced gingivitis on a reduced periodontium

Destructive periodontal diseases result in the loss of attachment and a decrease in the height and volume of alveolar bone around teeth, leading to an overall reduction of the periodontium. It should be noted that not all inflammation present around teeth with attachment and bone loss denotes a periodontitis lesion. If there is resolution of periodontal inflammation subsequent to periodontal treatment that results in healthy periodontal tissues (but with a reduced connective tissue attachment and alveolar bone height), then recurrent inflammation must be considered to be plaque-induced gingivitis (Mariotti 1999). Therefore, plaque-induced gingivitis on a reduced periodontium is characterized by the return of bacteria-induced inflammation of the gingival margin on a reduced periodontium with no evidence of progressive attachment loss (i.e. no indication of active disease) (Fig. 19-8). The clinical findings for plaque-induced gingivitis on a reduced periodontium

are similar to those for plaque-induced gingivitis, except for the presence of pre-existing attachment and bone loss.

Gingival diseases associated with endogenous hormones

Since the 19th century, evidence has accumulated to support the concept that tissues of the periodontium are modulated by androgens, estrogens, and progestins. The majority of information concerning sex hormone-induced effects has been gender-specific observations in the gingiva. Much of the evidence that has been documented concerning the effects of sex steroid hormones on the periodontium has come from observing the changes in gingival tissues during distinct endocrinologic events (e.g. puberty, pregnancy, etc.). Although a significant amount of data has shown the gingiva to be a target for sex steroid hormones, the etiology for the changes has not been thoroughly elucidated (Mariotti 1994; Mariotti & Mawhinney 2013). The principal explanations for sex steroid hormone-induced changes in the gingiva have pointed to changes of microbiota in dental plaque, immune function, vascular properties, and cellular function in the gingiva (Mariotti 1994, 2005; Kumar 2013; Mariotti & Mawhinney, 2013). The actions of sex steroid hormones in the periodontium are multifactorial (Mariotti 1994; Mariotti & Mawhinney 2013). Theoretically, sex steroid hormones will affect the host by influencing cellular (i.e. in the blood vessels, epithelium, and connective tissue) and immune function and, together with hormone-selected bacterial populations that occupy the gingival sulcus, induce specific changes in gingival tissues that become clinically observable (Mariotti 1994; Mariotti & Mawhinney 2013).

Puberty-associated gingivitis

Puberty is not a single episode but a complex process of endocrinologic events that produce changes in the physical appearance and behavior of adolescents. The incidence and severity of gingivitis in adolescents are influenced by a variety of factors, including plaque levels, dental caries, mouth breathing, crowding of the teeth, and tooth eruption (Stamm 1986); however, the dramatic rise in steroid hormone levels during puberty in both sexes has a transient effect on the inflammatory status of the gingiva (Mariotti 1994; Mariotti & Mawhinney 2013). Several studies have demonstrated an increase in gingival inflammation in circumpubertal aged individuals of both genders without a concomitant increase in plaque levels (Parfitt 1957; Sutcliffe 1972; Hefti *et al*. 1981; Mombelli *et al*. 1989) (Fig. 19-9). Although puberty-associated gingivitis has many of the clinical features of plaque-induced gingivitis, this disease will develop frank signs of gingival inflammation in the presence of relatively small amounts of plaque during the circumpubertal period.

Fig. 19-9 Gingival inflammation can result from an increased secretion of sex steroid hormones during puberty.

Fig. 19-10 Heightened gingival response to plaque during pregnancy results in pregnancy-associated gingivitis.

Menstrual cycle-associated gingivitis

Following menarche, there is a periodicity of sex steroid hormone secretion over a 25–30-day period: the menstrual cycle. A clinical case report of significant and observable inflammatory changes in the gingiva during the menstrual cycle has been described (Muhlemann 1948); however, women rarely exhibit overt gingival changes that fluctuate in conjunction with the menstrual cycle (Mariotti 1994; Mariotti & Mawhinney 2013). The more common gingival inflammatory changes involve less dramatic signs of inflammation in the gingiva during ovulation (Machtei *et al*. 2004). More specifically, gingival exudate increased approximately 20% during ovulation in roughly three-quarters of women tested (Hugoson 1971), while observable signs of gingival inflammation have been shown to be clinically insignificant (Machtei *et al*. 2004). Since these changes in crevicular fluid flow and gingival color are not readily observable, most young women with gingival inflammation induced by the menstrual cycle will present with a very mild, and not clinically observable, form of the condition.

Pregnancy-associated gingival diseases

Some of the most remarkable endocrine and oral alterations accompany pregnancy due to the prominent increase in plasma hormone levels over several months. During human gestation, pregnancy-associated gingivitis is characterized by an increase in the prevalence and severity of gingivitis during the second and third trimesters of pregnancy (Löe & Silness 1963; Löe 1965; Hugoson 1971; Arafat 1974b; Gürsoy *et al*. 2008) (Fig. 19-10). Both longitudinal and

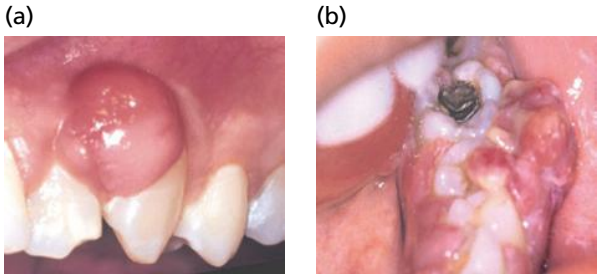

Fig. 19-11 (a) Pyogenic granuloma of pregnancy. (b) Large pyogenic granuloma of pregnancy interfering with occlusal function.

cross-sectional studies have found the prevalence and severity of gingival inflammation to be significantly higher in the pregnant versus the post-partum subject even though plaque scores remained the same between the two groups (Löe & Silness 1963; Hugoson 1971; Moss *et al*. 2005; Gürsoy *et al*. 2008). In addition, gingival probing depths are deeper (Löe & Silness 1963; Hugoson 1971; Miyazaki *et al*. 1991), bleeding on probing or toothbrushing is increased (Arafat 1974b; Miyazaki *et al*. 1991), and gingival crevicular fluid flow is elevated in pregnant women (Hugoson 1971). The features of pregnancy-associated gingivitis are similar to those of plaque-induced gingivitis, except for the propensity to develop frank signs of gingival inflammation in the presence of relatively little plaque during pregnancy.

Pregnancy-associated pyogenic granuloma or "pregnancy tumor" was described over a century ago (Coles 1874); this is not a tumor but an exaggerated inflammatory response during pregnancy to an irritation that results in a solitary polyploid capillary hemangioma which can easily bleed upon mild provocation (Sills *et al*. 1996) (Fig. 19-11). Pregnancy-associated pyogenic granuloma presents clinically as a painless, protuberant, mushroom-like, exophytic mass that is attached by a sessile or pedunculated base and arises from the gingival margin or more commonly from an interproximal space (Sills *et al*. 1996). Pregnancy-associated pyogenic granuloma has been reported to occur in 0.5–5.0% of pregnant women (Ziskin & Nesse 1946; Maier & Orban 1949; Arafat 1974a; Kristen 1976). It is more common in the maxilla (Sills *et al*. 1996) and may develop as early as the first trimester (Sills *et al*. 1996), ultimately regressing or completely disappearing following parturition (Ziskin & Nesse 1946).

Gingival diseases associated with medications

In the past century, an astonishing array of medications for the alleviation of human diseases has led to the creation of new side effects in the oral cavity. Drugs that specifically affect the gingival tissues have principally caused an increase in inflammation and/or size.

Fig. 19-12 Severe enlargement of the gingiva associated with cyclosporine medication in a kidney transplant patient.

Drug-influenced gingival enlargement

Esthetically disfiguring overgrowth of gingiva is a significant side effect which may be associated with (Hassell & Hefti 1991; Seymour *et al*. 1996; Seymour 2006):

- Anticonvulsants (e.g. phenytoin, sodium valproate, etc.)
- Immunosuppressant (e.g. cyclosporine A) (Fig. 19-12)
- Calcium channel blocking agents (e.g. nifedipine, verapamil, etc.).

The common clinical characteristics of drug-influenced gingival enlargements (Table 19-4) include patient variations in the pattern of enlargement (i.e. genetic predisposition) (Hassell & Hefti 1991; Seymour *et al*. 1996), a tendency to occur more often in the anterior gingiva (Hassell & Hefti 1991; Seymour *et al*. 1996), a higher prevalence in younger age groups (Esterberg & White 1945; Rateitschak-Pluss *et al*. 1983; Hefti *et al*. 1994), onset within 3 months of use (Hassell 1981; Hassell & Hefti 1991; Seymour 1991; Seymour & Jacobs 1992) that is usually first observed in the papilla (Hassell & Hefti 1991); although enlargement can be found in the periodontium with or without bone loss, it is not associated with attachment loss or tooth mortality (Hassell & Hefti 1991; Seymour *et al*. 1996). Furthermore, all of these drugs produce clinical lesions and histologic characteristics that are indistinguishable from one another (Hassell & Hefti 1991; Seymour *et al*. 1996).

The influence of plaque on the induction of gingival enlargements by drugs in humans has not been fully elucidated (Hassell & Hefti 1991); however, it does appear that the severity of the lesion is affected by the oral hygiene of the patient (Steinberg & Steinberg 1982; Addy *et al*. 1983; Hassell *et al*. 1984; Tyldesley & Rotter 1984; Daley *et al*. 1986; McGaw *et al*. 1987; Modeer & Dahllof 1987; Yahia *et al*. 1988; Barclay *et al*. 1992).

The first description of a drug causing an enlargement of the gingiva was reported in 1939 and the drug was phenytoin (Kimball 1939). Phenytoin, which is used on a chronic regimen for the control of epileptic seizures, induces gingival enlargements in

Table. 19-4 Characteristics of drug-influenced gingival enlargement.

- Variation in inter- and intra-patient pattern
- Predilection for anterior gingiva
- Higher prevalence in children
- Onset within 3 months
- Change in gingival contour leading to modification of gingival size
- Enlargement first observed at the interdental papilla
- Change in gingival color
- Increased gingival exudate
- Bleeding upon provocation
- Found in gingiva with or without bone loss but is not associated with attachment loss
- Pronounced inflammatory response of gingiva in relation to the plaque present
- Reductions in dental plaque can limit the severity of the lesion
- Must be using phenytoin, cyclosporine A or certain calcium channel blockers; the plasma concentrations to induce the lesion have not been clearly defined in humans

Source: Mariotti (1999). Reproduced from the American Academy of Periodontology.

approximately 50% of patients using this agent (Angelopoulous & Goaz 1972). One prominent theory of the etiology of phenytoin-associated gingival enlargements suggests that the growth is an increase in connective tissue that has resulted from a multifaceted interaction of fibroblast biology, connective tissue metabolism, inflammation, growth factors, and cytokines in an environment dependent on complex gene interactions (Hassell & Hefti, 1991; Gulati 2012).

Calcium channel blockers have also been identified as agents that affect enlargement of the gingiva. Calcium channel blockers are a class of drugs that exert effects, principally at voltage-gated Ca^{2+} channels located in the plasma membrane, and are commonly prescribed as antihypertensive, antiarrhythmic, and antianginal agents. In 1984, calcium channel blockers were first linked to gingival enlargements (Ramon *et al*. 1984) and the prevalence of gingival lesions associated with these drugs has been estimated to be approximately 20% (Barclay *et al*. 1992), with nifedipine being the primary calcium channel blocker associated with gingival enlargement (Ellis *et al*. 1999). Presently, the mechanism(s) of gingival enlargement by calcium channel blockers is still under investigation, but these drugs may directly influence gingival connective tissues by stimulating an increase in gingival fibroblasts as well as an increase in the production of the connective tissue matrix (Fu *et al*. 1998).

The final drug class that has been associated with increases in gingival mass is cyclosporine A (CsA), which is a powerful immunoregulating drug used primarily in the prevention of organ transplant rejection (Seymour & Jacobs 1992). The clinical features of cyclosporine-influenced gingival enlargement were first described in 1983 (Rateitschak-Pluss *et al*. 1983) and cyclosporine appears to affect between 25% and 30% of the patients taking this medication (Hassell & Hefti 1991; Seymour *et al*. 1987). Hypotheses explaining why CsA affects the gingiva are diverse, but a leading theory suggests that its principal metabolite, hydroxycyclosporine (M-17), in conjunction with the parent compound, stimulates fibroblast proliferation (Mariotti *et al*. 1998). This increase in cell number coupled with a reduction in the breakdown of gingival connective tissues (Hassell & Hefti 1991) has been speculated to be the cause of excessive extracellular matrix accumulation in CsA-associated gingival enlargements (Seymour 2006).

Oral contraceptive-associated gingivitis

Oral contraceptives are one of the most widely utilized classes of drugs in the world. Today, as a result of the early onset of menarche, changing social mores, and increased emphasis on family planning, the use of oral contraceptives in adolescents and young adults has increased to reduce unwanted pregnancies. Clinical case reports have described gingival enlargement induced by oral contraceptives in otherwise healthy females with no history of gingival overgrowth (Lynn 1967; Kaufman 1969; Sperber 1969). In all cases, the increased gingival mass was reversed when oral contraceptive use was discontinued or the dosage reduced. Early clinical studies demonstrated that women using hormonal contraceptive drugs had a higher incidence of gingival inflammation in comparison to women who did not use these agents (Lindhe & Bjorn 1967; El-Ashiry *et al*. 1970; Pankhurst *et al*. 1981) and that long-term use of oral contraceptives may affect periodontal attachment levels (Knight & Wade 1974). All studies of the effect of oral contraceptives prior to the 1980s were studying much higher contraceptive concentrations than are currently available today. A more recent clinical study evaluating the effects of low-dose oral contraceptives on gingival inflammation in young women found no effect of these hormonal agents on gingival tissues (Preshaw *et al*. 2001). Furthermore, cross-sectional data from National Health and Nutrition Examination Survey (NHANES) III have failed to show a relationship between low-dose oral contraceptive use and increased levels of gingivitis (Taichman & Eklund 2005). From these data it appears that current low-dose compositions of oral contraceptives are not harmful to the periodontium (Preshaw 2013).

Gingival diseases associated with systemic diseases

Diabetes mellitus-associated gingivitis

Diabetes mellitus (DM) is a chronic systemic disease characterized by disorders in insulin production, metabolism of carbohydrate, fat, and protein, and

the structure and function of blood vessels. DM most commonly appears as one of two recognized clinical entities: type 1 DM (insulin-dependent DM or juvenile onset) and type 2 DM (non–insulin-dependent DM or adult onset). DM-associated gingivitis is a consistent feature in children with poorly controlled type 1 DM (Cianciola *et al*. 1982; Gusberti *et al*. 1983; Ervasti *et al*. 1985). The features of gingivitis associated with DM are similar to those of plaque-induced gingivitis, except that the level of diabetic control is more important than plaque control in determining the severity of the gingival inflammation (Cianciola *et al*. 1982; Gusberti *et al*. 1983; Ervasti *et al*. 1985). In adults with DM, it is difficult to detect the effects of this endocrine disease on gingival diseases since most studies have evaluated gingival inflammation in association with attachment loss (AAP 1999); however, young adults with type 1 DM developed an earlier and more pronounced inflammatory response compared to non-diabetic controls in experimental gingivitis studies (Salvi *et al*. 2005). These data suggest that the gingival inflammatory response in adults with diabetes is an overt response to the dental biofilm. In addition to the effects of DM on the gingiva, reports in the literature have suggested that reductions in gingival inflammation of patients with diabetes will also reduce the amount of insulin they need to control blood glucose levels (Mealey & Oates 2006). This has been a controversial premise given the conflicting results of numerous studies. Moreover, despite several meta-analyses of periodontal intervention studies to evaluate glycemic levels, there is no clear consensus to support the assertion that control of gingival inflammation will substantially affect glycemic control in patients with diabetes (Janket *et al.* 2005; Jones *et al*. 2007; Sgolastra *et al.* 2012)

Leukemia-associated gingivitis

Leukemia is a progressive, malignant hematologic disorder characterized by an abnormal proliferation and development of leukocytes and precursors of leukocytes in the blood and bone marrow. Leukemia is classified according to the duration (acute or chronic), the type of cell involved (myeloid or lymphoid), and the number of cells in the blood (leukemic or aleukemic). There are noticeable correlations of leukemias with age. For example, acute lymphoblastic leukemia accounts for 80% of all childhood leukemias, while acute myelogenous leukemia usually affects adults. Oral manifestations have primarily been described in acute leukemias and include cervical adenopathy, petechiae, mucosal ulcers, as well as gingival inflammation and enlargement (Fig. 19-13) (Lynch & Ship 1967; Javed *et al*. 2012). Signs of inflammation in the gingiva include swollen, glazed, and spongy tissues which are red to deep purple in appearance (Dreizen *et al*. 1984). Gingival bleeding

Fig. 19-13 Gingival changes associated with acute monocytic leukemia. Note the acute candidosis superimposed upon the infiltrative gingival changes.

is a common sign in patients with leukemia and is the initial oral sign and/or symptom in 17.7% and 4.4% of patients with acute and chronic leukemias, respectively (Lynch & Ship 1967). Gingival enlargement has also been reported, beginning at the interdental papilla, followed by at the marginal and attached gingiva (Dreizen *et al*. 1984). Although local irritants can predispose and exacerbate the gingival response in leukemia, they are not prerequisites for lesions to form in the oral cavity (Dreizen *et al*. 1984).

Linear gingival erythema

Infection with the human immunodeficiency virus (HIV) produces an irreversible and progressive immunosuppression that renders a person susceptible to a variety of oral diseases. In humans, HIV depletes CD4-positive lymphocytes (T helper cells), which leads to the development of a variety of fungal, viral, and bacterial oral infections (Connor & Ho 1992; Mataftsi *et al*. 2011).

Oral manifestations of HIV infection have been used to stage HIV disease (Justice *et al*. 1989; Royce *et al*. 1991; Prevention, 1992), identify prophylactic treatment of other serious infections (Force USPHST Force, 1993), and indicate disease prognosis (Dodd *et al*. 1991; Katz *et al*. 1992). In the gingiva, manifestations of HIV infection were formerly known as HIV-associated gingivitis, but currently are designated as linear gingival erythema (LGE). LGE is distinguished by a 2–3-mm marginal band of intense erythema in the free gingiva (Winkler *et al*. 1988). This band of gingival erythema may extend into the attached gingiva as a focal or diffuse erythema and/or extend beyond the mucogingival line into the alveolar mucosa (Winkler *et al*. 1988). LGE may be localized to one or two teeth but it is more commonly a generalized gingival condition.

With the advent of antiretroviral therapy for HIV-positive patients, the prevalence of HIV-specific lesions has been dramatically reduced (Mataftsi *et al*. 2011); even so, plaque accumulation with reduced CD4-positive counts, without antiretroviral therapy, will still account for a pronounced gingival inflammatory response (Kroidl *et al*. 2005).

Gingival diseases associated with malnutrition

Although some nutritional deficiencies can significantly exacerbate the response of the gingiva to plaque bacteria, the precise role of nutrition in the initiation or progression of periodontal diseases remains to be elucidated. Studies that have attempted to investigate the relationship of nutrition to periodontal disease examined the periodontal status of individuals in developed and in developing countries, but failed to show a relationship between periodontal disease and nutrition (Russell 1962; Waerhaug 1967; Wertheimer *et al*. 1967). While there is a paucity of information available regarding the effects of a specific, single nutritional deficiency on human periodontal tissues, severe ascorbic acid (vitamin C) deficiency or scurvy was one of the earliest nutritional deficiencies to be examined in the oral cavity (Lind 1953). Even though scurvy is unusual in areas with an adequate food supply, certain populations on restricted diets (e.g. infants from low socioeconomic families) are at risk of developing this condition (Oeffinger 1993). The classical clinical sign of scurvy is a bright red, swollen, ulcerated gingiva which is susceptible to hemorrhage (van Steenberghe 1997). Although there is no dispute about the necessity of dietary ascorbic acid for periodontal health, in the absence of frank scurvy, the effect of declining ascorbic acid levels on the gingiva can be difficult to detect clinically (Woolfe *et al*. 1980) and when it is detected, usually has characteristics that are similar to plaque-induced gingivitis (Fig. 19-14).

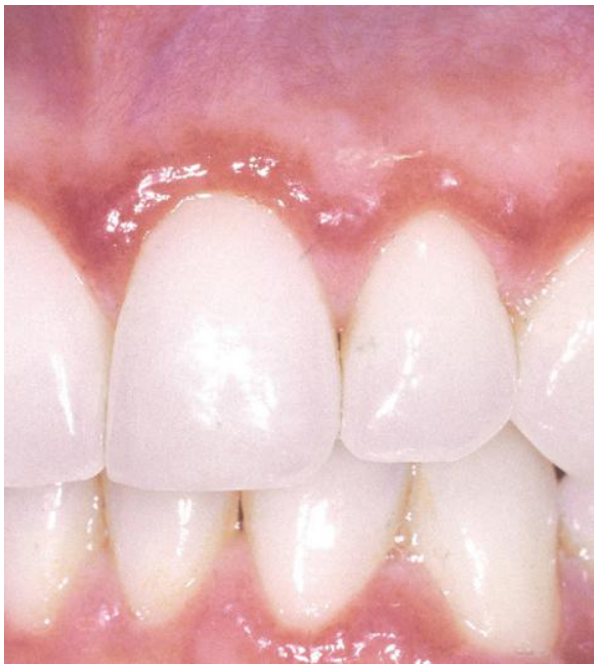

Fig. 19-14 Gingival changes associated with vitamin C deficiency. Note the absence of dental plaque and the distances of the color changes from marginal gingiva.

Gingival diseases associated with heredity

Benign, non-inflammatory fibrotic enlargement of the maxillary and/or mandibular gingiva associated with a familial aggregation has been designated by the terms gingivomatosis elephantiasis, familial elephantiasis, juvenile hyaline fibromatosis, congenital familial fibromatosis, idiopathic fibromatosis, idiopathic gingival fibromatosis, hereditary gingival hyperplasia, and hereditary gingival fibromatosis. Although there have been over 100 reports of gingival enlargements associated with heredity in the literature over the past century, knowledge concerning the natural history of this disease is extremely limited and the etiology of this rare condition has not been determined.

Hereditary gingival fibromatosis appears to be a slowly progressive gingival enlargement that develops upon eruption of the permanent dentition; however, gingival enlargement can also occur in the primary dentition (Emerson 1965; Jorgenson & Cocker 1974; Lai *et al*. 1995; Miyake *et al*. 1995). The disease can be localized or generalized and may ultimately cover the occlusal surfaces of teeth. The enlarged gingiva is non-hemorrhagic and firm, but there can be an overlay of gingival inflammation which can augment the enlargement (Fig. 19-15). The histologic features of hereditary gingival fibromatosis include dense fibrotic connective tissue as well as epithelial hyperplasia with elongated and increased rete pegs (Johnson *et al*. 1986; Clark 1987).

Hereditary gingival fibromatosis can be inherited as a simple Mendelian trait in some chromosomal disorders, and as a malformation syndrome (Witkop 1971; Jones *et al*. 1977; Skrinjaric & Bacic 1989; Takagi *et al*. 1991; Goldblatt & Singer 1992; Hallet *et al*. 1995). A mutation in the *son of sevenless-1* gene has been implicated as a genetic factor responsible for hereditary gingival fibromatosis (Hart *et al*. 2002). Research into the cellular responses of this disease suggests an accumulation of specific populations of gingival fibroblasts that result in an abnormal accumulation of connective tissues (Huang *et al*. 1997; Tipton *et al*. 1997; Lee *et al*. 2006).

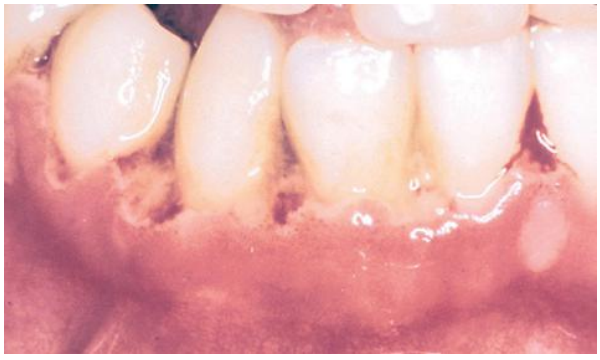
Fig. 19-15 Generalized, benign, non-inflammatory, fibrotic enlargement of gingival tissues.

Gingival diseases associated with ulcerative lesions

Necrotizing ulcerative gingivitis (NUG) has been observed for centuries and recognized by numerous names, including trench mouth and Vincent's infection. Acute necrotizing ulcerative gingivitis is a term now used to describe the clinical onset of the disease, but should not be used as a diagnostic classification since some forms of NUG may be recurrent or possibly chronic.

NUG is most often distinguished by a sudden onset. The clinical signs of NUG include intense gingival pain that usually is responsible for the patient seeking professional care; papillary necrosis, described as a "punched out" appearance of the gingival papilla; and gingival bleeding that requires little or no provocation (Fig. 19-16) (Grupe & Wilder 1956; Goldhaber & Giddon 1964; Johnson & Engel 1986). Although these three signs must be present to diagnose NUG, other signs and symptoms also may be present but do not necessarily occur in all individuals with this disease. These signs and symptoms include fever, malaise, lymphadenopathy, metallic taste, and malodor (Schluger 1943; Wilson 1952; Murayama *et al*. 1994). Systemic reactions of acute NUG are usually more severe in children. Significant destruction of the gingival connective tissue is possible with NUG, but when attachment loss occurs this condition should be considered as a necrotizing ulcerative periodontitis (NUP).

(a)



(b)

Fig. 19-16 Necrotizing ulcerative gingivitis. (a) Destruction of the interdental papilla, pseudomembrane, and spontaneous bleeding. (b) Although usually confined to the papilla, occasionally the marginal tissues are involved.

The etiology of NUG has been associated with a bacterial infection. The four zones of the NUG gingival lesion include the bacterial zone (the superficial area that consists of various bacteria and some spirochetes), neutrophil-rich zone (follows the bacterial zone and contains leukocytes and bacteria including spirochetes), necrotic zone (consists of disintegrated cells and connective tissue elements with many large and intermediate spirochetes), and spirochetal infiltration zone (the deepest zone that is infiltrated only with intermediate and large spirochetes) (Listgarten 1965). The cultivable flora of NUG that predominates includes *Provetella intermedia* and *Fusobacterium* spp., while microscopically *Treponema* and *Selenomonas* spp. are observed (Loesche *et al*. 1982; Rowland *et al*. 1993b). Additional factors such as smoking (AAP 1996), psychological stress (Moulton *et al*. 1952; Cohen-Cole *et al*. 1983), malnutrition (Grupe & Wilder 1956; Goldhaber & Giddon 1964; Johnson & Engel 1986), and immune suppression (Moulton *et al*. 1952; Rowland *et al*. 1993a) can predispose an individual to NUG.

NUG can affect any age group, but is considered to be a disease of young adults in industrialized countries (Melnick *et al*. 1988). In developing countries, NUG is a disease found in children from families with a low socioeconomic status (Melnick *et al*. 1988). The onset of NUG in children is associated with inappropriate nutritional intake, especially low protein consumption (Sheiham 1966; Taiwo 1995). In addition, viral infections such as measles can induce NUG in malnourished children (Enwonwu 1972; Osuji 1990). Even though NUG has occurred in epidemic patterns, this disease is not considered communicable (Rosebury 1942).

Treatment of plaque-induced gingival diseases

Personal and professional mechanical oral hygiene measures are critical aspects in the treatment of plaque-induced gingival diseases. Proper oral hygiene reduces the build-up of dental plaque on tooth surfaces and diminishes the incidence of various types of gingival diseases (Garmyn *et al*. 1998). For effective, self-care, mechanical plaque control, the appropriate use of manual (Jepsen 1998) or powered (van der Weijden *et al*. 1998) toothbrushes combined with interdental mechanical cleaning (Kinane 1998) is essential. Dentifrices also have important roles in the reduction of dental plaque: (1) to help in the removal of dental plaque by enhancing the mechanical scrubbing and cleaning power of the toothbrush (Mariotti 2014) and (2) as drug-delivery systems; agents (e.g. tricolsan) present in a toothpaste will provide a pharmacologic advantage by reducing the bacteria found in dental biofilms and/or inflammation in gingival tissues (DeVizio & Davies 2004). Additionally,

adjunctive, self-applied, locally delivered, pharmacologic agents (e.g. chlorhexidine) can also be an effective option for individuals with physical or medical limitations that constrain their ability to perform adequate home care.

Professional intervention is required as an adjunct to self-performed oral hygiene when plaque-retaining factors, such as dental calculus, defective restorations or anatomic factors, prevent an individual from effectively removing dental plaque. In instances where systemic factors modify the gingival response to dental biofilms, a combined treatment plan with the appropriate medical professional can be effective in addressing the root causes of the gingival inflammation.

Significance of gingivitis

Since gingival inflammation has been found to be a ubiquitous finding in children and adults, it has been suggested that this condition represents a normal response of the gingiva to an insult, and is not a disease. By analogy, a paper cut to a finger will induce an inflammatory response but would not be considered a "fingeritis" (i.e. a disease). On the other hand, inflammation in the gingiva that has been induced by a bacteria-laden biofilm changes the form and function of the tissue, creating a morbid condition in the gingiva that can be considered a disease.

Although the presence of gingival inflammation was once considered a normal variant of health, in the mid-20th century that concept changed dramatically when it was hypothesized that sites with untreated gingivitis were destined to progress to destructive periodontal disease. Although this concept was supported by some clinical studies showing an association between gingivitis and bone loss (Marshall-Day *et al*. 1955), longitudinal studies examining the natural history of periodontal disease failed to show complete conversion of chronic gingivitis to periodontitis (Löe *et al*. 1986). Gingival inflammation is probably a necessary precursor for periodontitis (Löe & Morrison 1986; Page & Kornman 1997; Schätzle *et al*. 2003, 2004; Lang *et al*. 2009), given that the risk of losing a tooth increases dramatically when surrounded by inflamed gingival tissue (Schätzle *et al*. 2003, 2004; Lang *et al*. 2009). Despite the increased risk for tooth loss associated with gingival inflammation, the presence of gingivitis does not mean that all sites that exhibit gingival inflammation progress to periodontitis (Schätzle *et al*. 2003, 2004).

If the majority of the adult population exhibits some form of plaque-induced gingivitis, how does one determine which inflamed sites within particular individuals are susceptible to conversion to destructive periodontal disease? There has been an awareness that differences in the inflammatory responsiveness to dental plaque cannot be fully accounted for by the quantity or quality of the plaque (Tatakis & Trombelli 2004). More specifically, there seems to be a differential gingival inflammatory response that is independent of the amount or rate of accumulation of dental plaque (Trombelli *et al*. 2004). Hence, the predilection of inflamed gingival sites to convert to destructive forms of periodontal disease may be dependent on the susceptibility and responsiveness of the individual to gingivitis (van der Velden *et al*. 1985a, b; Abbas *et al*. 1986; Winkel *et al*. 1987; Dietrich *et al*. 2006). In other words, these data suggest that specific types of inflammatory responses in the gingiva are necessary to initiate destruction of connective tissue attachment apical to the cementoenamel junction. As we learn more about different gingival inflammatory phenotypes, our notions about the initiation of periodontal destruction continue to emerge.

Exacerbations of the inflammatory response in the gingiva also occur during fluctuant periods of sex steroid hormone secretion. Although the periodontium has not been considered a classical target tissue for ovarian or testicular hormones, during puberty or pregnancy, the acute gingival inflammatory response is an expression of the protective nature of sex steroid hormones (Mariotti & Mawhinney 2013). More specifically, during times of possible vulnerability of the individual (e.g. pregnancy), the intensified inflammatory response in the periodontium is necessary to protect both the local (i.e. periodontal attachment) and systemic (i.e. toxic sepsis) environments by destroying, diluting or walling off the invading organisms (Mariotti & Mawhinney 2013).

As knowledge of gingival diseases evolves, their impact on the periodontium will become more transparent. Nonetheless, our current ability to clinically detect inflammation in gingival tissues, which subsequently leads to a diagnosis of a specific gingival disease, remains an important cornerstone for the periodontal management of the patient.

Chronic periodontitis is considered to start as *plaque-induced gingivitis* (see Chapter 19), a reversible condition that if left untreated may develop into *chronic periodontitis*. Chronic periodontitis lesions are distinguished by loss of attachment and bone, and are regarded as irreversible. In this chapter, various aspects of chronic periodontitis will be described, including its association with plaque-induced gingivitis.

Clinical features of chronic periodontitis

The clinical features of chronic periodontitis include signs and symptoms such as (1) color, texture, and volume alterations of the marginal gingiva; (2) bleeding on probing (BoP) from the gingival pocket area; (3) reduced resistance of the soft marginal tissues to probing (increased pocket depth or periodontal pocketing); (4) loss of probing attachment level; (5) recession of the gingival margin; (6) loss of alveolar bone (even or angular pattern); (7) root furcation exposure; (8) increased tooth mobility; and (9) drifting and eventually exfoliation of teeth.

Figure 20-1 shows the clinical status of a 30-year-old male with severe chronic periodontitis. The clinical examination revealed that (1) multiple sites, particularly the palatal aspects of the premolars, exhibited BoP; (2) many teeth showed signs of increased mobility; and (3) gingival recession had occurred at a large number of buccal, lingual, and interproximal sites. In addition, although the patient appears to be adequately cleaning several surfaces, multiple sites have levels of plaque and calculus that are clearly being ignored in the oral hygiene routine and are inconsistent with gingival and periodontal health.

Figure 20-2 shows the radiographic status of the same patient. In the radiographs it can be observed that a large number of teeth have lost substantial amounts of bone support. The lower first molar exhibits marked bone loss in the furcation area which is open for "through and through" probing. Subgingival and supragingival calculus is evident particularly in the lower anterior regions and is consistent with the clinical picture. Widened periodontal ligament spaces are evident in the molar regions, particularly in the upper posterior regions, and indicate that forces elicited during function may be working with the periodontal attachment loss to loosen the molars. Clear evidence of marked attachment loss affecting the stability of the teeth is seen in the lower anterior regions where a splint has been placed in

order to share the occlusal load and attempt to stabilize the teeth. As can be seen in the clinical views, this strategy may be hampered by poor patient oral hygiene which, by maintaining gingival inflammation, ensures poor quality of bone support in addition to poor quantity.

Gingivitis as a risk factor for chronic periodontitis

Findings from epidemiologic studies (cross-sectional as well as longitudinal) indicate that gingival inflammation is invariably a component of chronic periodontitis and that gingivitis precedes the onset of periodontitis (see Chapter 7). The interpretation of data from early cross-sectional studies led to the belief that untreated gingivitis always progresses to chronic periodontitis. More recent studies have demonstrated, however, that this is not the case. Gingivitis lesions may remain stable for many years, and may never progress to become periodontitis lesions with features such as attachment and bone loss. The two conditions have been considered, therefore, as separate disease entities, as the bacterial plaque challenge will induce overt gingivitis but the degree of response of the host (the susceptibility) will determine whether or not chronic periodontitis will develop.

In a review paper, Kinane and Attström (2005) evaluated epidemiologic and experimental data on gingivitis and chronic periodontitis. The independence of these two conditions was called into question. It was proposed that gingivitis and periodontitis most likely represent different aspects of the same disease, namely chronic periodontitis.

Gingivitis becomes manifest after only days or weeks of plaque accumulation (Löe *et al*. 1965), while destructive chronic periodontitis is a condition that in the majority of cases requires far longer periods (years or decades) of plaque and calculus exposure to develop (Lindhe *et al*. 1975; Löe *et al*. 1978). The proportion of untreated gingival lesions in a given subject or in a population that converts to destructive periodontitis lesions is at present unknown. Furthermore, the factors that cause the conversion are not well understood (Schätzle *et al*. 2003).

Findings from epidemiologic studies and prospective clinical trials have indicated that the presence of gingivitis may be regarded as a risk factor for chronic periodontitis. In a 2-year longitudinal study of 15–24-year-old Chinese adolescents from a rural district, it was observed that the percentage of sites that bled on probing at baseline examination was related to overall attachment loss after 2 years of

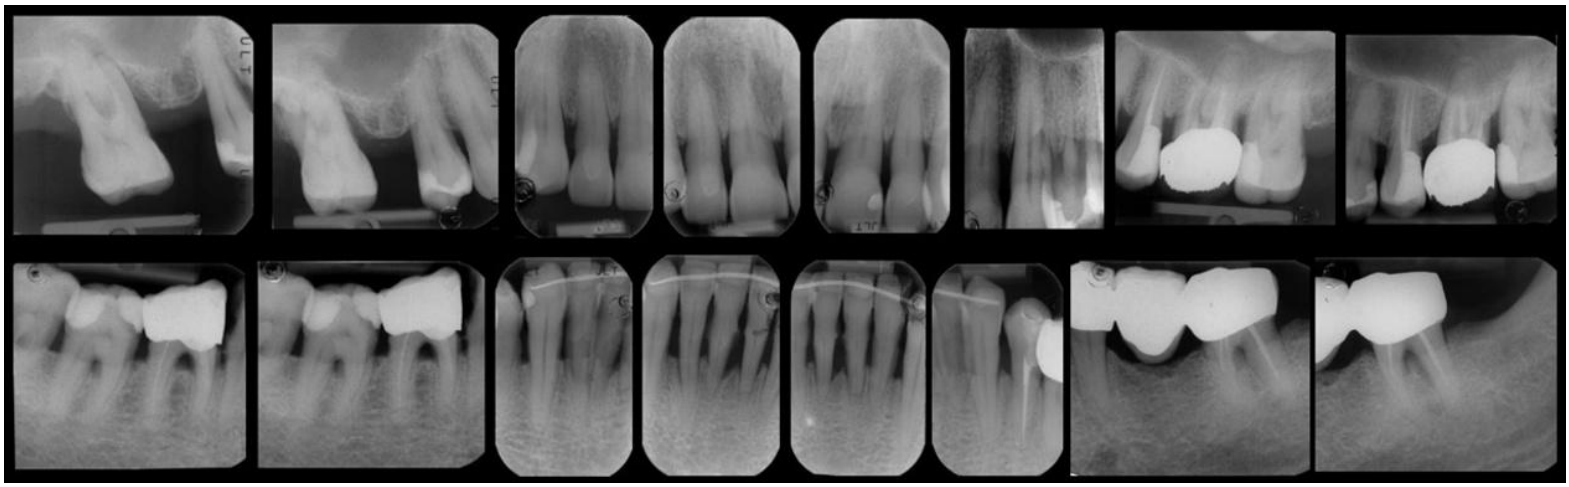

Fig. 20-2 Same patient as in Fig. 20-1. Radiographs from the initial examination.

monitoring (Suda *et al*. 2000). This suggests that gingival inflammation was a risk indicator for additional attachment loss in this cohort. The role of gingivitis in the pathogenesis of chronic periodontitis was further elucidated by Schätzle *et al*. (2004) in longitudinal studies on the initiation and progression of periodontal disease in a Norwegian population. The results demonstrated that gingival sites, which during a 20-year interval never showed signs of inflammation, experienced modest loss of attachment (1.86 mm). For sites which presented with mild inflammation at each examination, the corresponding attachment loss was 2.25 mm, while at sites with severe gingival inflammation, the mean loss of attachment was 3.23 mm. Moreover, while teeth surrounded by healthy gingival tissues were maintained during the study period, teeth with gingivitis lesions were 46 times more likely to be lost.

The above data indicate that gingival inflammation may represent a relevant risk factor not only for destructive chronic periodontitis but also for tooth loss. This conclusion is in agreement with results documenting the absence of gingivitis as a good indicator for long-term maintenance of periodontal health (subject-based stability) (Joss *et al*. 1994), as well as at a site level (Lang *et al*. 1990).

Susceptibility to chronic periodontitis

As stated above, plaque-induced gingivitis and chronic periodontitis represent different aspects of the same disease (Kinane & Attström 2005). The question is then whether or not both gingivitis and chronic periodontitis are affected by the subject response (the host response) to plaque. If this is the case, there are reasons to suggest that susceptibility to gingivitis may in fact also reflect susceptibility to chronic periodontitis.

Even in the very first reports from studies called "Experimental gingivitis in man" (Löe *et al*. 1965; Theilade *et al*. 1966) (see Chapter 13) evidence was presented that suggested that the onset and severity of the inflammatory response of the gingiva to plaque accumulation differed markedly among participants. The differences were, however, at that time attributed to differences in plaque accumulation rates (quantitative plaque differences) and/or differences in bacterial species present in plaque (qualitative plaque differences). More recent studies utilizing the "Experimental gingivitis in man" model have documented that significant differences in the inflammatory response occurred in different subjects, although quantitatively and/or qualitatively their plaque accumulation was similar (Trombelli *et al*. 2004, 2005). It was suggested that the intensity of the inflammatory response to the plaque challenge may represent an individual trait (Tatakis & Trombelli 2004). Thus, an individual's susceptibility to gingivitis may be dependent on host-related factors, possibly of genetic origin (Shapira *et al*. 2005; Scapoli *et al*. 2005, 2007; Trombelli *et al*. 2008, 2010).

With the use of the "Experimental gingivitis in man" model, it was also demonstrated that the susceptibility to gingivitis differed between two groups of patients with apparently different susceptibility to periodontitis (Abbas *et al*. 1986; Winkel *et al*. 1987). Thus, the group with greater periodontitis susceptibility had also a greater susceptibility to gingivitis. Furthermore, in more recent studies, it was documented that subjects with a history of aggressive periodontitis showed significantly more gingivitis in response to *de novo* plaque accumulation when compared to periodontally-healthy subjects matched for extent and rate of supragingival plaque accumulation (Trombelli *et al*. 2006). Thus, pre-existing gingivitis is indeed a risk indicator for chronic inflammatory periodontitis. The reader is referred to Chapter 12 for a comprehensive discussion of the risk factors for gingivitis.

Prevalence of chronic periodontitis

From epidemiologic studies (see Chapter 7) it was concluded that chronic periodontitis is the most commonly occurring form of periodontal disease. While most subjects above 50 years of age have suffered moderate amounts of periodontal tissue destruction, advanced forms of chronic periodontitis are seen in only a small (<10%) subset of the population. Both age of onset of chronic periodontitis and subsequently rate of progression of the disease vary between individuals, and are probably influenced by genetics (see Chapter 15) and environmental risk factors (see Chapters 7 and 12). Findings from examination of dizygotic and monozygotic twins indicated that (1) between 38% [regarding probing attachment loss (PAL)] and 82% (regarding gingivitis) of the population variance could be attributed to genetic factors (Michalowicz *et al*. 1991), and (2) that chronic periodontitis has heritability of about 50% (Michalowicz *et al*. 2000). More recent evidence is available evaluating whether or not genetic characteristics in general, and gene polymorphisms in particular, contribute to exacerbated gingival inflammation in response to plaque accumulation. Since the host immune response is a dominant gene expression pathway during gingivitis onset and resolution, with several genes being significantly up- or down-regulated (Offenbacher *et al*. 2009), studies have focused particularly on the potential association between cytokine gene polymorphism and gingivitis. In this context, data from observational, cohort studies suggested that gene polymorphisms related to specific cytokines which are also implicated in the pathogenesis of chronic periodontitis, such as interleukin-1 (IL-1), IL-10, and matrix metalloproteinase (MMP)-9, may affect the individual gingival inflammatory response to dental biofilm (Dashash *et al*. 2005; Scapoli *et al*. 2005; Dashash *et al*. 2007; Müller &

Table 20-1 Overall characteristics of chronic periodontitis.

- Prevalent in adults but may occur in children
- Amount of destruction of the periodontal tissues seen in a given patient is commensurate with oral hygiene and plaque levels, local predisposing factors, smoking, stress, and systemic risk factors
- Subgingival biofilm harbors a variety of bacterial species; the composition of the biofilm varies between subjects and sites
- Subgingival calculus is invariably present at diseased sites
- Chronic periodontitis is classified as localized when <30% of sites are affected and generalized when this level is exceeded
- Severity of chronic periodontitis at the site level may be classified based on the degree of attachment loss (PAL): *mild* = 1–2 mm, *moderate* = 3–4 mm and *severe* = ≥5 mm
- Although chronic periodontitis is initiated and sustained by microbial plaque, host factors determine the pathogenesis and (rate of) progression of the disease
- Rate of progression of chronic periodontitis is in most cases slow to moderate; periods of rapid tissue destruction may however occur
- Additional periodontal tissue breakdown is likely to occur in diseased sites that are left untreated

Barrieshi-Nusair 2007; Vokurka *et al*. 2009; Müller & Barieshi-Nusair 2010).

Chronic periodontitis on a population basis is often classified according to number (prevalence) of diseased sites (extent) and severity of tissue breakdown (PAL) at such sites: low, 1–10 diseased (gingivitis and PAL) sites; medium, 11–20 diseased sites; and high, >20 diseased sites. The amount of PAL at a given site may be used to describe the severity of chronic periodontitis: mild, 1–2 mm; moderate, 3–4 mm; and severe, (≥5 mm. It has been documented that the *extent* and *severity* of chronic periodontitis are useful predictors of future disease progression.

Clinical (probing) attachment loss of 1 or 2 mm at one or several sites can be found in nearly all members of an adult population. The prevalence of subjects with one or more sites with a PAL of ≥3 mm increases with age (Table 20.1). Furthermore, the number of diseased sites in any one individual increases with age. Also, the population prevalence (extent and severity) of chronic periodontitis increases with age.

Progression of chronic periodontitis

Chronic periodontitis is generally a slowly progressing form of periodontal disease that at any stage may exacerbate, leading to additional loss of attachment and bone.

Tissue destruction in chronic periodontitis does not affect all teeth evenly, but has a site predilection. In other words, in the same dentition, some teeth may be severely affected with periodontal tissue destruction, while other teeth are almost free of signs of attachment and bone loss. When considering changes in attachment level over time, it is also peculiar that only relatively few sites in a subject with chronic periodontitis undergo marked, additional tissue destruction during any given observation period. Based on data from a series of longitudinal studies, Socransky *et al.* (1984) proposed that chronic periodontitis progresses in episodes of exacerbation and remission. They termed this the "burst hypothesis" of disease progression. Findings from other similar studies, however, indicated that the progression of chronic periodontitis may be a continuous, slowly destructive process, rather than exhibiting a "burst" pattern. The current consensus is that the progression of chronic periodontitis in most subjects and at most sites is a continuous process, but that periods of exacerbation occasionally may occur. Clinically, the progressive nature of the disease can only be confirmed by repeated examinations over time, but it is a safe assumption that untreated lesions of chronic periodontitis will progress and cause additional attachment and bone loss. In an untreated population, there was a mean additional PAL of ≥3 mm in up to 27% of subjects over a 1-year period (Flemmig 1999). When progression was studied on a site basis, the overall annual incidence of progression ranged from 0.3% to 4.2% (Flemmig 1999). This indicates that the number of sites that actually exhibited progression within a given time varied considerably between subjects.

It is important to realize that factors associated with the initiation of chronic periodontitis may also influence disease progression. Furthermore, the extent and severity of disease within an individual, that is the number of sites with attachment loss, bone loss, and/or deep pockets, are good predictors of future disease occurrence. In fact, the best predictor of disease progression is previous disease experience.

Risk factors for chronic periodontitis

The term "risk factor" means an aspect of lifestyle, an environmental exposure, or an inborn or inherited characteristic, which on the basis of epidemiologic evidence is known to be associated with a given disease. Risk factors may be part of the causal chain of a disease and/or may predispose the host to develop a disease. An individual presenting with one or more risk factors has an increased probability of contracting the disease or of the disease being worse.

Bacterial factors

These factors are dealt with in Chapters 8 and 10, and from these the reader can ascertain that a cumulative risk for a given microbiota can be estimated. It is not clear, however, if the specific microbiota is the principal disease-causing factor or whether it reflects the disease process. Specific microorganisms have been considered as potential periodontal pathogens, but it is clear that although pathogens are necessary, their mere presence may not be enough for disease activity to occur. Microbial plaque (biofilm) is a crucial factor

in inflammation of the periodontal tissues, but the progression of gingivitis to periodontitis is largely governed by host-based risk factors (Michalowicz 1994; Shapira *et al*. 2005). Microbial biofilms of particular compositions will initiate chronic periodontitis (Marsh 2005) in certain individuals whose host response and cumulative risk factors predispose them to periodontal destruction rather than to gingivitis. The reader is referred to Chapter 8 for a more in-depth discussion of the biofilm and its role in disease induction and maintenance.

Age

Although the prevalence of periodontal disease increases with age, it is unlikely that becoming older in itself greatly increases susceptibility to periodontal disease. It is more likely that the cumulative effects of disease over a lifetime, that is deposits of plaque and calculus, and the increased number of sites capable of harboring such deposits, as well as attachment and bone loss experience, explain the increased prevalence of disease in older people.

Smoking

The association between periodontal disease and smoking is dealt with in detail in Chapter 12. Only a brief discussion of smoking as a risk factor for chronic periodontitis is thus given here. The literature consistently indicates a positive association between smoking and chronic periodontitis across the many cross-sectional and longitudinal studies performed over the years (Kinane & Chestnutt 2000): the risk attributable to tobacco for chronic periodontitis is between 2.5 and 7.0. It is not only the risk of developing the disease that is enhanced by smoking, but also the response to periodontal therapy is impaired in smokers. A further feature in smokers is that their signs and symptoms of both gingivitis and chronic periodontitis, mainly gingival redness and BoP, are masked by the dampening of inflammation seen for smokers as compared to non-smokers.

Systemic disease

It is difficult to determine the precise role any systemic disease may play in the pathogenesis of chronic periodontitis. There are several reasons for this. First, in epidemiologic studies attempting to evaluate the effect of systemic disease, control groups should be carefully matched in respect of age, gender, oral hygiene, and socioeconomic status. Many studies, particularly those conducted before the etiologic importance of dental plaque was recognized, failed to include such controls. Second, because of the chronicity of periodontal disease, longitudinal studies spanning several years are preferable in individuals both with and without systemic disease. Unfortunately, most of the available data are derived from cross-sectional studies (Kinane 1999).

A reduction in number or function of polymorphonuclear leukocytes (PMNs) generally results in an increased rate and severity of periodontal tissue destruction (Wilton *et al.* 1988). Many drugs, such as phenytoin, nifedipine, and cyclosporine, predispose to gingival overgrowth in response to plaque and thus may modify pre-existing chronic periodontitis (Ellis *et al*. 1999). Changes in circulating hormone levels may increase the severity of plaque-induced gingival inflammation, but typically do not result in any increased susceptibility to periodontitis. Hormonal changes following menopause have been associated with osteoporosis, but studies are lacking to link this disease or an estrogen-deficient state to a higher susceptibility to periodontal disease. Immunosuppressive drug therapy and any disease resulting in suppression of inflammatory and immune processes [such as human immunodeficiency virus (HIV) infection] may predispose the individual to exaggerated periodontal tissue destruction (Barr *et al*. 1992).

Nutritional deficiencies in animals have been shown to affect the periodontal tissues, but epidemiologic data do not support the suggestion that such deficiencies play an important role in chronic periodontal disease, although nutritional influences on inflammation are now accepted and are being actively researched (Ritchie & Kinane 2005). Gingival bleeding is the most consistent oral feature of vitamin C deficiency or scurvy, but there is also some evidence to suggest that avitaminosis C may aggravate established chronic periodontitis.

The periodontal features of histiocytosis X and other conditions in the rare histiocytoses disease group may present as necrotizing ulcerative periodontitis (Kinane 1999). Diabetes appears to be one of the most fascinating systemic diseases that interacts with periodontitis. Periodontitis severity and prevalence are increased in subjects with long-duration diabetes, particularly when poorly controlled, compared to in those without diabetes. On the other hand, periodontitis may also exacerbate diabetes as it may decrease glycemic control (Thorstensson 1995).

Despite the paucity of high quality data on individuals both with and without systemic disease, the following general conclusions can be drawn (Kinane 1999):

1. Blood cells have a vital role in supplying oxygen to, the hemostasis of, and the protection of the tissues of the periodontium. Systemic hematologic disorders can thus have profound effects on the periodontium by denying any of these functions necessary for the integrity of the periodontium.
2. The PMN cell is undoubtedly crucial to the defense of the periodontium. To exert this protective function, several activities of PMNs must be integrated, namely chemotaxis, phagocytosis, and killing or neutralization of the ingested organism or substance. Individuals with either quantitative (neutropenia) or qualitative (chemotactic or phagocytic)

PMN deficiencies exhibit severe destruction of the periodontal tissues, which is strong evidence that PMNs are an important component of the host's protective response to the subgingival biofilm. Quantitative deficiencies are generally accompanied by destruction of the periodontium of all teeth, whereas qualitative defects are often associated with localized destruction affecting only the periodontium of certain teeth (i.e. chronic periodontitis may be modified).

3. Leukemias which give rise to excessive numbers of leukocytes in the blood and tissues also cause a greatly depleted bone marrow function with concomitant anemia, thrombocytopenia, neutropenia, and reduced range of specific immune cells, leading to some characteristic periodontal features: anemic gingival pallor, gingival bleeding, and gingival ulceration. Leukemic features are further complicated by the potential for the proliferating leukocytes to infiltrate the gingiva and cause gingival enlargement.
4. In broad terms, leukemias result in gingival pathologies, whereas periodontal bone loss is the consequence of neutrophil functional defects or deficient numbers, and other severe functional defects such as deficiency of leukocyte adhesion receptors.
5. Numerous confounding variables must be considered in determining the true relationship between periodontitis and diabetes. The current consensus is that individuals with diabetes are at increased risk of periodontal disease, and whilst periodontitis can be successfully treated, both disease susceptibility and the outcome of therapy are influenced by poor metabolic control. Thus, it may be of benefit to the dentist to have knowledge of the control status of diabetes in an individual patient, as in the longer term metabolic control could indicate the probable outcome of periodontal therapy. In addition, it is now accepted that periodontal therapy can improve metabolic control in patients with diabetes, meaning that the relationship is two-way and periodontal therapy is beneficial to the control of both diseases.
6. Medications such as phenytoin, cyclosporine, and nifedipine may predispose to gingival overgrowth in patients with gingivitis.
7. Genetic traits, which result in diseases that modify the periodontal structures or change the immune or inflammatory responses, can result in gross periodontal destruction in the affected individual and although the destruction seen may imitate periodontitis, this is not etiopathologically chronic periodontitis.

Stress

Stressful life events and negative emotions have been shown to modulate several physiologic systems, including the endocrine and the immune system, leading to health changes (Kiecolt-Glaser *et al*. 2002; LeResche & Dworkin 2002). The association between stress and disease is particularly strong for infectious diseases, inflammatory conditions, and impaired wound healing (Kiecolt-Glaser *et al*. 2002; LeResche & Dworkin 2002; Broadbent *et al*. 2003). Specific periodontal conditions have been associated with psychosocial variables, including chronic periodontitis (Green *et al*. 1986; Linden *et al*. 1996; Genco *et al*. 1999; Wimmer *et al*. 2002; Pistorius *et al*. 2002), necrotizing ulcerative gingivitis (Shields 1977; Cohen-Cole *et al*. 1983; Horning & Cohen 1995), chronic and experimental gingivitis (Minneman *et al*. 1995; Deinzer *et al*. 1998; Waschul *et al*. 2003). In adults, the reported contribution of psychosocial factors to enhanced gingivitis expression (Deinzer *et al*. 1998) may relate to the stress-associated increase in plaque accumulation (Deinzer *et al*. 2001). However, the possible association of other psychosocial variables, such as personality traits and coping behavior which are associated with either susceptibility or resistance to stress, with changes in the inflammatory response of the gingiva to *de novo* plaque accumulation remains uncertain (Trombelli *et al*. 2005).

Most of the literature on stress and periodontal conditions is quite old, and reports of acute necrotizing ulcerative gingivitis (or trench mouth) were made on stressed soldiers on the front line during World War I. It is understood that stress may be immunosuppressive and that acute necrotizing ulcerative gingivitis may occur in the immunosuppressed patient (also in HIV patients), but there is insufficient data as yet to substantiate the assumption that psychosocial factors are indeed of etiologic importance in chronic periodontitis.

Genetics

There is convincing evidence from twin studies for a genetic predisposition to the periodontal diseases. Twin studies have indicated that risk of chronic periodontitis has a high inherited component (see Chapter 15). A great deal of research is underway attempting to identify the genes and polymorphisms associated with all forms of periodontitis. It is likely that chronic periodontitis involves many genes, the composition of which may vary across individuals and races. Much attention has focused on polymorphisms associated with the genes involved in cytokine production (Shapira *et al*. 2005). Such polymorphisms have been linked to an increased risk for chronic periodontitis, but these findings have yet to be corroborated (Kinane & Hart 2003; Kinane *et al.* 2005) (see Chapter 15).

Scientific basis for treatment of chronic periodontitis

Chronic periodontitis is initiated and sustained by microorganisms living in biofilm communities which are present in supra- and sub-gingival plaque in the

form of uncalcified and calcified (calculus) biofilms. Prevention of initiation or primary prevention of periodontitis is clearly related to preventing formation and/or eradication of the microbial plaque biofilm and it follows that prevention of gingivitis is a primary preventive measure for chronic periodontitis. Initial periodontal therapy or basic treatment of periodontitis involves the removal of both sub- and supra-gingival plaque. The clinical outcome is largely dependent on the skill of the operator in removing subgingival plaque and the skill and motivation of the patient in practicing adequate home care. A further variable is the innate susceptibility of the patient, which is related to the way in which his/her innate inflammatory and immune systems operate in response to the microbial challenge. In addition, local and systemic risk factors can influence the quantity and quality of both the microbial challenge and the host response to these pathogens. The relative contribution of these risk factors has yet to be fully determined, but their influence would be limited if the periodontium is kept free of microbial plaque. Thus, sub- and supra-gingival debridement and the quality of the patient's home care are of vital importance in preventing inflammation that manifests as both gingivitis and periodontitis.

Chapter 21

Aggressive Periodontitis

Maurizio S. Tonetti[1] and Andrea Mombelli[2]

[1] European Research Group on Periodontology (ERGOPerio), Genoa, Italy
[2] Department of Periodontology, School of Dental Medicine, University of Geneva, Geneva, Switzerland

Periodontitis is an infection that can have many different clinical presentations. This has led to the recognition of different clinical syndromes. The question of whether or not these dissimilar clinical presentations represent different forms of disease has been open to discussion. Today, several lines of evidence support the existence of truly different forms of periodontitis. These include:

1. The growing evidence and clinical consensus of differential prognoses and need for specific treatment approaches for the various syndromes
2. Heterogeneity in etiology with possible therapeutic implications
3. Possible heterogeneity in genetic and environmental susceptibility.

At the 1999 International Classification Workshop (Lang *et al.* 1999), the different forms of periodontitis were reclassified into three major forms (chronic, aggressive, and necrotizing) and into periodontal manifestations of systemic diseases. This chapter deals with aggressive, type 1, periodontitis. Until recently, this group of diseases was defined primarily based on the age of onset/diagnosis and was thus named early-onset periodontitis (EOP). Features of this form of disease, however, can present themselves at any age and this form of periodontitis is not necessarily confined to individuals under the arbitrarily chosen age of 35 years.

Aggressive periodontitis (AgP) comprises a group of rare, often severe, rapidly progressive forms of periodontitis, often characterized by an early age of clinical manifestation and a distinctive tendency for cases to aggregate in families. At the above-mentioned classification workshop, AgP was characterized by the following major common features (Lang *et al*. 1999):

- Non-contributory medical history
- Rapid attachment loss and bone destruction
- Familial aggregation of cases.

Frequently, AgP presents early in the life of the individual; this implies that etiologic agents have been able to cause clinically detectable levels of disease over a relatively short time. This fact is central to the current understanding of these diseases, since it implies infection with a highly virulent microbial biofilm and/or a high level of subject susceptibility to periodontal disease. AgP, however, can occur at any age. Diagnosis of AgP requires exclusion of the presence of systemic diseases that may severely impair host defenses and lead to premature tooth loss (periodontal manifestations of systemic diseases).

The existence of specific forms of AgP has also been recognized based on specific clinical and laboratory features: localized aggressive periodontitis [LAP, formerly termed localized juvenile periodontitis (LJP)],

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

and generalized aggressive periodontitis [GAP, formerly termed generalized juvenile periodontitis (GJP), generalized early-onset periodontitis (G-EOP) or rapidly progressive periodontitis (RPP)] (Tonetti & Mombelli 1999).

In spite of its rare occurrence, AgP has been the focus of many investigations aimed at understanding its etiology and pathogenesis. Difficulties in gathering sufficiently large populations, however, have resulted in few clinical studies addressing both diagnostic and therapeutic procedures for this disease. Utilization of both clinical and advanced diagnostic procedures as well as a variety of treatment approaches remains largely anecdotal and based on the specific experience of individual clinicians rather than on well-documented scientific evidence.

Classification and clinical syndromes

In the absence of an etiologic classification, aggressive forms of periodontal disease have been defined based on the following primary features (Lang *et al*. 1999):

- Non-contributory medical history
- Rapid attachment loss and bone destruction
- Familial aggregation of cases.

Secondary features that are considered to be generally, but not universally, present are:

- Amounts of microbial deposits inconsistent with the severity of periodontal tissue destruction
- Elevated proportions of *Aggregatibacter actinomycetemcomitans* (previously named *Actinobacillus actinomycetemcomitans*) and, in some Far East populations, *Porphyromonas gingivalis*
- Phagocyte abnormalities
- Hyper-responsive macrophage phenotype, including elevated production of prostaglandin E_2 (PGE_2) and interleukin-1β (IL-1β) in response to bacterial endotoxins
- Progression of attachment loss and bone loss may be self-arresting.

The International Classification Workshop identified clinical and laboratory features deemed specific enough to allow subclassification of AgP into localized and generalized forms (Lang *et al*. 1999; Tonetti & Mombelli 1999). The following features were identified:

- *Localized aggressive periodontitis* (LAP) (Fig. 21-1):
  - Circumpubertal onset
  - Localized first molar/incisor presentation with interproximal attachment loss on at least two permanent teeth, one of which is a first molar, and involving no more than two teeth other than first molars and incisors
  - Robust serum antibody response to infecting agents
- *Generalized aggressive periodontitis* (GAP) (Fig. 21-2):
  - Usually affecting persons under 30 years of age, but patients may be older
  - Generalized interproximal attachment loss affecting at least three permanent teeth other than first molars and incisors
  - Pronounced episodic nature of the destruction of attachment and alveolar bone
  - Poor serum antibody response to infecting agents.

Diagnosis of one of these AgP forms requires the absence of systemic diseases that may severely impair host defenses and lead to premature exfoliation of teeth. In such instances, the appropriate clinical diagnosis will be periodontal manifestation of systemic disease.

GAP represents the most heterogeneous group and includes the most severe forms of periodontitis. They comprise forms originally described as generalized juvenile periodontitis (emphasis on a possible relationship with LAP), severe periodontitis (emphasis on the advanced destruction in relation to the patient's age), or rapidly progressing periodontitis (emphasis on the fast rate of progression of lesions in these forms). Each of these GAP forms, however, remains highly heterogeneous in terms of clinical presentation and response to therapy. The European Workshop on Periodontology has therefore suggested that, while a better etiologic classification remains unavailable, these forms should be considered as a group to be further defined by the use of various clinical descriptors of the disease based on clinical, microbiologic, and immunologic parameters (Attström & Van der Velden 1993). A further rationale for an imprecise classification of these GAP forms comes from the fact that, given the severity of the disease and the heterogeneity of clinical presentation, each of these rare cases deserves individual consideration.

Subjects often present with attachment loss that does not fit the specific diagnostic criteria established for either AgP or chronic periodontitis; this occurrence has been termed *incidental attachment loss*. It includes: recession associated with trauma or tooth position; attachment loss associated with impacted third molars; attachment loss associated with removal of impacted third molars, etc. It may include initial clinical presentations of periodontitis. Patients with this clinical diagnosis should be considered as a high-risk group for AgP or chronic periodontitis.

Besides clinical presentation, a variety of radiographic, microbiologic, and immunologic parameters are currently being used, along with the assessment of environmental exposures such as cigarette smoking, to further describe the AgP affecting the individual subject. These descriptors are important in treatment selection and to establish long-term prognosis. They will be further discussed in the section on diagnosis later in this chapter.

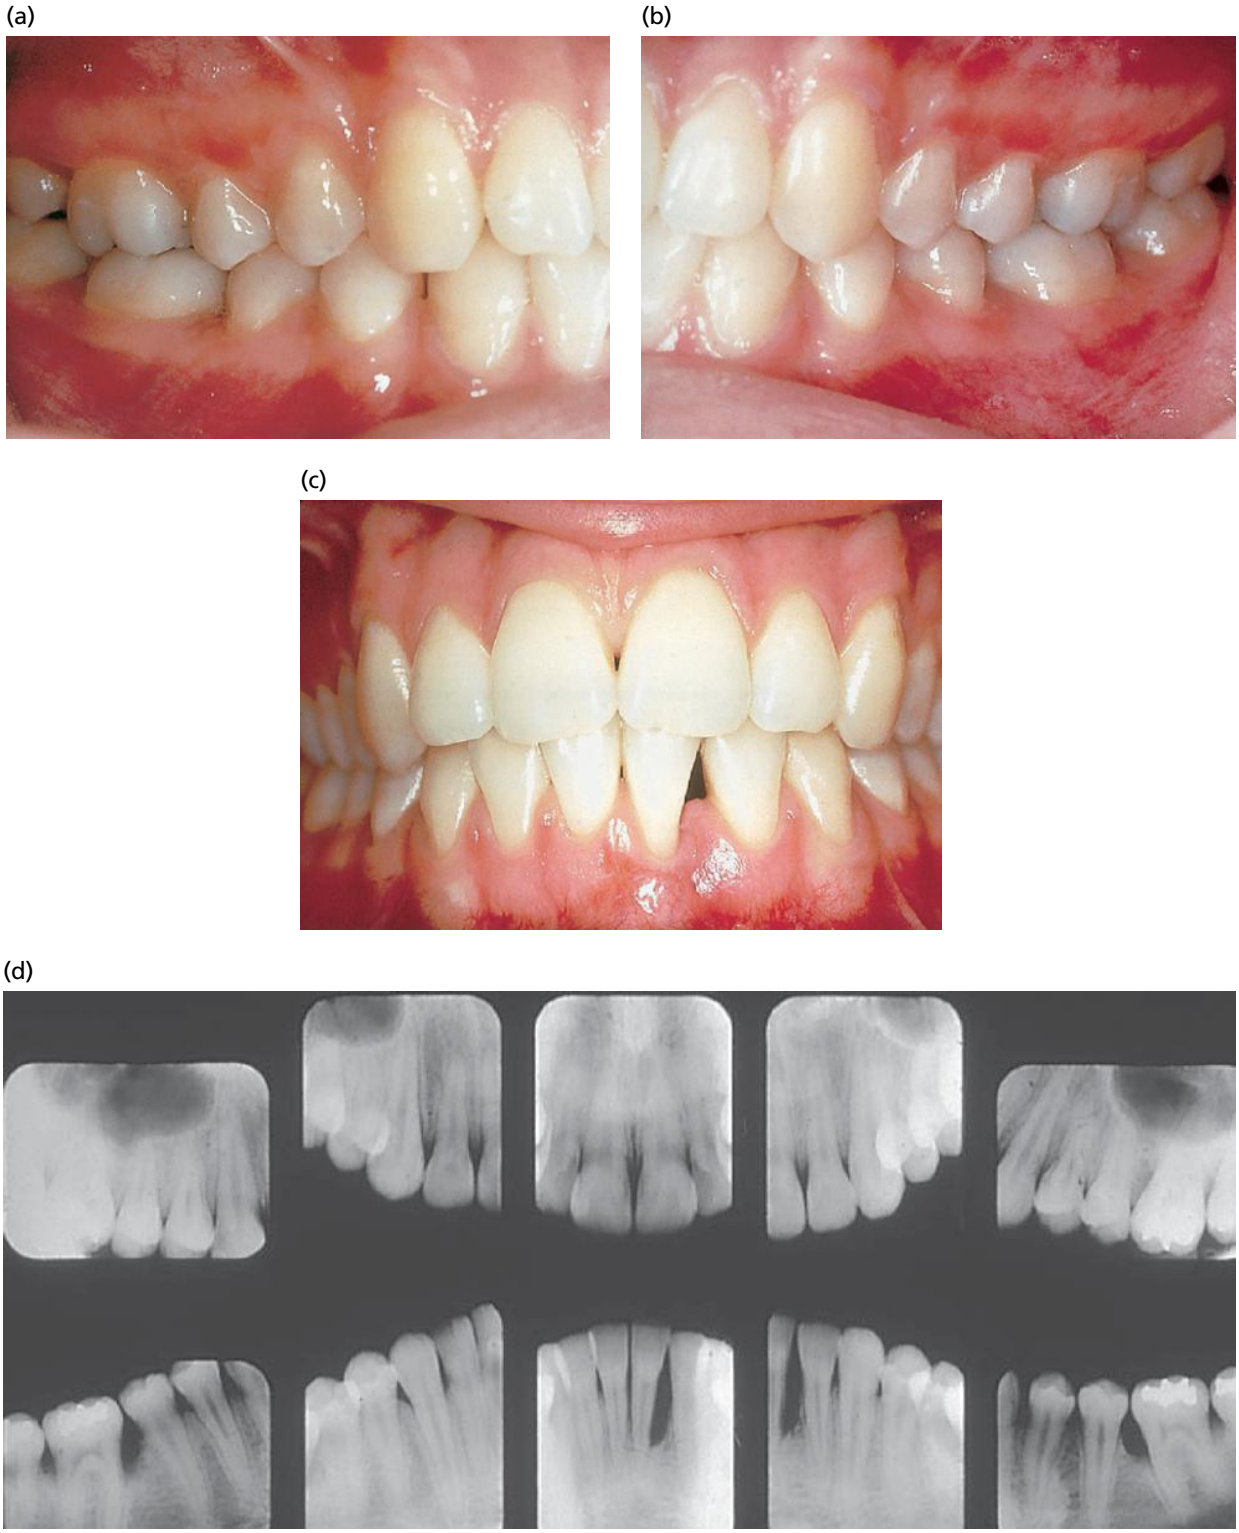

Fig. 21-1 (a–c) Clinical appearance of the periodontal tissues of a 15-year-old girl suffering from localized aggressive periodontitis (AgP). Note the proper oral hygiene conditions and the scalloped outline of the gingival margin. In the lower anterior region, the interdental papilla between teeth 31 and 32 has been lost. (d) Intraoral radiographs show the presence of localized angular bony defects, associated with clinical attachment level loss, at the mesial aspect of teeth 46 and 36, and at the distal aspect of tooth 31. No significant bone loss and/or attachment loss was detectable in other areas of the dentition. Diagnosis: localized aggressive periodontitis (LAP). (e–g) Clinical appearance of the 14-year-old sister of the proband depicted in (a–d). Note that in spite of the excellent oral hygiene status, bleeding on probing was provoked in the mesial of the molars, where deep pockets were present. (h) Angular bone loss is evident on the mesial aspect of teeth 16, 26, and 46.

It is also important to underline that, in the present state of uncertainty regarding both the causative agents and the genetic and environmental susceptibility to AgP, it is possible that, in spite of the lines of evidence presented above, LAP and GAP may simply represent phenotypic variations of a single disease entity. Conversely, it is possible that different AgP forms may manifest with a common clinical presentation. This aspect is of great diagnostic and therapeutic importance.

(e)

(f)

(g)

(h)

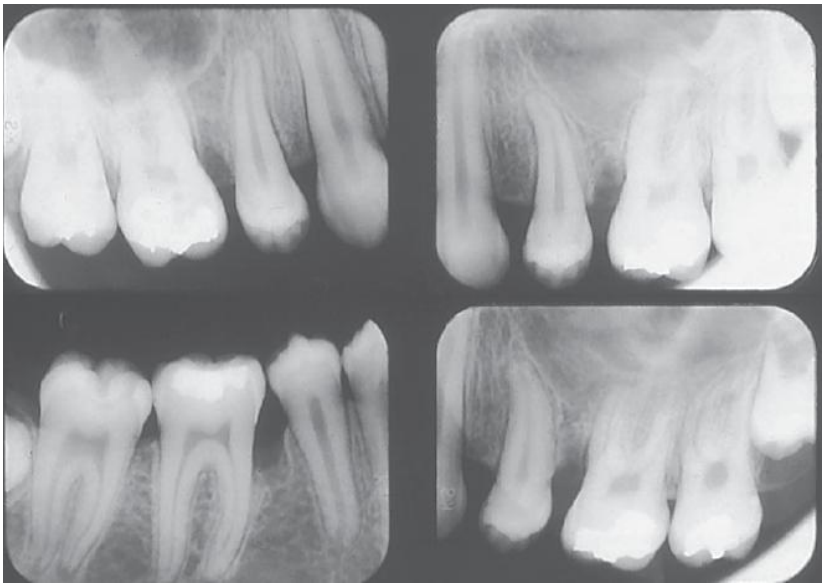

Fig. 21-1 *Continued.*

Some case reports have indicated that some subjects may experience periodontitis affecting the primary dentition, followed by LAP and later by GAP (Shapira *et al*. 1994a). One investigation indicated that 20–52% of LAP patients showed bone loss at primary molars, suggesting that LAP may initially affect the primary dentition in at least some cases (Sjødin *et al*. 1989, 1993). Furthermore, in LAP subjects an association between the number of lesions and the age of the subject has been described, suggesting an age-dependent shift from localized to generalized forms of AgP (Hormand & Frandsen 1979; Burmeister *et al*. 1984).

Epidemiology

Given the history of changes in disease definition of AgP and the fact that it does not represent just a new term for the previously defined EOP, available

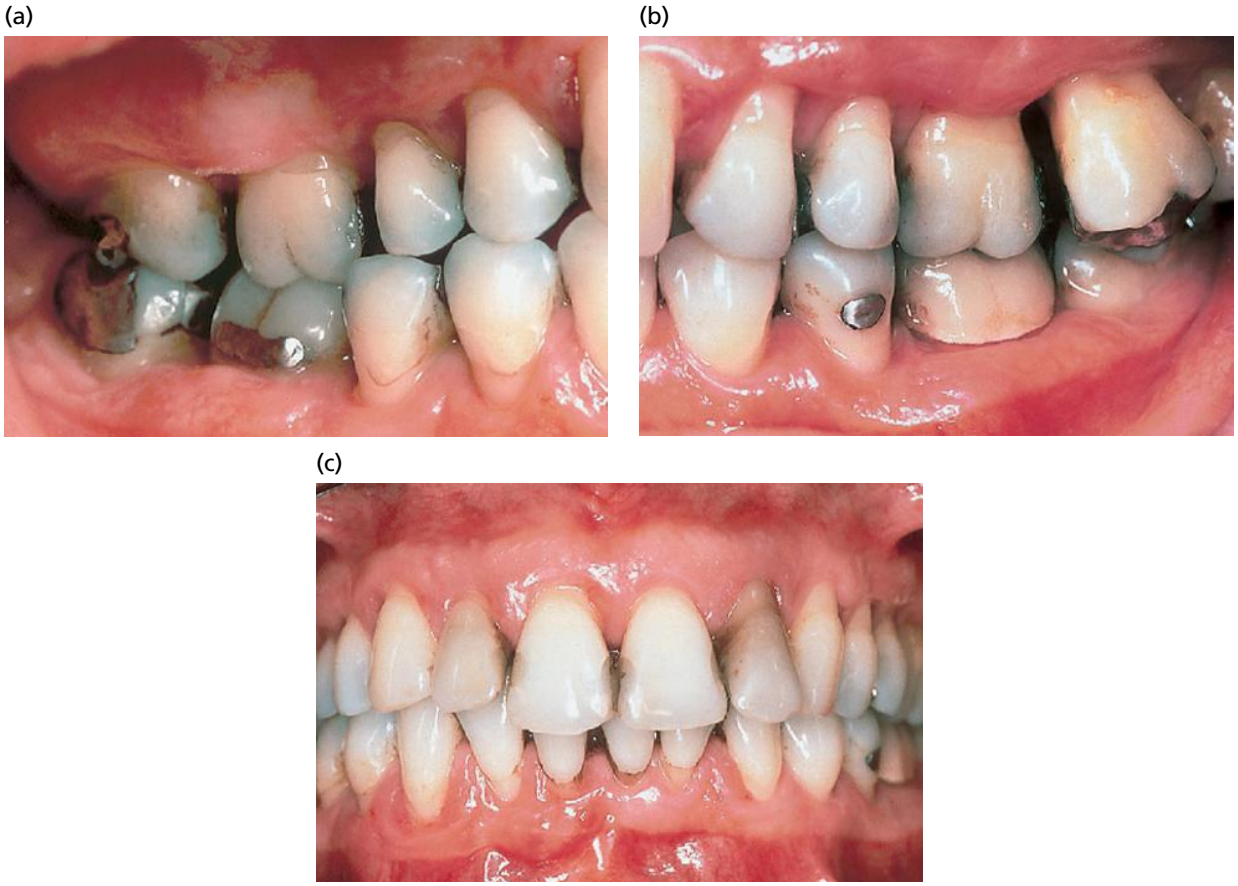

Fig. 21-2 (a–c) Clinical presentation in 1990 of a 32-year-old female with generalized severe bone loss and clinical attachment loss, recession of the gingival margin and presence of deep periodontal pockets. Presence of local factors, and intense inflammation and edema of the gingival margin are evident.

epidemiologic studies relate primarily to EOP. Relatively few investigations employing different epidemiologic techniques have estimated the prevalence and the progression of EOP in the primary and permanent dentition(s) of children and young adults. All available investigations, however, indicate that early-onset (aggressive) forms of periodontal diseases are detectable in all age and ethnic groups (Papapanou 1996). Wide variation in prevalence, however, has been reported, with some studies showing up to 51.5% of individuals affected. This variation is probably due to differences in the epidemiologic methodologies and definition of EOP employed.

Primary dentition

Little evidence is available concerning the prevalence of AgP affecting the primary dentition. In the few studies from industrialized countries, marginal alveolar bone loss has been found to affect the primary dentition of 5–11-year olds with frequencies ranging from 0.9% to 4.5% of subjects (Sweeney *et al*. 1987; Bimstein *et al*. 1994; Sjødin & Mattson 1994). In this respect, it should be emphasized that periodontitis affecting the primary dentition does not necessarily mean the presence of an aggressive form of periodontitis, but may indicate a chronic form of disease with relative abundance of local factors (plaque and calculus). A clinical case of localized periodontitis affecting the primary dentition is shown in Fig. 21-3. More severe cases affecting the primary dentition and leading to tooth exfoliation early in life are usually interpreted as periodontal manifestations of systemic (hematologic) diseases, such as leukocyte adhesion deficiency (Fig. 21-4) (see also Chapter 7).

Permanent dentition

In the permanent dentition of 13–20-year-old individuals, the majority of studies have reported a prevalence of periodontitis of <1% (usually 0.1–0.2% in Caucasian populations). The risk of developing periodontitis at such an early age, however, does not seem to be shared equally in the population: among US school children aged 5–17 years, the prevalence of periodontitis has been estimated to range from about 0.2% for Caucasian subjects to about 2.6% for Black subjects (Löe & Brown 1991). Furthermore, in these young age groups a higher prevalence of periodontitis has been reported in studies from some developing countries (see Chapter 7).

Longitudinal studies of disease progression in adolescents indicate that subjects with signs of destructive periodontitis at a young age are prone to further deterioration. Such deterioration appears to be more

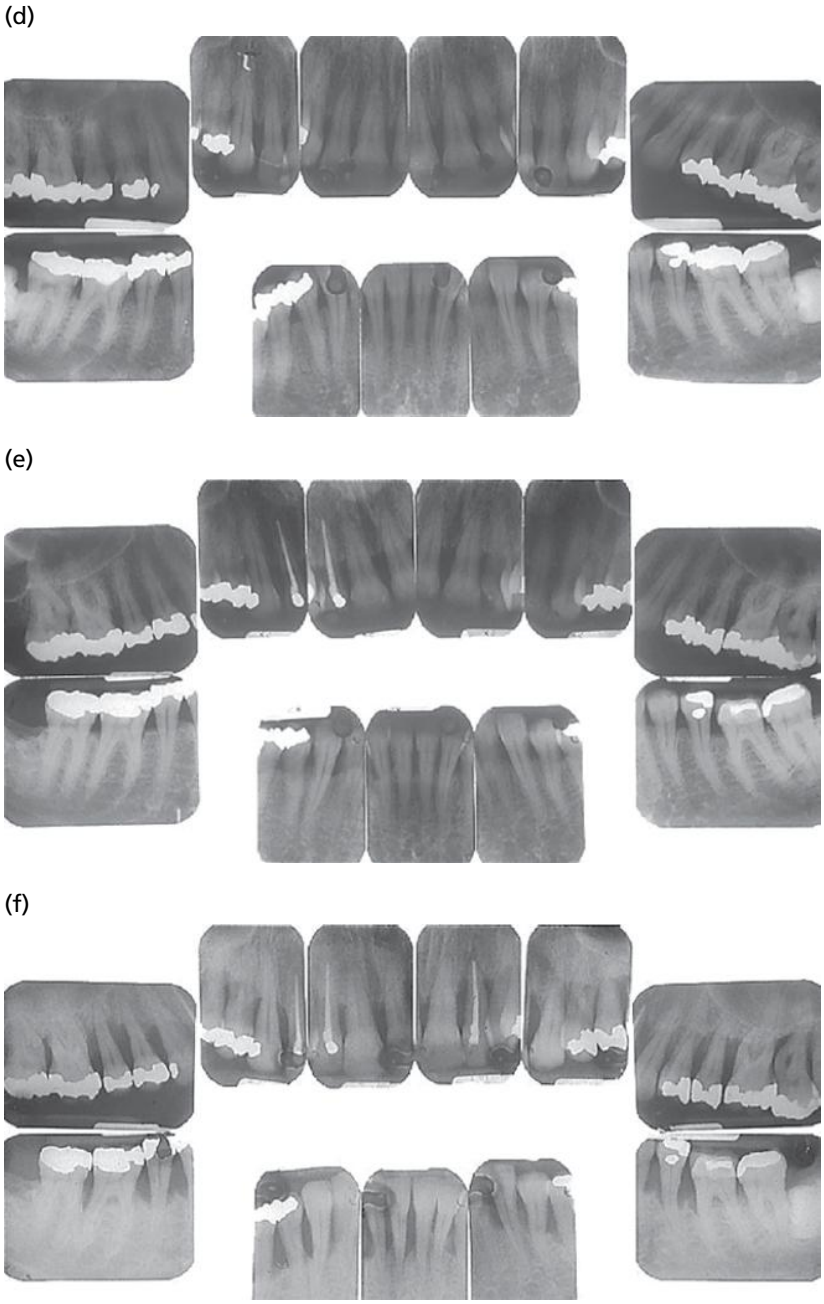

Fig. 21-2 *(Continued).* (d–f) Previous radiographic examinations were available from 1984 and 1987. Comparison of the radiographs obtained over the 6-year period from 1984 to 1990 indicates that most of the periodontal destruction occurred during the last 3 years. The patient had been smoking 20 cigarettes/day for >10 years. Diagnosis: generalized aggressive periodontitis (GAP) in a cigarette smoker.

pronounced at initially affected sites, and in patients diagnosed with LAP and from low socioeconomic groups. Deterioration of the periodontal status involves both an increase in extent (number of lesions within the dentition) and in severity of lesions (further alveolar bone loss at initially diseased sites) (Fig. 21-5) (Clerehugh *et al*. 1990; Lissau *et al*. 1990; Albandar *et al*. 1991a, b; Albandar 1993; Aass *et al*. 1994).

Some epidemiologic investigations have reported a high prevalence of attachment loss in adolescents and young adults who do not fit the characteristics of recognized periodontitis clinical syndromes. Such occurrences have been termed *incidental attachment loss*, and have been reported in 1.6–26% of subjects. This group is thought to comprise both initial forms of periodontitis (including AgP) and a variety of defects, such as recession due to traumatic toothbrushing, attachment loss associated with removal of impacted third molars, interdental caries/placement of restoration, etc.

Conclusion: A small but significant proportion of children and young adults is affected by some form of periodontitis. A substantial proportion of these subjects is thought to be affected by AgP. Given the severity of these forms of periodontal disease and their tendency to progress, early detection of periodontitis and AgP in particular, should be a primary concern

Fig. 21-3 Seven-year-old African–American female presenting with radiographic alveolar bone loss and probing attachment loss at the primary molars and permanent first molars and incisors. (a–c) Clinical photographs, buccal view. (d, e) Bitewing radiographs. Clinical presentation shows moderate plaque accumulation, localized gingival inflammation, with ulceration of the gingival margin and loss of the interdental papilla mesial aspect of tooth 65. In the primary molar regions there were 4–6-mm pockets with bleeding on probing. Bone loss and attachment loss were limited to the molar region. The mesial aspects of the first permanent molars were also initially involved. Radiographic subgingival calculus is evident. Note that the upper left posterior sextant seems to be more severely affected than the other posterior segments. Diagnosis: localized aggressive (type 1) periodontitis.

of both practitioners and public health officers. The whole population, including children and young adults, should receive a periodontal screening as part of their routine dental examination.

Screening

Given the low prevalence of AgP patients within the population, cost-effective detection of cases requires utilization of a sensitive screening approach, in other words the application of a diagnostic approach that can correctly identify most of the cases with disease. The objective of screening is the detection in a population of possibly diseased subjects who require a more comprehensive examination. In periodontology, the most sensitive diagnostic test for the detection of periodontitis is the measurement of attachment loss by probing. Application of this diagnostic procedure in the mixed dentition and in teeth that are not fully erupted, however, may be difficult.

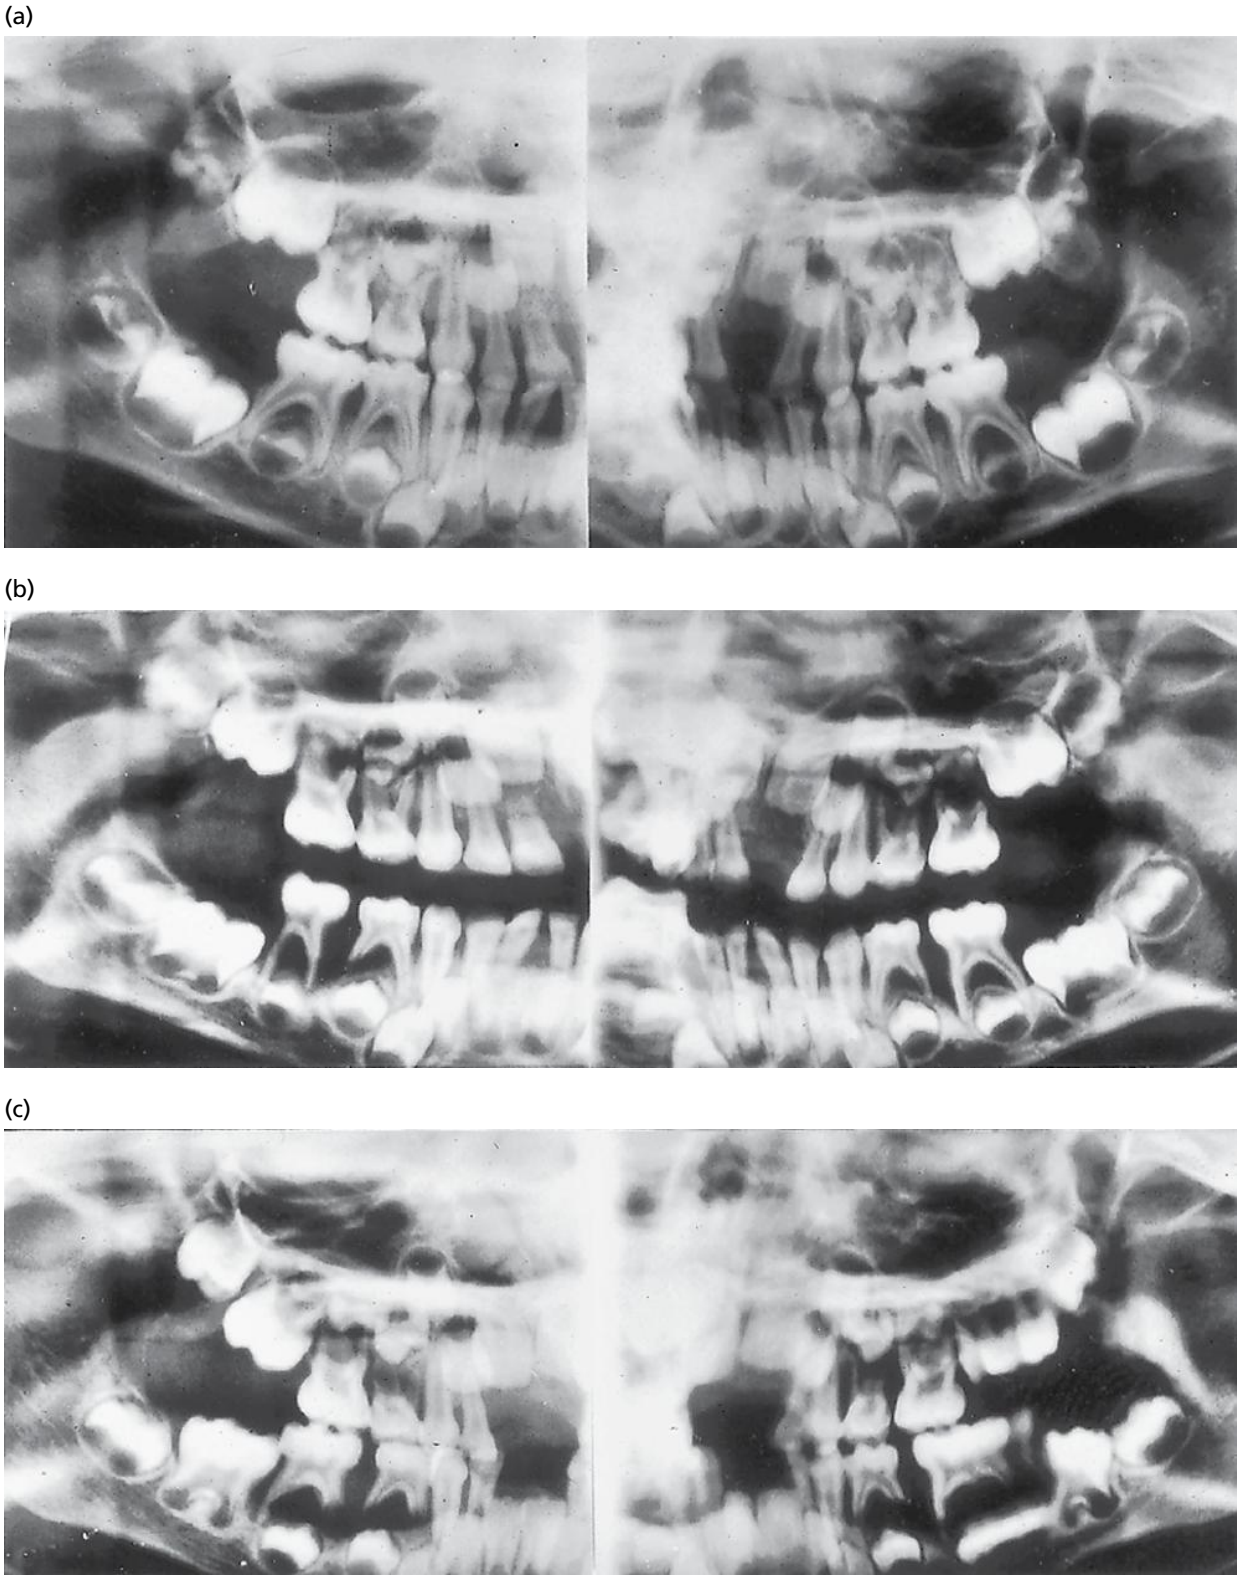

Fig. 21-4 Radiographs obtained from a Caucasian female with generalized prepubertal periodontitis. (a) Radiographic situation in April 1978 when she was 4–5 years old, (b) December 1978, and (c) August 1979. The radiographs illustrate the widespread alveolar bone loss that occurred over the 15-month period. During infancy, this patient had severe, recurrent skin and ear infections sustained by *Staphylococcus aureus* and *Pseudomonas aeruginosa*, respectively. Delayed healing was also observed following minor injuries. White cell counts revealed a persistent leukocytosis, with absolute neutrophil counts always >8000/mm^3. Gingival biopsy indicated that the inflammatory infiltrate consisted almost completely of plasma cells and lymphocytes. No neutrophils were present, in spite of the abundance of these cells in the circulation. This history and clinical manifestation appears to be consistent with the diagnosis of periodontal manifestations of systemic disease in a subject with leukocyte adhesion deficiency (LAD). (Source: Page *et al*. 1983. Reproduced from the American Academy of Periodontology.)

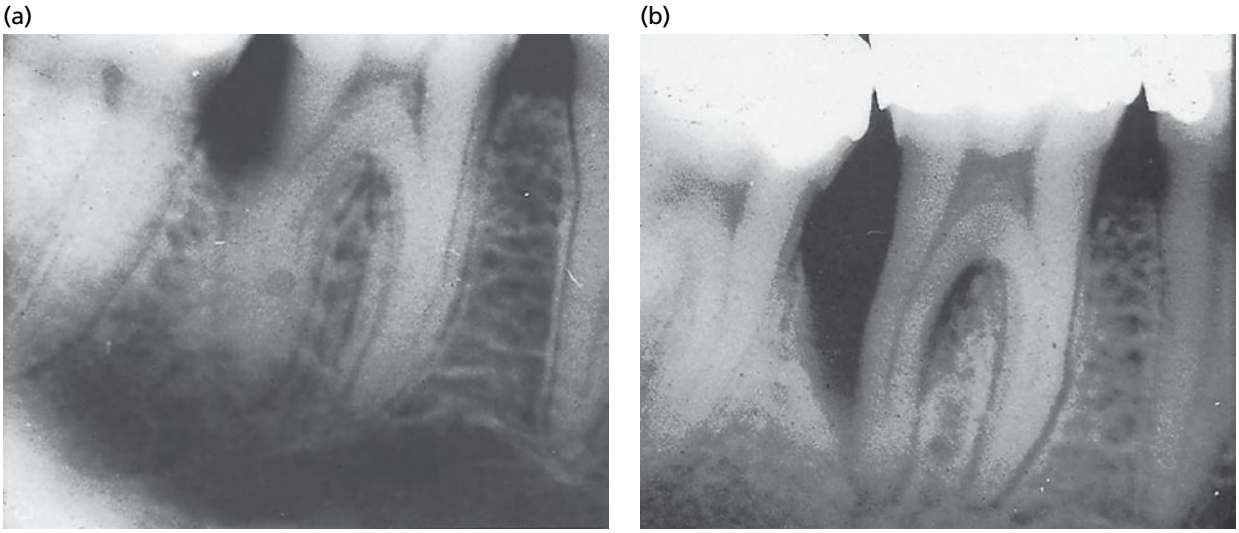

Fig. 21-5 Radiographs illustrating bone loss at the distal aspect of the mandibular first molar in a 15-year-old girl (a) and progression of disease 1 year later (b).

In younger subjects, therefore, a currently utilized screening approach is the measurement of the distance between the alveolar crest and the cementoenamel junction (CEJ) on bitewing radiographs. An advantage of this approach relates to the fact that in most industrialized countries, bitewing radiographs of children and young adolescents in mixed dentition are routinely taken for caries prevention programs; these radiographs should therefore be screened not only for carious lesions but also for the presence of marginal alveolar bone loss.

Previous investigations have attempted to determine the "normal" distance between the CEJ and the alveolar crest of primary and permanent molars in 7–9-year-old children (Sjødin & Mattson 1992; Needleman *et al*. 1997). Median distances at primary molars were 0.8–1.4 mm. These values were in agreement with those previously reported for primary molars of 3–11-year-old children (Bimstein & Soskolne 1988). The CEJ of permanent molars was 0–0.5 mm apical to the alveolar crest in 7–9-year olds. These values were age dependent, and related to the state of eruption of the tooth. In general, however, it should be noted that the majority of children present with distances significantly smaller than the 2–3 mm considered normal for the completely erupted dentitions of adults. In children, significantly greater distances have been detected at sites with caries, fillings or open contacts, indicating that these factors may contribute to bone loss in similar ways to those in adult patients. Furthermore, presence of one of these local factors may suggest a local cause of bone loss, other than periodontitis. A distance of 2 mm between the CEJ and the alveolar crest, in the absence of the above-mentioned local factors, argues therefore for a suspected diagnosis of periodontitis (Figs. 21-6, 21-7) (Sjødin & Mattson 1992). This tentative diagnosis will have to be confirmed by a complete periodontal examination. In utilizing bitewing radiographs for the screening of patients, clinicians should be aware that radiographic marginal bone loss (in the presence of probing attachment loss) is a highly specific diagnostic sign of periodontitis. Its sensitivity, however, is lower than that of periodontal probing because initial intrabony lesions may not appear on radiographs as a result of the masking effects of intact cortical plates (Suomi *et al*. 1968; Lang & Hill 1977). Some initial cases of periodontitis may therefore remain undetected.

In older adolescents and adults, periodontal probing is a more appropriate screening examination than the use of radiographs. It is important to differentiate between clinical use of periodontal probing to perform a complete periodontal examination, and its use as a screening tool. Using probing to detect attachment loss during a screening examination requires circumferential probing to evaluate all sites around the tooth. In a screening examination, however, attachment loss values for all sites are usually not recorded. Furthermore, the screening examination can be stopped once evidence of attachment loss has been detected, and therefore the need for a comprehensive examination has been established. The American Academy of Periodontology has endorsed a simplified screening examination for this purpose. This examination is based on a modification of the Community Periodontal Index of Treatment Needs (CPITN) (Ainamo *et al*. 1982; American Academy of Periodontology & American Dental Association 1992).

There is no evidence that orthopantomograms or cone-beam computed tomography (CT) are useful contributors to the screening process.

Once a case has been detected by a screening examination, a comprehensive periodontal examination will be necessary to establish a proper diagnosis. At this stage, once a case of periodontitis has been confirmed, a differential diagnosis between aggressive (type 1) periodontitis and chronic (type 2) periodontitis needs to be made in accordance with the criteria mentioned above and keeping in mind that

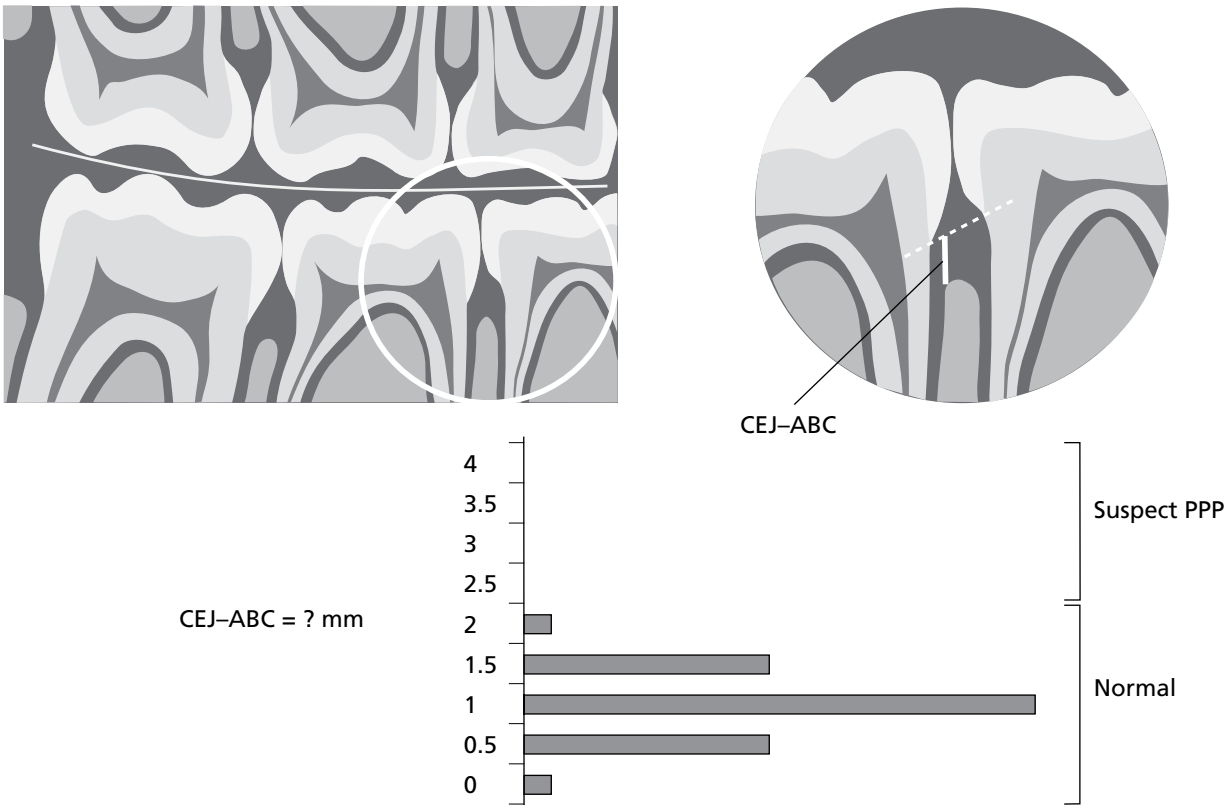

Fig. 21-6 Schematic representation of the use of bitewing radiographs to screen for prepubertal periodontitis in mixed dentition. The distance from the cementoenamel junction (CEJ) and the alveolar bone crest (ABC) is measured from a line connecting the CEJ of the two adjacent teeth. Measurements are taken for each mesial and distal surface. Normal CEJ–ABC distances for 7–9-year olds are <2.0 mm. If the measurement exceeds this value, prepubertal periodontitis (PPP) should be suspected, and a comprehensive periodontal examination should be performed.

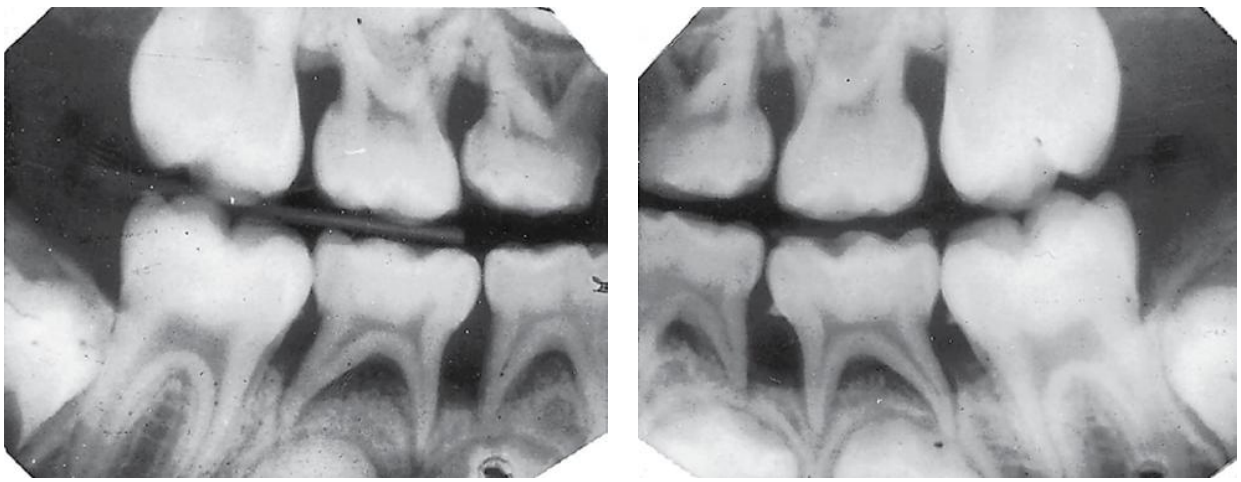

Fig. 21-7 Bitewing radiographs showing advanced bone loss at primary molars, and initial involvement of the mesial aspect of the first molar in a child with early-onset periodontitis. Note the marginal pattern of bone loss, which is significantly different from the pattern expected in association with the normal exfoliation of deciduous teeth. Subgingival calculus can also be observed.

cases who do not fit the AgP criteria should be diagnosed as chronic periodontitis.

Conclusion: Screening periodontal examinations should be performed as part of every dental visit. Marginal bone loss assessed on bitewing radiographs, though less sensitive than periodontal probing, may be used as a screening tool in subjects with primary and mixed dentitions. Attachment loss evaluated by periodontal probing is the most sensitive screening approach currently available; it should be used in older adolescents and adults. Differential diagnosis between AgP and chronic periodontitis is based on exclusion of AgP.

Etiology and pathogenesis

As a group, aggressive forms of periodontitis are characterized by severe destruction of the periodontal attachment apparatus at an early age. This early

manifestation of clinically detectable lesions is generally interpreted as being the expression of highly virulent causative agents or high levels of susceptibility of the individual patient, or a combination of the two.

Bacterial etiology

The evidence implicating bacteria in the etiology of periodontitis has been described in Chapter 10. The most abundant evidence regarding a bacterial etiology of AgP comes from studies of LAP. Evidence relating to other forms of AgP (GAP) will be discussed only when specifically different from LAP.

Acceptance of a bacterial etiology of aggressive forms of periodontitis has been particularly difficult since the clinical presentation of cases frequently shows little visible plaque accumulation, and proximal caries, another dental disease of bacterial origin affecting younger individuals, seems much less prevalent in LAP patients than in age-, gender-, and race-matched controls (Fine *et al*. 1984; Sioson *et al*. 2000). Of great importance, in this respect, were microscopic studies demonstrating the presence of a layer of bacterial deposits on the root surface of advanced AgP lesions (Listgarten 1976; Westergaard *et al*. 1978). Early studies attempted to identify the bacteria involved using culture techniques (Newman *et al*. 1976; Slots 1976; Newman & Socransky 1977). In these studies, Gram-negative organisms comprised approximately two-thirds of the isolates from deep periodontal pockets. In contrast, these organisms averaged only about one-third of the isolates in control sites with normal gingiva. A substantial part of the isolates was not identifiable at that time due to methodologic limitations and ambiguous classification schemes. Dominant microorganisms in LAP included *A. actinomycetemcomitans*, *Capnocytophaga* spp., *Eikenella corrodens*, saccharolytic *Bacteroides*-like organisms now classified as *Prevotella* spp., and motile anaerobic rods today labeled *Campylobacter rectus*. Gram-positive isolates were mostly streptococci, actinomycetes, and peptostreptococci. *A. actinomycetemcomitans*, *Capnocytophaga* spp., and *Prevotella* spp. were also shown to be the most prominent members of the subgingival microbiota of periodontitis lesions in the primary dentition. The microbial patterns observed in periodontal lesions of the primary dentition seemed, however, to be more complex than the ones found in LAP patients.

One of these organisms, *A. actinomycetemcomitans*, a short, facultatively anaerobic, non-motile, Gram-negative rod, received particular attention and was increasingly viewed as a key microorganism in LAP. This view was principally based on four lines of evidence (Socransky & Haffajee 1992):

1. Association studies, linking the organism to the disease: *A. actinomycetemcomitans* was isolated in periodontal lesions from >90% of LAP patients and was much less frequent in periodontally healthy individuals (Table 21.1) (see also Ashley *et al*. 1988; Van der Velden *et al*. 1989; Albandar *et al*. 1990; Gunsolley *et al*. 1990; Slots *et al*. 1990; Asikainen *et al*. 1991; Aass *et al*. 1992; Ebersole *et al*. 1994; Listgarten *et al*. 1995). In some studies it was possible to demonstrate elevated levels of *A. actinomycetemcomitans* in sites showing evidence of recent or ongoing periodontal tissue destruction (Haffajee *et al*. 1984; Mandell 1984; Mandell *et al*. 1987).
2. Demonstration of virulence factors: *A. actinomycetemcomitans* was shown to produce several

potentially pathogenic substances, including a leukotoxin, that were capable of translocating across epithelial membranes, and could induce disease in experimental animals and non-oral sites (for review see Zambon *et al*. 1988; Slots & Schonfeld 1991).

3. Findings of immune responses towards this bacterium: investigators repeatedly reported significantly elevated levels of serum antibodies to *A. actinomycetemcomitans* in LAP patients (Listgarten *et al*. 1981; Tsai *et al*. 1981; Altman *et al*. 1982; Ebersole *et al*. 1982, 1983; Genco *et al*. 1985; Vincent *et al*. 1985; Mandell *et al*. 1987; Sandholm *et al*. 1987). Such patients were furthermore shown to produce antibodies locally against this organism at diseased sites (Schonfeld & Kagan 1982; Ebersole *et al*. 1985b; Tew *et al*. 1985).
4. Clinical studies showing a correlation between treatment outcomes and levels of *A. actinomycetemcomitans* after therapy: unsuccessful treatment outcomes were linked to a failure in reducing the subgingival load of *A. actinomycetemcomitans* (Slots & Rosling 1983; Haffajee *et al*. 1984; Christersson *et al*. 1985; Kornman & Robertson 1985; Mandell *et al*. 1986, 1987; Preus 1988).

In consideration of these findings, *A. actinomycetemcomitans* was one of the few oral microorganisms recognized by many to be a true infectious agent, and LAP as an infection essentially caused by *A. actinomycetemcomitans*. Accepting such a concept has far-reaching consequences with regards to strategies for prevention and therapy. For example, if *A. actinomycetemcomitans* is a real exogenous pathogen for LAP, or AgP in general, avoidance of exposure to the organism becomes a relevant issue in prevention (the mere presence of *A. actinomycetemcomitans* would be an indication for intervention), and the elimination of *A. actinomycetemcomitans* may be a valid treatment goal. Consequently, highly sensitive tests to detect the bacterium would be a useful diagnostic tools. Several studies have, in fact, provided evidence for transmission of *A. actinomycetemcomitans* between humans, for example from parent to child or between spouses (DiRienzo *et al*. 1990; Preus *et al*. 1992; Petit *et al*. 1993a, b; DiRienzo *et al*. 1994b; Poulsen *et al*. 1994; Von Troil-Lindén *et al*. 1995). Other studies have indicated that *A. actinomycetemcomitans* can be eliminated with appropriate mechanical treatment and adjunctive antibiotic therapy (Rams *et al*. 1992; Pavicic *et al*. 1994).

However, the view of LAP as an *A. actinomycetemcomitans* infection has not remained undisputed. It was contested by citing cross-sectional studies showing a high general *A. actinomycetemcomitans* prevalence in certain populations, particularly from developing countries (Eisenmann *et al*. 1983; Dahlén *et al*. 1989; McNabb *et al*. 1992; Al-Yahfoufi *et al*. 1994; Gmür & Guggenheim 1994). It was also argued that *A. actinomycetemcomitans* could be detected in subgingival plaque samples from sites with and without disease, and that there were patients with LAP who apparently neither showed the presence of *A. actinomycetemcomitans* in the oral flora nor had elevated antibody titers to the organism (Loesche *et al*. 1985; Moore 1987). A systematic review with the purpose of determining to what extent adjunctive microbiologic testing could distinguish between chronic and aggressive periodontitis concluded that the presence or absence of *A. actinomycetemcomitans* (as well as of four other suspected periodontal pathogens) could not discriminate subjects with AgP from those with chronic periodontitis (Mombelli *et al*. 2002). Although a diagnosis of AgP was more likely in a subject positive for *A. actinomycetemcomitans* than in an subject negative for this organism, any *A. actinomycetemcomitans*-positive subject with periodontitis was three times more likely to be suffering from chronic than from aggressive periodontitis.

If a putative pathogen can be detected frequently in subjects without a given clinical diagnosis, this suggests that not all humans are equally susceptible and/or that there is variation in virulence and pathogenic potential. Strong evidence has been produced in recent years demonstrating that the virulence of *A. actinomycetemcomitans* is in fact variable, and proving the existence of at least one particularly virulent subpopulation of *A. actinomycetemcomitans.*

Using monoclonal antibody technology, five serotypes (a, b, c, d, e) of *A. actinomycetemcomitans* can be distinguished. Each of these serotypes represents a separate evolutionary lineage. A serotype-dependent pattern of association with LAP was found in the US, where serotype b strains were more often isolated from patients with LJP than from other subjects (Zambon *et al*. 1983b, 1996). A higher frequency of serotype b strains was also reported in Finnish subjects with periodontitis (Asikainen *et al*. 1991, 1995). Differing results were, however, reported from other parts of the world, suggesting that there may be specific distribution patterns in ethnically distinct populations (Chung *et al*. 1989; Gmür & Baehni 1997; Hölttä *et al*. 1994). Using restriction fragment length polymorphism (RFLP) analysis, DiRienzo *et al*. (1994a, b) could discriminate 12 genotypes of *A. actinomycetemcomitans*. One of them (RFLP type II) was uniquely associated with periodontal disease. Others, however, were linked to healthy periodontal conditions.

Several properties of *A. actinomycetemcomitans* are regarded as important determinants of virulence and pathogenic potential (Table 21.2). All Gram-negative bacteria are enveloped by two membranes, of which the outer is rich in endotoxin. This identifying feature of Gram-negative bacteria has a lipid and a polysaccharide part and is therefore frequently termed lipopolysaccharide (LPS). LPS is set free when bacterial cells die or multiply. *A. actinomycetemcomitans* can also secrete membrane vesicles that can serve as transport vehicles to spread endotoxin as well as other pathogenic substances produced by the

Table 21-2 Determinants of virulence and pathogenic potential of *Aggregatibacter actinomycetemcomitans*.

Factor	Significance
Leukotoxin	Destroys human polymorphonuclear leukocytes and macrophages
Endotoxin	Activates host cells to secrete inflammatory mediators (prostaglandins, interleukin-1β, tumor necrosis factor-α)
Bacteriocin	May inhibit growth of beneficial species
Immunosuppressive factors	May inhibit IgG and IgM production
Collagenases	Cause degradation of collagen
Chemotactic inhibition factors	May inhibit neutrophil chemotaxis

bacterium. The LPS of *A. actinomycetemcomitans* can activate host cells, and macrophages in particular, to secrete inflammatory mediators such as prostaglandins, IL-1β, and tumor necrosis factor-alpha (TNF-α). It is also highly immunogenic, since high titers of antibodies against its antigenic determinant are frequently detected in infected individuals. Additional virulence factors interfering with fibroblast proliferation have been identified for certain strains of *A. actinomycetemcomitans*. Immunosuppressive properties of *A. actinomycetemcomitans*, as well as collagenolytic activity and inhibition of neutrophil chemotaxis, have been demonstrated (for review see Fives-Taylor *et al*. 1996). The key element of virulence and pathogenicity of *A. actinomycetemcomitans*, however, is considered to be the production of a leukotoxin, which plays an important role in the evasion of local host defenses. The leukotoxin produced by *A. actinomycetemcomitans* exhibits cytotoxic specificity and destroys human polymorphonuclear leukocytes (PMNs) and macrophages, but neither epithelial and endothelial cells nor fibroblasts. It belongs to the family of RTX (Repeats in ToXin) toxins, which are pore-forming lytic toxins (for details see Lally *et al*. 1996).

Leukotoxin production varies significantly among strains of *A. actinomycetemcomitans* (Zambon *et al*. 1983a; Kolodrubetz *et al*. 1989; Spitznagel *et al*. 1991; Brogan *et al*. 1994). The strain-specific difference in leukotoxin production seems to be regulated at the level of transcription (Spitznagel *et al*. 1991). Brogan *et al*. (1994) detected a 530-bp deletion in the promoter region of the leukotoxin operon and found that strains with this feature produced 10–20 times more leukotoxin. Subsequent analysis showed that the occurrence of such highly toxigenic strains coincided with the high frequency of serotype b in patients with LJP, and that these strains actually constituted a specific clone of serotype b, now referred to as the JP2 clone (the initial isolate of this clone is strain JP2, from an African–American child with prepubertal periodontitis) (Tsai *et al*. 1984). Extensive further research (Poulsen *et al*. 1994; Haubek *et al*. 1995, 1996, 1997; Tinoco *et al*. 1997; Bueno *et al*. 1998; He *et al*. 1999; Macheleidt *et al*. 1999; Mombelli *et al*. 1999; Contreras *et al*. 2000; Haraszthy *et al*. 2000; Haubek *et al*. 2001; Tan *et al*. 2001; Cortelli *et al*. 2005) has clearly identified the JP2 clone as a common isolate in patients of North and West African descent suffering from AgP, even if they lived in another geographic region (e.g. North and South America or Europe). The disease association with RFLP type II reflects the fact that the JP2 clone represents a subpopulation of strains showing the RFLP type II pattern.

Our current knowledge with regards to the genetic and phenotypic diversity of *A. actinomycetemcomitans*, and its distribution in various populations and cohorts, with or without a clinical diagnosis of LAP, suggests that *A. actinomycetemcomitans* may be considered an opportunistic pathogen, or even a commensal bacterial species as a whole. However, at least one distinct subpopulation, the JP2 clone, displays the properties of a true pathogen in at least one group of humans of North and West African descent (Kilian *et al*. 2006; Haubek *et al*. 2008). Prevention of vertical transmission of such virulent clones may be a feasible measure to prevent AgP (Van Winkelhoff & Boutaga 2005).

Generalized aggressive periodontitis (GAP), formerly named generalized early-onset periodontitis (G-EOP) and rapidly progressive periodontitis (RPP), has been frequently associated with the detection of *P. gingivalis*, *Tannerella forsythia*, and *A. actinomycetemcomitans*. In contrast to *A. actinomycetemcomitans*, which is facultatively anaerobic, *P. gingivalis* and *T. forsythia* are fastidious strict anaerobes. *P. gingivalis* produces several potent enzymes, in particular collagenases and proteases, endotoxin, fatty acids, and other possibly toxic agents (Shah 1993). A relationship between the clinical outcome of therapy and bacterial counts has also been documented for *P. gingivalis*, and non-responding lesions often contain this organism in elevated proportions. High local and systemic immune responses against this bacterium have been demonstrated in patients with GAP (Tolo & Schenck 1985; Vincent *et al*. 1985; Ebersole *et al*. 1986; Murray *et al*. 1989).

Bacterial damage to the periodontium

Disease-associated bacteria are thought to cause destruction of the marginal periodontium via two related mechanisms: (1) the direct action of the microorganisms or their products on the host tissues, and/or (2) as a result of their eliciting tissue-damaging inflammatory responses (see Chapter 13) (Tonetti 1993). The relative importance of these two mechanisms in AgP remains speculative. Investigations in humans have indicated that *A. actinomycetemcomitans* is able to translocate across the junctional epithelium and invade the underlying connective tissue (Saglie *et al*. 1988). These data support the hypothesis that

Table 21-3 Host defense mechanisms in the gingival sulcus.

- Intact epithelial barrier and epithelial attachment
- Salivary flushing action, agglutinins, antibodies
- Sulcular fluid flushing action, opsonins, antibodies, complement, and other plasma components
- Local antibody production
- High levels of tissue turnover
- Presence of normal flora or beneficial species
- Emigrating PMNs and other leukocytes

PMNs, polymorphonuclear leukocytes.

direct bacterial invasion may be responsible for some of the observed tissue breakdown. Data from chronic periodontitis, however, seem to indicate that two-thirds of attachment loss and alveolar bone resorption is preventable through the action of non-steroidal anti-inflammatory drugs, and therefore tissue destruction seems to be driven by the inflammatory process (Williams *et al*. 1985, 1989). Apical spread of bacteria loosely adhering to the hard, non-shedding surface of the tooth is thought to be controlled through a first line of defense consisting of mechanisms such as the high turnover of junctional epithelium keratinocytes, the outward flow of crevicular fluid, and the directed migration of PMNs through the junctional epithelium; the efficiency of these innate immune mechanisms is highly enhanced by the presence of specific antibodies and complement fragments in the gingival crevicular fluid (Page 1990) (Table 21.3) (see Chapter 13).

Host response to bacterial pathogens

Both local and systemic host responses to AgP-associated microflora have been described. Local inflammatory responses have been characterized by an intense recruitment of PMNs both within the tissues and into the periodontal pocket. Such a preponderance of PMNs underlines the importance of these cells in the local defense against bacterial aggression and their potential role in host-mediated tissue destruction. B cells and antibody-producing plasma cells represent a significant component of the mononuclear cell-dominated connective tissue lesion (Liljenberg & Lindhe 1980). Plasma cells have been shown to be predominantly IgG-producing cells, with a lower proportion of IgA-producing cells (Mackler *et al*. 1977, 1978; Waldrop *et al*. 1981; Ogawa *et al*. 1989). Local IgG_4-producing cells, in particular, seem to be elevated. Another important component of the local inflammatory infiltrate is T cells. Subset analysis of local T cells has indicated a depressed T-helper-to-T-suppressor ratio as compared to both healthy gingiva and peripheral blood. These findings have been interpreted to suggest the possibility of altered local immune regulation (Taubman *et al*. 1988, 1991). Peripheral blood mononuclear cells from AgP patients have been reported to exhibit a reduced autologous mixed lymphocyte reaction, as well as a higher than normal response to B-cell mitogens (for review see Engel 1996). Local inflammatory responses are characterized by high levels of PGE_2, IL-1α, and IL-1β in both crevicular fluid and tissue (Masada *et al*. 1990; Offenbacher *et al*. 1993). PGE_2 production, in particular, has been shown to be highly elevated in AgP subjects when compared to periodontally healthy individuals and patients with chronic periodontitis.

Specific antibodies against AgP-associated microorganisms (Lally *et al*. 1980; Steubing *et al*. 1982; Ebersole *et al*. 1984, 1985a, b) and cleaved complement fragments (Schenkein & Genco 1977; Patters *et al*. 1989) have also been detected in crevicular fluid from AgP lesions. Of interest is the evidence indicating that crevicular fluid titers of antibodies against AgP-associated microorganisms are frequently higher than in the serum of the same patient (Ebersole *et al*. 1984, 1985a, b). This observation, together with substantial *in vitro* and *ex vivo* data, strongly suggests that substantial fractions of these antibodies are locally produced in the inflammatory infiltrate (Steubing *et al*. 1982; Hall *et al*. 1990, 1991, 1994). Substantial titers of antibodies against *A. actinomycetemcomitans* and *P. gingivalis* have also been detected in the serum of AgP patients. Furthermore, in some patients, titers of antibodies reactive to *A. actinomycetemcomitans* have been shown to be as high as those against *Treponema pallidum* present in tertiary syphilis (0.1–1 g/mL); this clearly indicates the extent of the host response that can be mounted against these periodontal pathogens (for a review see Ebersole 1990, 1996).

Investigations have identified the immunodominant *A. actinomycetemcomitans* antigen to be the serotype-specific carbohydrate; furthermore, it has been shown that the vast majority of antibodies reactive to this carbohydrate in AgP patients consist of IgG_2 (Califano *et al*. 1992). High titers and high avidity of *A. actinomycetemcomitans*-specific IgG_2 have been demonstrated in LAP patients, where high antibody titers are thought to be associated with the host's ability to localize attachment loss to a few teeth; conversely, GAP patients are frequently seronegative for *A. actinomycetemcomitans* or display low titers and avidity. Anti-*A. actinomycetemcomitans* serotype polysaccharide IgG_2, therefore, is considered to be protective against widespread AgP (Tew *et al*. 1996).

Of importance are findings reporting antibody response to *P. gingivalis* in GAP forms. Patients suffering from these forms of disease frequently show both low levels of serum antibodies against *P. gingivalis* and low levels of antibody avidity, indicating a specific inability of some GAP patients to cope effectively with these bacteria. Importantly, however, both titers and avidity of antibodies reacting with *P. gingivalis* can be improved as a result of therapy.

Another important aspect of the host response towards AgP microorganisms has been the recognition that the PMNs of some LAP and GAP patients show decreased migration and antibacterial functions (Genco *et al*. 1980, 1986; Van Dyke *et al*. 1982, 1986,

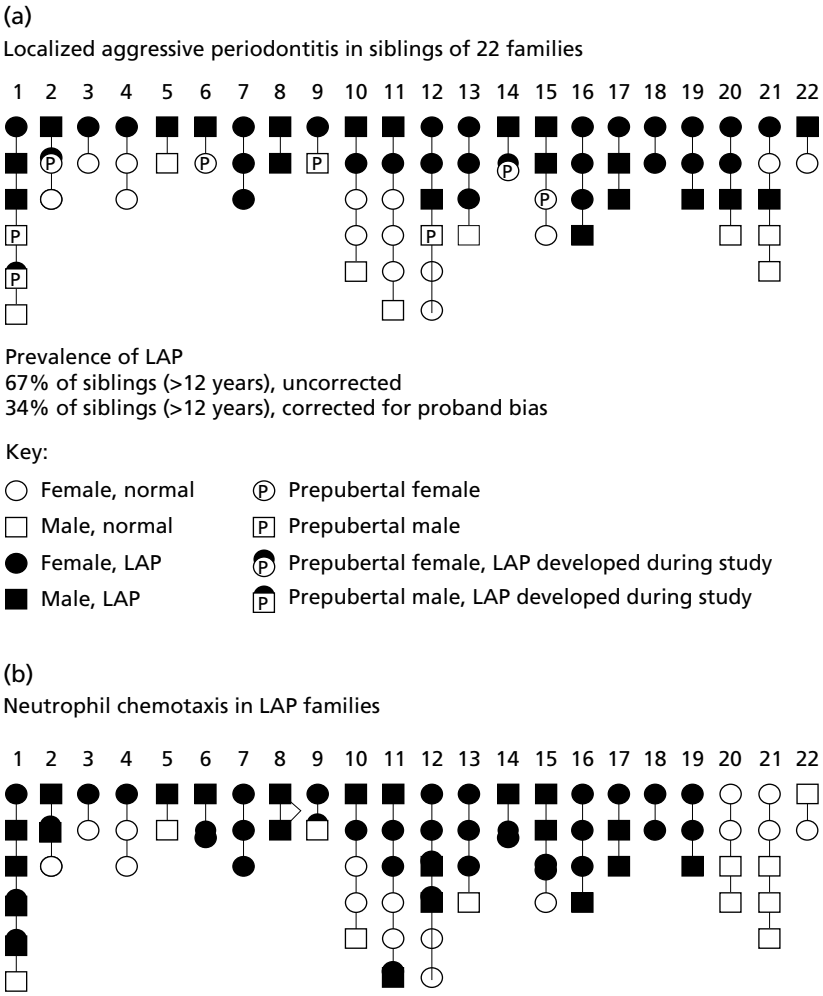

Fig. 21-8 (a) Patients suffering from localized aggressive periodontitis (LAP) in 22 families are represented by solid black shapes. In each family the proband is on the left. (b) Schematic representation of sibships involved in the study group. Numbers are the same as in (a). Solid black shapes represent patients exhibiting depressed neutrophil chemotaxis. In this group, after correcting for sampling bias, 40% of subjects presented with abnormal chemotaxis. Subjects in sibship 8 are identical twins. (Source: Van Dyke *et al*. 1985. Reproduced with permission from John Wiley & Sons.)

1988). These abnormalities are frequently minor in the sense that they are usually not associated with infections other than periodontitis. A key report has indicated that PMN abnormalities in LAP patients seem to cluster in families, much in the same way as AgP does (Fig. 21-8) (Van Dyke *et al*. 1985). This evidence has been interpreted as a suggestion that the LAP-associated PMN defect may be inherited. Other reports have indicated that PMN abnormalities in LAP patients may be, at least in part, the result of a hyperinflammatory state resulting in the presence of pro-inflammatory cytokines in the serum of some AgP patients (Shapira *et al*. 1994b; Agarwal *et al*. 1996).

Genetic aspects of host susceptibility

Several family studies have indicated that the prevalence of AgP is disproportionately high among certain families, where the percentage of affected siblings may reach 40–50% (Saxen & Nevanlinna 1984; Beaty *et al*. 1987; Long *et al*. 1987; Boughman *et al*. 1992; Marazita *et al*. 1994; Llorente & Griffiths 2006). Such a dramatic familial aggregation of cases indicates that genetic factors may be important in susceptibility to AgP. Genetic studies in these families suggest that the pattern of disease transmission is consistent with Mendelian inheritance of a gene of major effect (Saxen & Nevanlinna 1984; Beaty *et al*. 1987; Boughman *et al*. 1992; Hart *et al*. 1992; Marazita *et al*. 1994). This means that the observed familial pattern can be partly accounted for by one or more genes that could predispose individuals to develop AgP.

Segregation analyses have indicated that the likely mode of inheritance is autosomal dominant (Fig. 21-9a) (Saxen & Nevanlinna 1984; Beaty *et al*. 1987; Hart *et al*. 1992; Marazita *et al*. 1994). Most of these investigations were carried out in African–American populations; it is therefore possible that other modes of inheritance may exist in different populations. Segregation analysis can provide information about the mode of inheritance of a genetic trait, but does not provide information about the specific gene(s) involved. The chromosomal location of a gene of major effect for a trait such as AgP susceptibility can be determined by linkage analysis. An investigation utilizing this methodology reported linkage of LAP to the vitamin D-binding locus on region q of chromosome 4 in a large family of the Brandywine population (Boughman *et al*. 1986). These results, however, were not confirmed in a subsequent study utilizing a different population (Hart *et al*. 1993). Another study has linked localized AgP with the q25 region of chromosome 1 in an area close to the cyclooxygenase 2 (*COX-2*) gene (Li *et al*. 2004), and another has established evidence of linkage

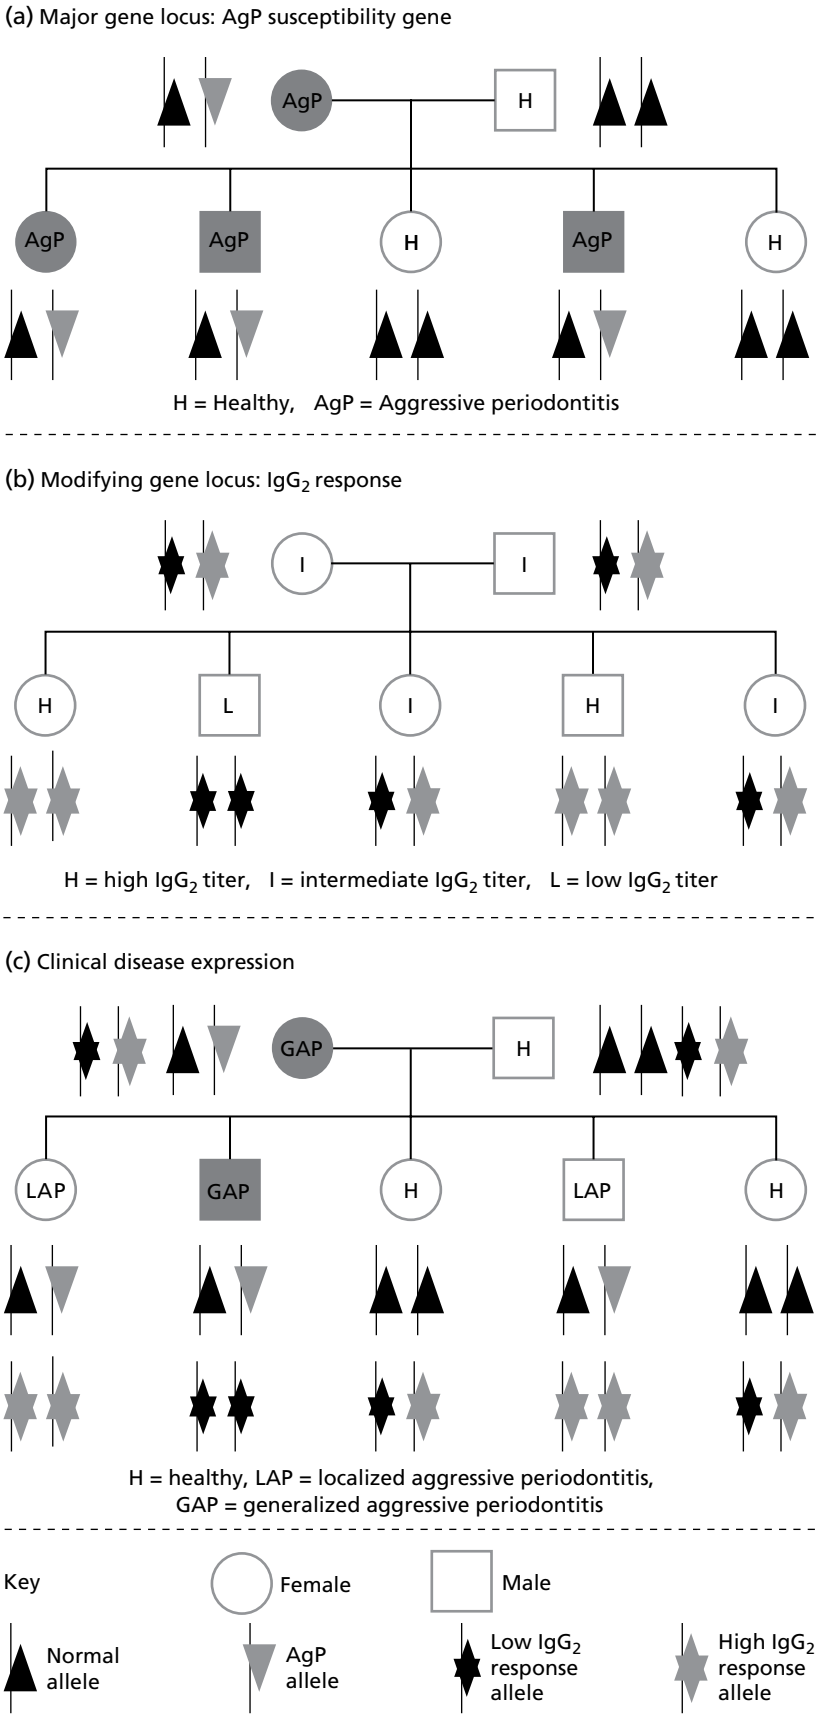

Fig. 21-9 (a) Genetic predisposition to aggressive periodontitis (AgP) is determined by a single gene of major effect, inherited as an autosomal dominant trait. (b) Modifying genes may control immune responses that determine the clinical extent and severity of periodontal destruction in AgP. Here an allele controlling IgG_2 levels is inherited as a co-dominant trait. (c) Independent inheritance of major locus and modifying locus illustrating how localized aggressive periodontitis (LAP) and generalized aggressive periodontitis (GAP) may segregate within the same family. The propensity to develop AgP is dependent upon the inheritance of a major susceptibility gene. The clinical phenotype is dependent upon the host's ability to produce IgG_2 in response to periodontopathic bacteria. High IgG_2 titers limit disease extension. Intermediate and low IgG_2 titers are less effective in limiting intermediate disease progression. (Adapted from Hart 1996, reproduced from the American Academy of Periodontology. Adapted from Schenkein & Van Dyke, 1994 from John Wiley & Sons.)

with the q13–14 region of chromosome 2 that contains the *IL-1* gene complex (Scapoli *et al*. 2005). Such data are currently considered to support the existence of genetic heterogeneity in LAP forms, and of distinct forms of AgP. Therefore, it is currently maintained that although formal genetic studies of AgP support the existence of a gene of major effect, it is unlikely that all forms of AgP are due to the same genetic variant (Hart 1996; Loos *et al*. 2005). This notion is consistent with the fact that numerous diseases and syndromes with

Table 21-4 Genes known to affect human polymorphonuclear leukocyte (PMN) function or host response to lipopolysaccharide (LPS) load and/or thought to be among the candidate genes of major effect in early-onset periodontitis (EOP) susceptibility.

Condition	OMIM[a]	Transmission	Chromosome location	Comments
Bactericidal permeability increasing protein (BPIP)	109195	AD	20q11–12	BPIP is associated with PMN granules and is bactericidal to Gram organisms. It binds to LPS with high affinity. BPIP is 45% homologous to LPS-binding protein
LPS binding protein (LBP)	151990	AD	20q11–12	Produced during acute phase of infection: binds to LPS and functions as a carrier for LPS; functions in monocyte response
Monocyte differentiation antigen (CD14)	158126	AD	5q31	Receptor for LBP–LPS complex
Prostaglandin synthase 2 (PTGS2)	600262	AR	1q25.2–3	Major role in regulation of prostaglandin synthesis. Dramatic induction of PTGS2 mRNA occurs in normal peripheral blood leukocytes in response to LPS
PMN actin dysfunction (NAD)	257150	AR	?	Carriers (heterozygotes) have a 50% decrease in actin filament assembly; affected individuals (homozygotes) have recurrent bacterial infections. PMN severely defective in migration and particle ingestion; basic defect due to failure of PMN actin polymerization
Myeloperoxidase deficiency (MPO)	254600	AR	17q12–21	Absence of MPO. MPO is a dimeric protein that catalyzes the production of oxidating agents with microbicidal activity against a wide range of microbes. Several variants have been described
IgE elevation with PMN chemotaxis defect	147060	AD	?	Impaired lymphocyte response to *Candida* antigen; recurrent bacterial infections
Fc receptor gamma IIA polymorphism (FCGR2A)	146790	AD	1q21–q23	Allelic variants of the Fc-gamma receptor 2A confer distinct phagocytic capacities providing a possible mechanism for hereditary susceptibility to infection. The H131 allele is the only FCGR2A that recognizes IgG_2 efficiently, and optimal IgG_2 handling occurs only in the homozygous state for H131. The allelic variant R131 has low binding of IgG_2
Immunoglobulin G_2m allotypes	N/A	?	N/A	Specific allotypes associated with IgG_2 response to specific bacterial antigens Subjects lacking specific allotypes may be selectively unable to mount efficient antibody response against specific antigens

similar clinical appearance are known to result from different genetic polymorphisms.

Additional evidence for a genetic component to AgP was provided by a study demonstrating substantial levels of hereditability in quantitative parameters for periodontal disease severity of AgP patients (Diehl *et al*. 2005).

Based on current knowledge that AgP subjects have a high prevalence of PMN functional defects, that they produce high levels of inflammatory mediators in response to LPS stimulation, and that connective tissue homeostasis is relevant in periodontitis, several loci have been proposed as genes conferring increased susceptibility to AgP. Hart (1996) compiled a list of candidate genes (Table 21.4) associated with increased susceptibility to AgP.

A series of studies has been performed to assess whether or not specific polymorphisms in these candidate genes are associated with AgP (for a review see Shapira *et al*. 2005 and Loos *et al*. 2005). Significant associations have been observed for genes encoding proteins that are associated with neutrophil function (Fu *et al*. 2002; Loos *et al*. 2003; Kaneko *et al*. 2004; Jordan *et al*. 2005; Nibali *et al*. 2006; de Souza & Colombo 2006), with inflammation, and with the host's ability to effectively deal with exposure to

bacterial components such as endotoxin (Suzuki *et al.* 2004; Scapoli *et al.* 2005; Brett *et al.* 2005; Noack *et al.* 2006), and with connective tissue homeostasis (Suzuki *et al.* 2004; Park *et al.* 2006; Soedarsono *et al.* 2006). It should be emphasized, however, that the validity of the conclusions of the majority of these studies suffers from small sample sizes, study of a single or few specific polymorphisms in the gene, as well as failure to account for ethnic variations or to correct for environmental factors (e.g. cigarette smoking) (Tonetti & Claffey 2005). These three factors may be responsible for false-positive associations and larger studies need to be performed to establish consistent associations.

Besides genes of major effect that may determine susceptibility to AgP, other genes may act as modifying genes and influence clinical expression of the disease. In this respect, particular interest has focused on the impact of genetic control of antibody responses against specific AgP-associated bacteria and against *A. actinomycetemcomitans* in particular. These studies have indicated that the ability to mount high titers of specific antibodies is race dependent and probably protective (Gunsolley *et al*. 1987, 1988). This has been shown to be under genetic control as a co-dominant trait, independent of the risk for AgP. In individuals susceptible to AgP, therefore, the ability to mount high titers of antibodies (IgG_2 in particular) may be protective and prevent extension of disease to a generalized form (Schenkein 1994; Diehl *et al.* 2003) (Fig. 21-9b, c). Allelic variations in the Fc receptor for IgG_2 have also been suggested to play a role in suboptimal handling of *A. actinomycetemcomitans* infections. PMNs expressing the R131 allotype of FcγRIIa (i.e. with an Fc receptor containing an arginine instead of a histidine at amino acid 131) show decreased phagocytosis of *A. actinomycetemcomitans* (Wilson & Kalmar 1996).

Table 21-5 Effect of smoking on extent and severity of generalized acute periodontitis.

Smoking status	Mean percentage of sites with PAL >5 mm[a]	Mean PAL (mm)[a]
Smokers	49.0 ± 3.9	2.78 ± 0.2
Non-smokers	36.8 ± 3.8	2.14 ± 0.2

[a] Values adjusted for age and mean plaque index, subject as unit of analysis. Smokers showed significantly greater extent and severity of periodontal disease than non-smokers after correcting for age and oral hygiene level.
PAL, periodontal attachment loss.

Environmental aspects of host susceptibility

Recent evidence has indicated that, besides genetic influences, environmental factors may affect the clinical expression of AgP. In a large study, cigarette smoking was shown to be a risk factor for patients with generalized forms of AgP (Schenkein *et al*. 1995). Smokers with GAP had more affected teeth and greater mean levels of attachment loss than patients with GAP who did not smoke (Table 21.5). Environmental exposure to cigarette smoking, therefore, seems to add significant risk of more severe and prevalent disease to this group of already highly susceptible subjects. The mechanism(s) for this observation are not completely understood, but findings from the same group indicate that IgG_2 serum levels as well as antibody levels against *A. actinomycetemcomitans* are significantly depressed in subjects with GAP who smoke. Since these antibodies are considered to represent a protective response against *A. actinomycetemcomitans*, it is possible that depression of IgG_2 in smokers may be associated with the observed increase in disease extent and severity in these subjects.

Current concepts

Aggressive forms of periodontitis are currently considered to be multifactorial diseases developing as a result of complex interactions between specific host genes and the environment. Inheritance of AgP

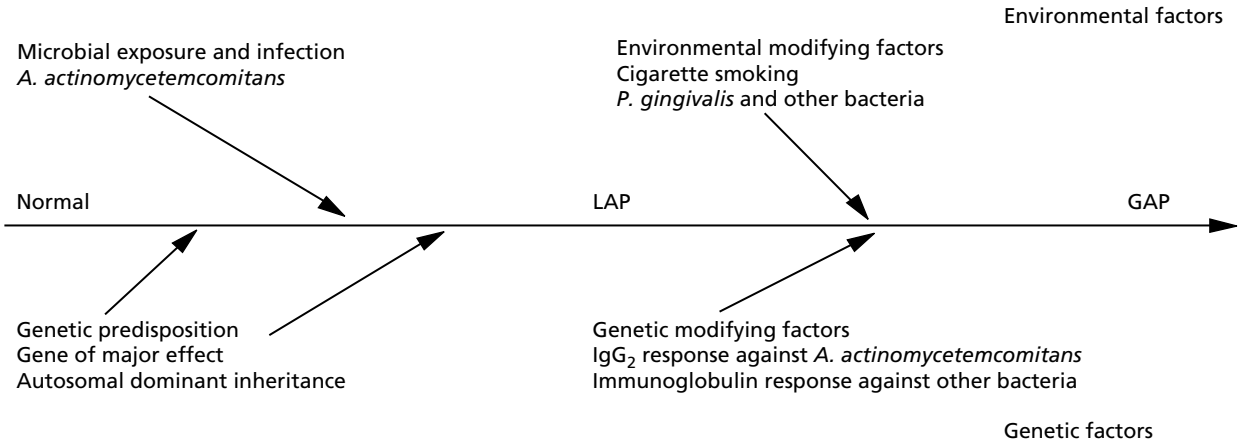

Fig. 21-10 Schematic representation of the current understanding of the ecogenetic interactions leading to the development of localized aggressive periodontitis (LAP) and generalized aggressive periodontitis (GAP) in African–American populations (see text for explanation).

susceptibility is probably insufficient for the development of disease: environmental exposure to potential pathogens endowed with specific virulence factors is also a necessary step. A host's inability to effectively deal with the bacterial aggression and to avoid inflammatory tissue damage results in the initiation of the disease process. Interactions between the disease process and environmental (e.g. cigarette smoking) and genetically controlled (e.g. IgG_2 response to *A. actinomycetemcomitans*) modifying factors are thought to contribute to determining the specific clinical manifestation of disease (Figs. 21-9a–c, 21-10).

Diagnosis

Clinical diagnosis

Clinical diagnosis is based on information derived from a specific medical and dental history, and from the clinical examination of the periodontium. Limitations that will be discussed in this section, however, frequently require supplementation of clinical and anamnestic parameters with other, more advanced, approaches to properly diagnose, plan treatment for, and monitor these diseases. The purpose of clinical diagnosis is the identification of patients suffering from AgP and of factors that have an impact on how the case should be treated and monitored.

In the diagnosis of AgP the initial question that the clinician should ask is:

- Is there periodontitis?

This may sound like a trivial question, but in fact many cases of AgP are currently not identified because of a failure to detect signs of periodontitis. Conversely, some clinicians attribute to periodontitis pathologic changes associated with other unrelated and sometimes self-limiting processes. Correctly answering this question requires systematic collection of clinical information regarding the following items:

- Is there loss of periodontal support (loss of clinical attachment and marginal resorption of alveolar bone)?
- Is the loss of attachment accompanied by pocket formation or mostly the result of recession?
- Is there a plausible cause for attachment loss other than periodontitis?
- Is there another process imitating periodontal disease by pseudopocket formation?

From a clinical standpoint, it is important to realize that clinically detectable loss of attachment may occur as a result of pathologic events other than periodontitis. Examples are traumatic injuries, removal or presence of impacted teeth (Kugelberg 1992), tooth position, orthodontic tooth movement, advanced decay, subgingival margins of restorations, etc. This means that the clinician must recognize different causes for attachment loss and must rule out other causes of attachment loss by a combination of careful clinical examination and assessment of the dental history. Orthodontic considerations are necessary to evaluate attachment loss without pocket formation (recession). In such instances, the appropriate clinical diagnosis may be *incidental attachment loss*.

After establishing the presence of periodontitis, the clinician should determine which clinical diagnosis best describes the disease in the individual patient: chronic, aggressive or necrotizing periodontitis. Since the current classification is based on the combination of clinical presentation, rate of disease progression, and pattern of familial aggregation of cases in the absence of a systemic cause for the clinical observations, the next question should address these parameters:

- Does the patient have a systemic condition that would in itself explain the presence of periodontitis?

As indicated, the diagnosis of chronic, aggressive or necrotizing periodontitis implies the presence of periodontal destruction in the absence of systemic diseases that may severely impair host defense. A well-constructed and well-taken medical history is fundamental to identifying the presence of systemic involvements accompanied by periodontitis (see Chapter 7). Careful questioning regarding recurrent infections, their familiarity, and the presence of severe diseases or their symptoms and signs should be part of the evaluation of all periodontal patients. Consultation with the attending physician and evaluation of laboratory parameters are frequently necessary. Understanding of the medical condition that may be associated with periodontitis is fundamental. Some conditions are relatively frequent disorders such as poorly controlled diabetes mellitus; others are rare inherited disorders such as palmoplantar keratosis (Papillon–Lefèvre and Heim–Munk syndromes) or hypophosphatasia. Some are inborn defects such as the leukocyte adhesion deficiencies (LADs); others are acquired following exposure to pharmacologic agents such as drug-induced granulocytopenia. A confirmed positive history of a significant systemic condition results in the diagnosis of *periodontal manifestation of systemic disease*.

In such instances, the periodontitis is likely to represent an oral manifestation of the systemic disease. Examples of significant conditions are acquired immune deficiency syndrome (AIDS), leukemia, neutropenia, diabetes or rare genetic diseases such as histiocytosis X, Papillon–Lefèvre syndrome or Chediak–Steinbrinck–Higashi syndrome (see Fig. 21-4).

In the absence of significant systemic components, the next question relates to the exclusion of the rare but clearly identified necrotizing/ulcerative forms:

- Does the patient have signs or symptoms of necrotizing periodontitis?

If the answer to both of the previous questions is negative, differential diagnosis between chronic

or aggressive periodontitis will be required. In this respect, it is important to observe that chronic periodontitis has been defined as the common form of periodontitis whose diagnosis is achieved by excluding the presence of AgP (Armitage 1999). Diagnosis of AgP is made by verification of the primary and secondary features described in the International Classification Workshop (see earlier discussion).

In this respect it must be recognized that the features include both clinical and laboratory aspects. In the diagnosis of a case, clinical and history parameters are initially utilized to raise the suspicion of the presence of AgP, while laboratory tests are frequently utilized to confirm the diagnosis. In this respect, it is important to realize that periodontal diagnosis based only on periodontal probing and dental radiography does not classify causes; rather, it describes destruction patterns.

A tentative clinical diagnosis of AgP is made based on the following criteria:

- Absence of significant systemic conditions
- Rapid attachment loss and bone destruction
- Familial aggregation of cases
- Lack of consistency between clinically visible bacterial deposits and severity of periodontal breakdown.

A rapid rate of destruction of the periodontium is a major criterion for the diagnosis of AgP. It is aimed at identifying cases characterized by high virulence of the microflora and/or high levels of susceptibility. Although correct application of this criterion requires the availability of clinical or radiographic data from more than one time point, the presence of severe destruction in relation to the age of the subject is frequently considered to be sufficient information to infer rapid progression.

Establishing the presence of familial aggregation of cases is based on a combination of history and clinical examination of family members of the affected individual. At this stage there is inadequate evidence to establish the best approach to obtain a significant estimation of familial aggregation. One study questioned the reliability of family history as a way to establish familial aggregation (Llorente & Griffiths 2006).

It is maintained that in the majority of cases of AgP, the amount of periodontal destruction seems to be higher than that expected from the mere accumulation of local factors. This observation, however, may not be true for all cases. In general, a discrepancy between local factors and the amount of periodontal tissue breakdown is considered to be an indication for either infection with particularly virulent microorganisms, or presence of a highly susceptible host. This information may be consequential in determining surgical goals of therapy, the impact of antibiotics, and the possible impact of suboptimal hygiene as a risk factor for disease recurrence.

The International Classification Workshop consensus indicated that not all listed primary and secondary features need to be present in order to assign a diagnosis of AgP and that the diagnosis may be based on clinical, radiographic, and historical data alone. It also indicated that laboratory testing, although helpful, may not be essential in making an AgP diagnosis.

Once an AgP diagnosis has been made based on the criteria above, differential diagnosis between LAP and GAP is necessary. In this respect, specific clinical features have been suggested. A diagnosis of LAP is made based on evidence of circumpubertal onset and localized first molar/incisor presentation with interproximal attachment loss on at least two permanent teeth, one of which is a first molar, and involving no more than two teeth other than first molars and incisors. A diagnosis of GAP takes into account the fact that this form of disease usually affects persons under 30 years of age (but patients may be older) and that it presents with generalized interproximal attachment loss affecting at least three permanent teeth other than first molars and incisors. Furthermore, this pathology is characterized by a pronounced episodic nature of the destruction of attachment and alveolar bone. The differential diagnosis may benefit from additional laboratory investigations of the individual host response to the infecting organisms.

In order to properly describe a specific AgP case, modifying factors should also be explored by addressing the question of the presence of modifying or contributory factors such as smoking or drug abuse. Such additional information is relevant since these factors may explain a specific presentation of disease in terms of extent and severity. Furthermore, these factors, unlike genetic factors, are amenable to modification through appropriate intervention. Therapy should therefore include an approach aimed at controlling the impact of these factors.

Even though differential diagnosis between AgP and chronic periodontitis, and between LAP and GAP, is mostly based on history and clinical presentation, it must be emphasized that clinical parameters alone cannot further discriminate forms of disease with similar clinical appearance. Inferences regarding a specific etiology are speculative under such circumstances and further laboratory testing is required for confirmation.

In the previous classification system, age at onset or age at diagnosis was considered helpful to further characterize specific clinical syndromes. LAP, in particular, is thought to occur in those aged from 13–14 to 25 years, while GAP is generally found in adolescents or young adults younger than 30–35 years. It should be realized, however, that (1) some cases may present with initial LAP at an earlier age; (2) LAP may start before puberty and affect the primary dentition; (3) patterns of periodontal destruction compatible with LAP may be initially detected at an age older than 25 years; and (4) there may be a tendency toward spreading from a localized to a generalized pattern of AgP in older subjects in these groups.

Another difficulty is related to the fact that periodontal destruction is often diagnosed when the attachment loss is already fairly advanced. In general, distinct alterations in the morphology of the periodontium and substantial tissue damage are necessary for establishing a clear diagnosis. Milder or initial stages of disease or sites at risk for future periodontal breakdown cannot be detected based on clinical parameters. This makes it difficult to intercept and treat initial forms of AgP. Furthermore, such difficulty makes it extremely important to examine the other members of the family of the proband as well: siblings may present with clinically undetectable disease in spite of the presence of the putative pathogens. A common strategy employed to overcome the insufficient ability of clinical parameters to detect early disease is to closely monitor high-risk patients such as the siblings of the probands. It is in this respect important to underline that "incidental attachment loss" may, in some cases, represent an initial manifestation of AgP. In such a case, an isolated periodontal lesion characterized by attachment loss with pocketing may represent the only clinically evident AgP lesion. Such subjects should, therefore, be considered at high risk for the development of AgP and require close monitoring and possibly further microbiologic diagnosis.

Microbiologic diagnosis

The presence of specific microorganisms is considered to be one of the secondary features of AgP. There is an ongoing debate on the utility of microbiologic tests to identify such organisms in order to optimize periodontal therapy. A systematic review has shown that the presence or absence of suspected periodontal pathogens such as *A. actinomycetemcomitans* at the species level cannot fully discriminate subjects with AgP from subjects with chronic periodontitis. Although it is more than ten times more likely that *A. actinomycetemcomitans*-negative patients suffer from chronic than from aggressive periodontitis, any *A. actinomycetemcomitans*-positive patient with periodontitis is three times more likely to be suffering from chronic than from aggressive periodontitis (Mombelli *et al*. 2002). The noted limitations in power of discrimination between AgP and chronic periodontitis should not be interpreted to mean that a test aimed at the detection of target microorganisms is completely useless in any clinical situation. Treatment studies suggest that *A. actinomycetemcomitans* is particularly difficult to suppress with conventional mechanical therapy (Mombelli *et al*. 1994a, 2000), longitudinal and retrospective studies have indicated an increased risk for periodontal breakdown in positive sites (Fine 1984; Slots *et al*. 1986; Bragd *et al*. 1987; Slots & Listgarten 1988; Rams *et al*. 1996), and results of treatment seemed to be better if *A. actinomycetemcomitans* could no longer be detected at follow-up (Bragd *et al*. 1987; Carlos *et al*. 1988; Haffajee *et al*. 1991; Grossi *et al*. 1994; Haffajee & Socransky 1994). Therefore, even if microbiologic testing alone cannot distinguish between chronic and aggressive periodontitis, access to microbiologic data may improve the outcome of periodontal therapy. This should be taken into account particularly with regards to the highly leukotoxic variant of *A. actinomycetemcomitans*, which shows a stronger association with AgP than does *A. actinomycetemcomitans* as a whole. In discussing the diagnostic potential of a test, one should also consider that the main difference between clinical groups may not be the prevalence but rather the amount of putative pathogens found in positive samples (Gunsolley *et al*. 1990).

In theory, microbiologic data may be useful to establish a differential diagnosis in patients clinically diagnosed with AgP, and may have an impact on the decision to supplement mechanical therapy with antimicrobials and on the choice of these agents. However, as outlined in more detail in Chapter 43, strictly based on evidence from well-performed randomized clinical trials, and except for patients with known medical contraindications (e.g. confirmed hypersensitivity), it is difficult to define clear-cut exclusion criteria for systemic antibiotic therapy in patients with AgP. In fact, no study has demonstrated better results for treatments without antibiotics in certain patients identified with microbiologic techniques. There is recent convincing data that supplementing mechanical treatment specifically with systemic amoxicillin and metronidazole substantially improves the clinical outcomes of therapy for AgP (Guerrero *et al*. 2005; Xajigeorgiou *et al*. 2006; Kaner *et al*. 2007; Akincibay *et al*. 2008; Johnson *et al*. 2008; Machtei & Younis 2008; Mestnik *et al*. 2010; Yek *et al*. 2010; Baltacioglu *et al*. 2011; Heller *et al*. 2011; Varela *et al*. 2011). Results of a few studies comparing different antimicrobial regimens are available (Akincibay *et al*. 2008; Machtei & Younis 2008; Baltacioglu *et al*. 2011). No study has demonstrated better results than achieved with a protocol of systemic amoxicillin plus metronidazole for any clinically or microbiologically defined variant of AgP.

Evaluation of host defenses

Several forms of AgP have been associated with impairment of host defenses. Classical studies have indicated that in some populations, both LAP and GAP are associated with high incidence of phagocyte functional disturbances, such as depressed neutrophil chemotaxis and other phagocyte antibacterial dysfunctions. In many of these patients, AgP was the only infection that was associated with reduced phagocyte function(s); this observation is important in two respects. First, AgP-associated phagocyte defects are frequently insignificant in terms of increasing susceptibility to infections other than periodontitis. Furthermore, it is likely that such "mild" leukocyte defects may go unnoticed until laboratory testing is

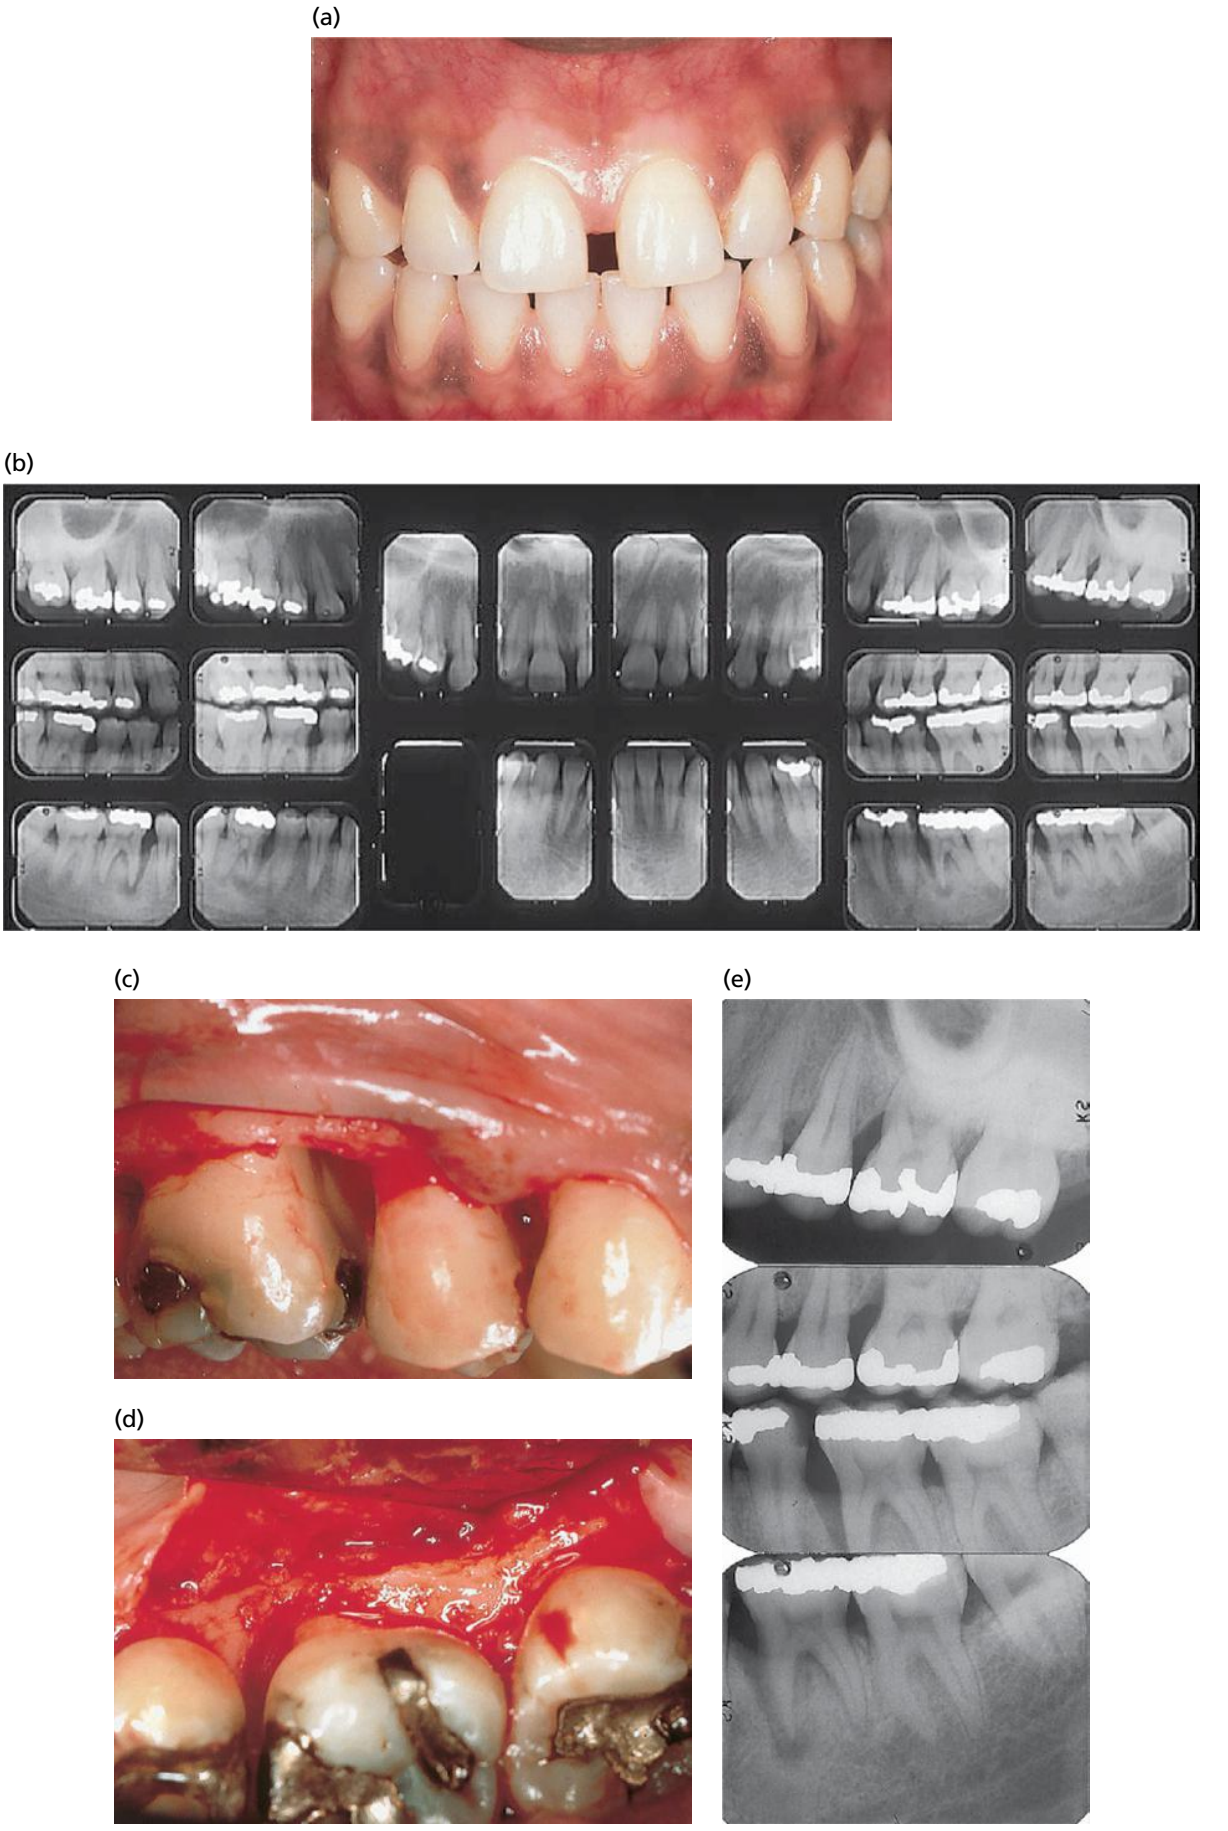

Fig. 21-11 (a, b) Clinical and radiographic presentation of a 22-year-old African–American female. Clinical attachment loss and alveolar bone loss are localized on the mesial aspect of the first molars, where deep, vertical defects are apparent. (c–e) Detailed views of the defect on the mesial aspect of tooth 26. No other tooth appears to be affected. Microbiology (DNA probe analysis of *A. actinomycetemcomitans*, *P. gingivalis*, and *P. intermedia*) confirmed the presence of high levels (>10^4 bacteria/sample) of *A. actinomycetemcomitans* in all four deep lesions. *P. intermedia* was also detectable in three of four sites, while *P. gingivalis* was undetectable. The patient did not display abnormal leukocyte functions; furthermore, she had a non-contributory medical history, and did not smoke. She had a younger brother (15 years old) and an older sister (27 years old); on clinical examination, the periodontium of both siblings appeared to be within normal limits. The following diagnosis was made: "localized aggressive periodontitis in a 22-year-old systemically healthy African–American female; associated with *A. actinomycetemcomitans* infection without clinically detectable levels of *P. gingivalis*; absence of demonstrable leukocyte defects; no known contributory factors; no cigarette smoking; no siblings displaying clinically detectable aggressive periodontitis".

performed in conjunction with periodontal diagnosis. Reports of such phagocyte defects relate mostly to AgP subjects from African–American groups; systematic evaluations of PMN and monocyte functions associated with clinical diagnosis of AgP in European Caucasians failed to confirm a high prevalence of abnormalities (Kinane *et al*. 1989a, b). It may be possible therefore to restrict the testing for these host defense parameters to specific populations. Another important aspect is that, so far, no specific study has attempted to associate treatment response or incidence of recurrent disease with the presence of the above-mentioned abnormalities.

More recent investigations have indicated that specific patterns of host response to bacterial pathogens are associated with different forms of AgP; this early evidence may be extremely helpful for the development of clinically useful tests to estimate the risk of developing AgP. In this respect, two findings deserve mention:

1. AgP patients show significantly higher levels of crevicular fluid PGE_2 than chronic periodontitis patients or healthy subjects. This finding may indicate that monocytes from these patients respond to bacterial and inflammatory stimuli with very high local release of inflammatory mediators. These may induce an exuberant inflammatory reaction associated with high levels of activation of tissue-degrading matrix metalloproteinases (MMPs).
2. GAP patients have a decreased ability to mount high titers of specific IgG_2 antibodies to *A. actinomycetemcomitans.* These subjects exhibit a tendency towards progressive periodontal destruction leading to tooth loss over a relatively short period of time. LAP patients, on the other hand, seem to have a better prognosis and do not express this trait. Since there are indications that at least some LAP cases may progress to generalized forms, early detection of patients infected with *A. actinomycetemcomitans* but producing low levels of specific antibodies, may allow early identification of a high-risk group for the development of GAP. Serum antibody titers (IgG_2 in particular) and/or avidity to *A. actinomycetemcomitans* may be particularly useful in the differential diagnosis of GAP and LAP syndromes and in the early detection of LAP cases with a high risk for progression to the more widespread forms of disease.

Genetic diagnosis

Given the disproportionately high incidence of AgP in the families of affected individuals, evaluation of siblings of the proband and other family members is a requirement. Clinical determination of different disease forms in the family should be followed by construction of a pedigree of the AgP trait. Such diagnosis may bring considerable information regarding the level of risk eventually shared within the family. Furthermore, it helps to establish the need for monitoring clinically unaffected individuals.

All the evidence gathered during the diagnostic process should contribute to the definition of a specific diagnosis. An example of such diagnosis is shown in Fig. 21-11: LAP in a 22-year-old systemically healthy African–American female patient, associated with *A. actinomycetemcomitans* infection without detectable levels of *P. gingivalis*, inconsistency between local factors and amount of clinically detectable breakdown, absence of demonstrable leukocyte defects, no known contributory factors, and no siblings displaying clinically detectable periodontitis.

Principles of therapeutic intervention

Treatment of AgP should only be initiated after completion of a careful diagnosis by a specifically trained periodontist. The severity of some of the AgP forms suggests that specialists, possibly working in association with highly specialized centers, could best perform both diagnosis and treatment of these rare forms of periodontitis. The roles of the general practitioner, the pedodontist or the orthodontist, however, are fundamental in the detection of possible cases to be referred for further evaluation and therapy.

Successful treatment of AgP is considered to be dependent on early diagnosis, directing therapy towards elimination or suppression of the infecting microorganisms and providing an environment conducive to long-term maintenance. The differential element of treatment of AgP, however, relates to specific efforts to affect the composition and not only the quantity of the subgingival microbiota.

Elimination or suppression of the pathogenic flora

A. actinomycetemcomitans elimination has been associated with successful therapy; conversely, recurrent lesions have been shown to still harbor this organism. Several investigators have reported that scaling and root planing of juvenile periodontitis lesions could not predictably suppress *A. actinomycetemcomitans* below detection levels (Slots & Rosling 1983; Christersson *et al*. 1985; Kornman & Robertson 1985). Soft tissue curettage and access flap therapy also had limited success in eliminating *A. actinomycetemcomitans* (Christersson *et al*. 1985).

A. actinomycetemcomitans is also difficult to eliminate by conventional mechanical therapy in adult periodontitis patients, and it is therefore not surprising to observe the presence of this microorganism in the subgingival microflora of many non-responding periodontitis patients (Bragd *et al*. 1985; van Winkelhoff *et al*. 1989; Renvert *et al*. 1990a, b; Rodenburg *et al*. 1990; Mombelli *et al*. 1994a). Similar but less systematic observations have also been reported for the ability to suppress the

microflora associated with some GAP forms, where high subgingival loads of *P. gingivalis*, *Bacteroides forsythus*, *A. actinomycetemcomitans*, and other highly virulent bacteria are frequently detected.

Use of antibiotics has been suggested as a rational complement to mechanical debridement in these cases. Regimens, including the adjunctive administration of tetracyclines or metronidazole, have been tested for the treatment of LAP and other forms of AgP (see Chapter 43).

The choice of antibiotic can either be empiric (based on published information on the efficacy of the regimen in similar populations) or guided by information about the nature of the involved pathogenic microorganism(s) and/or their antibiotic susceptibility profile. Both approaches have been suggested, but currently there is no direct evidence that microbiologic diagnosis and targeted selection of the antibiotic regimen provide an additional benefit compared to empiric use.

With regards to empiric use, effectiveness is based on outcomes of a series of trials that have assessed the clinical outcomes of therapy following administration of specific antibiotic regimens against placebo. Supported by a meta-analysis undertaken a decade ago (Haffajee *et al.* 2003) and numerous clinical trials conducted since then (Guerrero *et al*. 2005; Xajigeorgiou *et al*. 2006; Kaner *et al*. 2007; Akincibay *et al*. 2008; Johnson *et al*. 2008; Machtei & Younis 2008; Mestnik *et al*. 2010; Yek *et al*. 2010; Baltacioglu *et al*. 2011; Heller *et al*. 2011; Varela *et al*. 2011), significantly greater clinical improvements can be expected if thorough non-surgical periodontal treatment (i.e. scaling and root planing) is followed by systemic antibiotic therapy, specifically with amoxicillin and metronidazole. Subgingival *A. actinomycetemcomitans* especially can be eliminated or suppressed for a prolonged period by mechanical debridement supplemented with systemic amoxicillin plus metronidazole. Systemic antibiotics should only be administered as an adjunct to mechanical debridement because in undisturbed subgingival plaque, the target organisms are effectively protected from the antibiotic agent due to the biofilm effect (see Chapter 43).

Antibiotics have been used in essentially two ways for the treatment of AgP: (1) in combination with intensive instrumentation over a short period of time after achievement of adequate plaque control in a pretreatment motivation period; or (2) as a staged approach after completion of the initial therapy.

The following treatment approach (Guerrero *et al.* 2005) has been thoroughly validated in randomized controlled clinical trials (Guerrero *et al*. 2005; Mestnik *et al*. 2010; Aimetti et al 2012; Mestnik *et al.* 2012): (1) achievement of adequate supragingival plaque control (<25% of tooth sites with detectable plaque); (2) rigorous subgingival instrumentation with a combination of hand and ultrasonic instruments completed within 2 days; and (3) an adjunctive systemic antibiotic regimen consisting of metronidazole (500 mg, t.i.d. for 7 days) combined with amoxicillin (500 mg, t.i.d. for 7 days). The results of the placebo arm showed highly significant improvements in clinical parameters, including reductions of probing depth and improvement of clinical attachment levels throughout the dentition. The adjunctive antibiotic provided additional benefits in the deeper pockets for all parameters. Early results suggest that incomplete adherence to the antibiotic regimen results in suboptimal clinical outcomes (Guerrero *et al*. 2007). A follow-up analysis comparing the antibiotic retreatment of the placebo group of the Guerrero *et al.* (2005) trial (later antibiotic administration) with the mechanical retreatment of the antibiotic arm of the trial (early antibiotic administration) showed benefit from the earlier administration (Griffiths *et al*. 2011). These observations have been recently confirmed by a retrospective study (Beliveau *et al*. 2013).

The second approach implies starting therapy with an initial phase of mechanical instrumentation, including systematic scaling and planing of all accessible root surfaces and the introduction of meticulous oral hygiene. After a period of 3–6 months, the case is reassessed clinically. Based on persistence of periodontal lesions, a second phase of therapy is planned. Decisions are made as to how to gain access to deep lesions with appropriate surgical procedures and concerning the administration of antimicrobial agents. Microbial samples from the deepest pocket in each quadrant may provide additional information about the persistence of putative pathogens. Systemic antimicrobial therapy with an appropriate agent is initiated if judged necessary immediately upon completion of the surgical interventions or immediately after another round of mechanical instrumentation to ensure that subgingival plaque deposits have been reduced as much as possible and to disrupt the subgingival biofilm. This treatment option is preferred by some clinicians to minimize the potential overuse of antibiotics in periodontics. Currently, however, it needs to be pointed out that this approach is not backed by the same level of evidence as the first approach.

Microbiologic testing, if performed, may be repeated 1–3 months after completion of therapy to verify the elimination or marked suppression of the putative pathogen(s). After resolution of the periodontal infection, the patient should be placed on an individually tailored maintenance care program, including continuous evaluation of the occurrence and of the risk of disease progression. Optimal plaque control by the patient is of paramount importance for a favorable clinical and microbiologic response to therapy. Recurrence of disease is an indication for a repeat of the microbiologic tests, re-evaluation of the host immune response, and reassessment of the local and systemic modifying factors. Further therapy should be targeted against putative periodontal pathogens and should take into account the systemic immune responses of the subject.

Chapter 22

Necrotizing Periodontal Disease

Palle Holmstrup

Department of Periodontology, School of Dentistry, University of Copenhagen, Copenhagen, Denmark

Nomenclature

Necrotizing gingivitis (NG), necrotizing periodontitis (NP), and necrotizing stomatitis (NS) are the most severe inflammatory periodontal disorders caused by plaque bacteria. The necrotizing diseases usually run an acute course and therefore the term acute is often included in the diagnoses. They are rapidly destructive and debilitating, and they appear to represent various stages of the same disease process (Horning & Cohen 1995). A distinction between NG and NP has not always been made in the literature, but parallel to the use of the term gingivitis, NG should be limited to lesions involving gingival tissue only with no loss of periodontal attachment (Riley *et al*. 1992). Most often, however, the disease results in loss of attachment (MacCarthy & Claffey 1991), and a more correct term in cases with loss of attachment is NP, provided the lesions are confined to the periodontal tissues, including the gingiva, periodontal ligament, and alveolar bone. Further progression to include tissue beyond the mucogingival junction is characteristic of necrotizing stomatitis and distinguishes this disease from NP (Williams *et al*. 1990).

The necrotizing periodontal diseases have been mentioned under several names, including: "ulceromembranous gingivitis", "acute necrotizing ulcerative gingivitis" (ANUG), "Vincent's gingivitis" or "Vincent's gingivostomatitis", "necrotizing gingivostomatitis", and "trench mouth" (Pickard 1973; Johnson & Engel 1986; Horning & Cohen 1995). Vincent first described the mixed fusospirochetal microbiota of so-called "Vincent's angina", characterized by necrotic areas in the tonsils (Vincent 1898). A similar mixed microbiota has been isolated from NG lesions, but Vincent's angina and NG usually occur independently of each other, and should be regarded as separate disease entities.

NS has features in common with the far more serious *cancrum oris*, also denoted noma. This is a destructive and necrotizing, frequently mortal, stomatitis in which the same mixed fusospirochetal flora dominates. It occurs almost exclusively in certain developing countries, mostly in children suffering from systemic diseases including malnutrition (Enwonwu 1972, 1985). It has been suggested that cancrum oris always develops from pre-existing NG (Emslie 1963) and this connection

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

has been supported by similarities between the microflora of NG and that of noma (Bolivar *et al*. 2012).

In the literature, a distinction between NG, NP, and NS is seldom made and the reader should be aware of the consequences of this lack of distinction. The uncertainty in the distinction is reflected in the present chapter by the use of the term necrotizing periodontal disease (NPD) as a common denominator for NG, NP, and necrotizing stomatitis.

Prevalence

During World War II, up to 14% of the Danish military personnel encountered NPD (Pindborg 1951a). Large numbers of civilians also suffered from the disease (King 1943; Stammers 1944). After World War II, the prevalence of NPD declined substantially and in industrialized countries NPD is now rare. It occurs most often in young adults. In the 1960s NPD was found in 2.5% of 326 US students during their first college year, but over the next year more students became affected, with a total of 6.7% demonstrating the disease during their first two college years (Giddon *et al*. 1964). Among 9203 students in Chile, 6.7% showed at least one necrotic ulcerated lesion on the papillae (Lopez *et al*. 2002), and the presence of necrotizing lesions was associated with the occurrence of clinical attachment loss (Lopez & Bælum 2004). Other studies in industrialized countries have reported prevalences of ≤0.5% (Barnes *et al*. 1973; Horning *et al*. 1990). In Scandinavia, the disease is now very rare among otherwise healthy individuals, with a prevalence of 0.001% among young Danish military trainees (Finn Prætorius, personal communication). NPD can be observed in all age groups but there are geographic differences in the age distribution. Among human immunodeficiency virus (HIV)-infected individuals, the disease seems to occur slightly more often. Studies among groups of HIV-infected individuals have revealed prevalences of NPD of between 0% and 27.7% (Holmstrup & Westergaard 1994; Reichart *et al*. 2003). However, most studies have included cohorts of individuals connected with hospitals or dental clinics. Studies conducted outside these environments have shown relatively low prevalences. NP was found in 1% of 200 HIV-seropositive individuals in Washington, DC (Riley *et al*. 1992), a prevalence that may not be so different from that in the general population (Drinkard *et al*. 1991; Friedman *et al*. 1991; Barr *et al*. 1992). A prevalence similar to that in the general population has been particularly true since the introduction of highly active antiretroviral therapy (HAART), which has resulted in a declining incidence and prevalence of oral conditions associated with HIV infection (Tappuni & Flemming 2001; Ryder *et al*. 2012). The route of HIV transmission may influence the occurrence of NPD among HIV-infected individuals. Thus, NPD was more prevalent among HIV-infected intravenous drug users than among HIV-infected non-intravenous drug users. Also, mean probing depth and clinical attachment level were significantly higher in the former group (Ranganathan *et al*. 2012).

In developing countries, the prevalence of NPD is higher than in industrialized countries, and the disease frequently occurs in children. NPD is practically never seen in Western countries. In Nigerian villages, between 1.7% and 26.9% of 2–6-year-old children were found to have NPD (Sheiham 1966), and in India, 54–68% of NPD cases occurred in children below 10 years of age (Migliani & Sharma 1965; Pindborg *et al*. 1966).

Clinical characteristics

Development of lesions

NG is an inflammatory, destructive gingival condition characterized by ulcerated and necrotic papillae and gingival margins, giving a punched-out appearance. The ulcers are covered by a yellowish–white or grayish slough, which has been termed a "pseudomembrane". However, the sloughed material has no coherence, and bears little resemblance to a membrane. It consists primarily of fibrin and necrotic tissue with leukocytes, erythrocytes, and masses of bacteria. Consequently, the term is misleading and should not be used.

The necrotizing lesions develop rapidly and are painful, but in the initial stages, when the necrotic areas are relatively few and small, pain is usually moderate. Severe pain is often the chief reason for patients seeking treatment. Bleeding is readily provoked on removal of the sloughed material and exposure of the ulcerated underlying connective tissue. Bleeding may also start spontaneously as well as in response to even gentle touch. In early phases of the disease, lesions are typically confined to the top of a few interdental papillae (Fig. 22-1). The first lesions are often seen interproximally in the mandibular anterior region, but they may occur in any interproximal space. In regions where lesions first appear, there are usually also signs of pre-existing chronic

Fig. 22-1 Necrotizing gingivitis with initial punched out defects at the top of the interdental papillae of the mandibular incisor region. (Courtesy of F. Prætorius.)

gingivitis, but the papillae are not always edematous at this stage and gingival stippling may be maintained. Usually, however, the papillae rapidly swell and achieve a rounded contour, and this is particularly evident in the facial aspect. The zone between the marginal necrosis and the relatively unaffected gingiva usually exhibits a well-demarcated narrow erythematous zone, sometimes referred to as the linear erythema. This is an expression of hyperemia due to dilation of the vessels in the gingival connective tissue in the periphery of the necrotic lesions (see Fig. 22-17a).

A characteristic and pronounced *foetor ex ore* is often associated with NPD, but can vary in intensity and in some cases is not very noticeable. Strong *foetor ex ore* is not pathognomonic of NPD as it can also be found in other pathologic conditions of the oral cavity such as chronic destructive periodontal disease.

Interproximal craters

The lesions are seldom associated with deep pocket formation, because extensive gingival necrosis often coincides with loss of crestal alveolar bone. The gingival necrosis develops rapidly and within a few days the involved papillae are often separated into one facial and one lingual portion with an interposed necrotic depression, a negative papilla, between them. The central necrosis produces considerable tissue destruction and a regular crater is formed. At this stage of the disease, the disease process usually involves the periodontal ligament and the alveolar bone, and loss of attachment is now established. The diagnosis of the disease process is consequently NP. Along with the papilla destruction, the necrosis usually extends laterally along the gingival margin at the oral and/or facial surfaces of the teeth. Necrotic areas originating from neighboring interproximal spaces frequently merge to form a continuous necrotic area (Figs. 22-2, 22-3). Superficial necrotic lesions only rarely cover a substantial part of the attached gingiva, which becomes reduced in width as the result of the disease progression. The palatal and lingual marginal gingiva is less frequently involved than the corresponding facial area. Frequently, gingiva of semi-impacted teeth and in the posterior maxillary region are affected (Figs. 22-4, 22-5). Progression of

Fig. 22-2 Necrotizing gingivitis progressing along the gingival margin of the right maxilla. The interproximal necrotizing processes have merged.

Fig. 22-3 Necrotizing periodontitis with more advanced lesions of the interdental papillae and gingival margin. Note the irregular morphology of the gingival margin as determined by the progressive loss of the interdental papillae.

Fig. 22-5 Necrotizing periodontitis affecting the periodontium of the right maxillary second molar. Note the extensive punched-out lesion.

the interproximal process often results in destruction of most interdental alveolar bone (Fig. 22-6). In the more advanced cases, pain is often considerable and may be associated with a markedly increased salivary flow. As a result of pain, it is often difficult for the patients to eat, and a reduced food intake may be critical in HIV-infected patients because they may already have lost weight in association with their HIV infection.

(a)

(b)

Fig. 22-6 (a) Necrotizing periodontitis often results in major loss of interdental tissue, including alveolar bone of the molar regions, as demonstrated in the radiograph (b).

Sequestrum formation

The disease progression may be rapid and result in necrosis of small or large parts of the alveolar bone. Such a development is particularly evident in severely immunocompromised patients, including HIV-seropositive individuals. The necrotic bone, denoted a sequestrum, initially is irremovable, but after some time becomes loose, whereafter it may be removed with forceps. Analgesia may not be required for this. A sequestrum may not only involve interproximal bone, but also adjacent facial and oral cortical bone (Fig. 22-7).

Involvement of alveolar mucosa

When the necrotic process progresses beyond the mucogingival junction, the condition is denoted NS (Williams *et al*. 1990) (Figs. 22-8, 22-9). The severe tissue destruction characteristic of this disease is related to the seriously compromised immune functions typically associated with HIV infection or malnutrition (Fig. 22-10). Importantly, it may be life threatening. NS may result in extensive denudation of bone, resulting in major sequestration with the development of an oroantral fistula and osteitis (SanGiacomo *et al.* 1990; Felix *et al.* 1991).

Swelling of lymph nodes

Swelling of the regional lymph nodes may occur in NPD, but is particularly evident in advanced cases. Such symptoms are usually confined to the submandibular lymph nodes, but the cervical lymph nodes may also be involved. In children with NPD, swelling of lymph nodes and increased bleeding tendency are often the most pronounced clinical findings (Jiménez & Baer 1975).

Fig. 22-9 Necrotizing stomatitis of the right maxilla with an extensive necrotic ulcer of palatal mucosa.

Fever and malaise

Fever and malaise is not a consistent characteristic of NPD. Some investigations indicate that elevated body temperature is not common in NG and that, when present, is usually moderate (Grupe & Wilder 1956; Goldhaber & Giddon 1964; Shields 1977; Stevens *et al*. 1984). A small decrease in body temperature in NG has even been described. The disagreement on this point may, in fact, be due to misdiagnosis of primary herpetic gingivostomatitis as NG (see below).

(a)

(b)

Fig. 22-10 (a) Necrotizing stomatitis affecting the mandible of an HIV-seropositive patient. (b) Two years after treatment the result is satisfactory, and there has been no recurrence.

Oral hygiene

The oral hygiene in patients with NPD is usually poor. Moreover, brushing of teeth and contact with the acutely inflamed gingiva is painful. Therefore, large amounts of plaque on the teeth are common, especially along the gingival margin. A thin, whitish film sometimes covers parts of the attached gingiva (Fig. 22-11). This film is a characteristic finding in patients who have neither eaten nor performed oral hygiene for days. It is composed of desquamated epithelial cells and bacteria in a meshwork of salivary proteins. It is easily removed.

In general, the clinical characteristics of NPD in HIV-seropositive patients do not essentially differ from those in HIV-seronegative patients. However, the lesions in HIV-seropositive patients may not be associated with large amounts of plaque and calculus. Thus, the disease activity in these patients sometimes shows limited correlation with etiologic factors as determined by the amount of bacterial plaque (Holmstrup & Westergaard 1994). Further, lesions of NPD in HIV-seropositive patients have sometimes been revealed in gingival tissue affected by Kaposi's sarcoma (Fig. 22-12).

Fig. 22-11 A whitish film sometimes covers parts of the attached gingiva in patients with necrotizing periodontal disease, as demonstrated in the maxillary gingiva. The film is composed of desquamated epithelial cells which have accumulated because the patient has not eaten or performed oral hygiene for days.

Fig. 22-12 Necrotizing periodontitis affecting Kaposi's sarcoma of the gingiva of the left maxillary central incisor in an HIV-infected patient. The sarcoma affected almost the entire maxillary gingiva after 9 months.

Acute and recurrent/chronic forms of necrotizing gingivitis and periodontitis

In most instances, the course of the diseases is acute, as characterized by the rapid destruction of the periodontal tissue. However, if inadequately treated or left untreated, the acute phase may gradually subside. The symptoms then become less unpleasant for the patient, but the destruction of the periodontal tissues continues, although at a slower rate, and the necrotic tissues do not heal completely. Such a condition has been termed chronic necrotizing gingivitis, or periodontitis in the case of attachment loss (Fig. 22-13). The necrotizing lesions persist as open craters, frequently with a content of subgingival calculus and bacterial plaque. Although the characteristic ulcerative, necrotic areas of the acute phase usually disappear, acute exacerbations with intervening periods of quiescence may also occur. In recurrent acute phases, subjective symptoms again become more prominent and necrotic ulcers reappear. Some authors prefer the term recurrent rather than chronic

Fig. 22-13 Chronic necrotizing periodontitis with edematous gingiva particularly of the mandible. The slightly active necrotizing processes at the bottom of the negative papillae are not visible.

to describe this category of necrotizing disease (Johnson & Engel 1986). Plaque and necrotic debris in these phases are often less conspicuous than in the acute forms, because they are located in pre-existing interdental craters. Several adjoining interdental craters may fuse, resulting in total separation of facial and oral gingivae, which form two distinct flaps. Recurrent forms of NG and NP may produce considerable destruction of supporting tissues. The most pronounced tissue loss usually occurs in relation to the interproximal craters.

Diagnosis

The diagnosis of NG, NP, and NS is based on clinical findings as described above. The patient has usually noticed pain and bleeding from the gingiva, particularly upon touch. The histopathology of the necrotizing diseases is not pathognomonic for NG, and biopsy is certainly not indicated in the heavily infected area.

Differential diagnosis

NPD may be confused with other diseases of the oral mucosa. Primary herpetic gingivostomatitis (PHG) is not infrequently mistaken for NPD (Klotz 1973). The important differential diagnostic criteria for the two diseases are listed in Table 22-1. It should be noted that in the US and in Northern Europe, NPD occurs very rarely in children, whereas PHG is most commonly found in children. If the body temperature is markedly raised (≥38 °C), PHG should be suspected. NG and NP have a marked predilection for the interdental papillae, while PHG shows no such limitation and may occur anywhere on the free or the attached gingiva, or in the alveolar mucosa (Fig. 22-14). In PHG, the erythema is of a more diffuse character and may cover the entire gingiva and parts of the alveolar mucosa. The vesicular lesions in PHG, which disrupt and produce small ulcers surrounded by diffuse erythema, occur both on the lips and tongue, as well as on the buccal mucosa. PHG and NPD may occur

Table 22-1 Important characteristics for differential diagnosis between necrotizing periodontal disease (NPD) and primary herpetic gingivostomatitis (PHG)

	NPD	PHG
Etiology	Bacteria	Herpes simplex virus
Age	15–30 years	Frequently children
Site	Interdental papillae Rarely outside gingiva	Gingiva and the entire oral mucosa
Symptoms	Ulcerations, necrotic tissue and a yellowish–white plaque *Foetor ex ore* Moderate fever may occur	Multiple vesicles which disrupt, leaving small round fibrin-covered ulcerations *Foetor ex ore* Fever
Duration	1–2 days if treated	1–2 weeks
Contagious	No	Yes
Immunity	–	Partial
Healing	Destruction of periodontal tissue remains	No permanent destruction

Fig. 22-14 Primary herpetic gingivostomatitis. Note that the ulcers affect the gingival margin but are not primarily interdental papillae. A circular ulcer of the gingiva of the second premolar is highly suggestive of the diagnosis.

simultaneously in the same patient, and in such cases there may be mucosal lesions outside the gingiva, and fever and general malaise tend to occur more frequently than in NPD alone.

Oral mucosal diseases that have been confused with NPD include desquamative gingivitis, benign mucous membrane pemphigoid, erythema multiforme exudativum, streptococcal gingivitis, and gonococcal gingivitis. All of these are clinically quite distinct from NPD.

In some forms of leukemia, especially acute leukemia, necrotizing ulcers may occur in the oral mucosa and are not infrequently seen in association with the gingival margin, apparently as an exacerbation of an existing chronic inflammatory condition. The clinical appearance can resemble NPD lesions, and the symptoms they produce may be the reason the patient seeks professional consultation. In acute leukemia the gingiva often appears bluish–red and edematous with varying degrees of ulceration and necrosis. Generally, the patient has more marked systemic symptoms than with ordinary NPD, but can for a while feel relatively healthy. The dentist should be aware of the possibility that leukemias show such oral manifestations, which require medical examination of the patient; biopsy is usually not indicated.

Histopathology

Histopathologically, NG lesions are characterized by ulceration with necrosis of the epithelium and superficial layers of the connective tissue and an acute, non-specific inflammatory reaction (Fig. 22-15). An important aspect is the role of the microorganisms in the lesions, because they have been demonstrated not only in the necrotic tissue components but also in vital epithelium and connective tissue.

Sometimes the histologic findings demonstrate the formation of regular layers with certain characteristics (Listgarten 1965), but there may be variations in regularity. The surface cover of yellowish–white or grayish slough, which can be observed clinically, under the light microscope appears to be a meshwork of fibrin with degenerated epithelial cells, leukocytes, and erythrocytes, and bacteria and cellular debris. At the ultrastructural level, bacteria of varying sizes and forms, including small, medium-sized and large spirochetes, have been revealed between the inflammatory cells, the majority of which are neutrophilic granulocytes. Moreover, in presumably vital parts of the surface epithelium, compact masses of spirochetes and short, fusiform rods have been found intercellularly.

The vital connective tissue at the bottom of the lesion is covered by necrotic tissue, characterized by disintegrated cells, many large and medium-sized spirochetes, and other bacteria which, judging from their size and shape, may be fusobacteria. In the superior part of the vital connective tissue characterized by intact tissue components, the tissue is infiltrated by large and medium-sized spirochetes, but no other microorganisms have been seen. In the vital connective tissue the vessels are dilated. They also proliferate to form granulation tissue, and the tissue is heavily infiltrated by leukocytes. As always in acute processes, the inflammatory infiltrate is dominated by neutrophils (Figs. 22-15b, 22-16). In the deeper tissue, the inflammatory process also comprises large numbers of monocytes and plasma cells (Listgarten 1965; Heylings 1967).

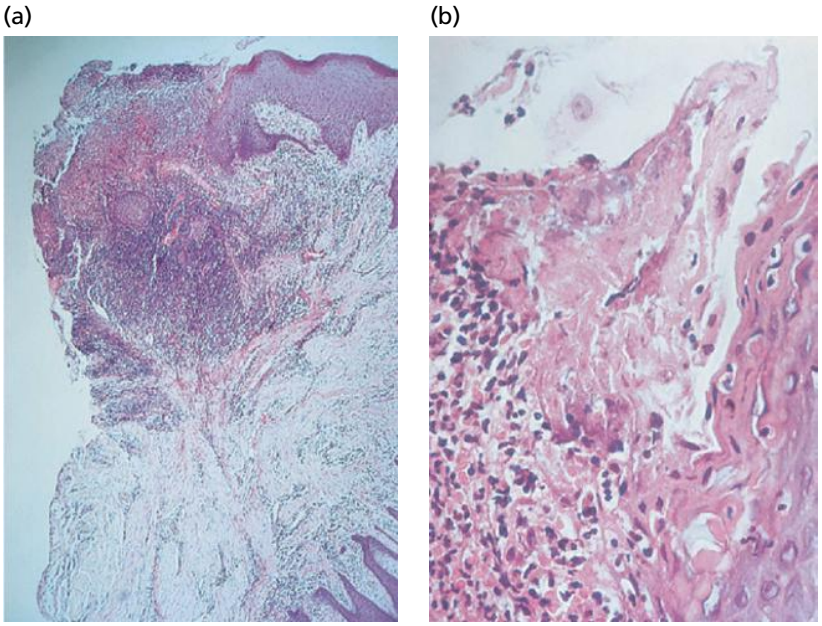

Fig. 22-15 Photomicrograph of the gingival tissue affected by necrotizing gingivitis. (a) Upper right part of the gingival biopsy shows gingival oral epithelium, whereas the upper left part has an ulcerated surface. Underneath the ulcer, the connective tissue is heavily infiltrated by inflammatory cells. (b) Higher magnification of the margin of the ulcer shows necrotic tissue infiltrated with neutrophils. The right border is covered by epithelium. (Courtesy of F. Prætorius.)

Microbiology

Microorganisms isolated from necrotizing lesions

Microbial samples from NPD lesions have demonstrated that there is a constant and a variable part of the flora. The "constant flora" primarily contained *Treponema* spp., *Selenomonas* spp., *Fusobacterium* spp., and *Bacteroides melaninogenicus* subsp. *intermedius (Prevotella intermedia)*, and the "variable flora" consisted of a heterogeneous array of bacterial types (Loesche *et al*. 1982; Ramos *et al*. 2012). Although the characteristic bacterial flora of spirochetes and fusobacteria has been isolated in large numbers from the necrotic lesions in several studies, their presence is not evidence of their primary etiologic importance. Their presence could equally well result from secondary overgrowth. Moreover, the microorganisms associated with NG are also harbored by healthy mouths and mouths with gingivitis or periodontitis (Johnson & Engel 1986). An important role for *Treponema* spp. and *B. intermedius (P. intermedia)* has been suggested from studies of antibodies to such bacteria in NPD patients, compared to levels in age- and gender-matched controls with healthy gingiva or simple gingivitis (Chung *et al*. 1983). A recent study has demonstrated that Synergistetes cluster B bacteria were more strongly associated with NG than with common gingivitis (Baumgartner *et al*. 2012), but the significance of this finding is uncertain.

There is little available information about the microbiology of HIV-associated NPD. *Borrelia*, Gram-positive cocci, beta-hemolytic streptococci, and *Candida albicans* have been isolated from the lesions (Reichart & Schiødt 1989). It has also been proposed that human cytomegalovirus (HCMV) may play a role in the pathogenesis of NPD (Sabiston 1986). This virus has been found in the digestive tract of HIV patients (Kanas *et al*. 1987; Langford *et al*. 1990), and a case of oral HCMV infection with similarities to NP has been reported (Dodd *et al*. 1993). The increased frequency of HCMV and other herpes viruses found in necrotizing lesions among Nigerian children supports a contributory role for these viruses (Contreras *et al*. 1997), although it remains to be demonstrated in future studies whether cytomegalovirus does play a causal role.

Pathogenic potential of microorganisms

Our knowledge of the pathogenic mechanisms by which the bacterial flora produces the tissue changes characteristic of NPD is limited. One reason is that it has been difficult to establish an acceptable animal experimental model. However, several of the pathogenic mechanisms which have been associated with chronic gingivitis and periodontitis may also be of etiologic importance in the necrotizing forms of the diseases.

An important aspect in the pathogenesis of periodontitis is the capacity of the microorganisms to invade the host tissues. Among the bacteria isolated from necrotizing lesions, spirochetes and fusiform bacteria can invade the epithelium (Heylings 1967). The spirochetes can also invade the vital connective tissue (Listgarten 1965). The pathogenic potential is further substantiated by the fact that both fusobacteria and spirochetes can liberate endotoxins (Mergenhagen *et al*. 1961; Kristoffersen & Hofstad 1970).

A number of observations indicate that the effects of endotoxins are more prominent in NPD than in chronic gingivitis and periodontitis. The large masses of Gram-negative bacteria liberate endotoxins in close contact with connective tissue. Endotoxins may destroy tissue by direct toxic effects and indirectly by activating and modifying the tissue responses of the host (Wilton & Lehner 1980). Through a direct

Fig. 22-16 Electron micrograph showing a phagocytosing neutrophil (N) close to the surface of a sequestrum (C), covered by numerous microorganisms including spirochetes (S) and rods (R). Bar = 1 µm.

toxic effect, endotoxins may lead to the damage of cells and vessels. Necrosis is a prominent feature in the so-called "Shwartzman reaction", which is caused by endotoxins. Indirectly, endotoxins can contribute to tissue damage in several ways: they can function as antigens and elicit immune reactions; they can activate complement directly through the alternative pathway and thereby liberate chemotoxins; and they can also activate macrophages, B and T lymphocytes and influence the host's immune reactions by interfering with cytokines produced by these cells. Studies have shown that endotoxins can stimulate catabolic processes with degradation of both connective tissue and bone induced by the released cytokines. The extent to which such reactions contribute to host defense or to tissue damage is not yet known.

An aspect which has been of major concern, especially in wartime, is the communicability of the disease. Several reports have considered this aspect, but it has been concluded that the necrotizing diseases are not transmissible by ordinary means of contact (Johnson & Engel 1986). Attempts to transmit the disease from one animal to another, or to produce necrotic lesions in experimental animals, have failed to yield conclusive results (MacDonald *et al*. 1963). Several suspect microorganisms and several combinations of microorganisms can produce similar lesions in experimental animals. A combination of four different bacteria, none of which is a fusobacterium or spirochete, has been found to possess such properties and there are indications that among the four bacterial species, *B. melaninogenicus* was the true pathogen (MacDonald *et al*. 1956, 1963). *B. melaninogenicus* may, under certain conditions, produce an enzyme which degrades native collagen (Gibbons & MacDonald 1961). It is still not clear, however, whether this microorganism is of particular importance in the pathogenesis of NPD. NG lesions have also been induced in dogs pretreated with steroids and inoculated with a fusiform–spirochete culture from dogs with gingival lesions similar to the NG lesions seen in humans (Mikx & van Campen 1982). However, the lesions produced in experimental animals may not be identical to those which occur in humans. It is also important to note that even if necrotic lesions can be transmitted by infectious material or bacterial cultures, this does not necessarily mean that the disease is truly contagious.

It is obvious from the above observations and assumptions that a fundamental question remains to be answered, and at this point it may be stated that the NPDs belong to those diseases to which Pasteur referred when he stated: "there are some bacteria that cause a disease, but there are some diseases that bring about a condition that is ideal for the growth of some bacteria" (Wilson 1952). If the microorganisms

mentioned above play a role in the etiology of the disease, then, presumably, the disease is caused by an opportunistic infection. Consequently, the pathogenic characteristics of the microorganisms are normally overcome by the host defense, and disease occurs when the host defense is impaired. The isolated microorganisms do possess biologic activities which may contribute to the pathogenesis, but the exact role of the various microorganisms has not yet been clarified (Johnson & Engel 1986).

Host response and predisposing factors

It is particularly evident for HIV-infected patients that the disease is associated with diminished host resistance, but among other predisposing factors, the basic mechanism may include altered host immunity. Changes in leukocyte function and immune system have been observed in some studies, although the biologic reason for and significance of these findings are unclear (Johnson & Engel 1986).

Significantly increased IgG and IgM antibody titers to intermediate-sized spirochetes and higher IgG titers to *B. melaninogenicus* subsp. *intermedius* have been found in NG patients as compared to age- and gender-matched healthy and gingivitis control groups (Chung *et al*. 1983). These results, however, are in disagreement with other data showing no differences in serum antibody levels to bacterial antigens (Wilton *et al*. 1971).

Total leukocyte counts have been found to be similar for patients and controls. NG patients, however, displayed marked depression in polymorphonuclear leukocyte chemotaxis and phagocytosis as compared with control individuals. Reduced mitogen-induced proliferation of peripheral blood lymphocytes has also been found in NG patients. It was suggested that elevated blood steroids may account for the reduced chemotactic and phagocytic responses (Cogen *et al*. 1983).

For many years it has been known that a number of predisposing factors may interact with the host defense systems and render the patient susceptible to NPD. Usually, a single one of these factors is not sufficient to establish disease. The factors which have been the focus of study include systemic diseases, including HIV infection and malnutrition, poor oral hygiene, pre-existing gingivitis and history of previous NPD, psychological stress and inadequate sleep, smoking and alcohol use, Caucasian ethnicity, and young age.

An analysis of suspected predisposing factors among American patients with NPD has shown that HIV seropositivity when present overwhelmed all other factors in terms of importance (Horning & Cohen 1995). Among the HIV-seronegative patients, the ranked importance of the predisposing factors was: history of previous NPD, poor oral hygiene, inadequate sleep, unusual psychological stress, poor diet, recent illness, social or greater alcohol use, smoking, Caucasian ethnicity, and age under 21 years. The various predisposing factors mentioned below are obviously not equally important in industrialized and developing countries, but many of these factors are known to relate to impaired immunity.

Systemic diseases

Systemic diseases which impair immunity predispose an individual to NPD. This is why NPD occurs more frequently in HIV-infected individuals and in patients with other leukocyte diseases, including leukemia (Melnick *et al*. 1988). Examples of other predisposing diseases are measles, chicken pox, tuberculosis, herpetic gingivostomatitis, and malaria, but malnutrition is also important. Whereas these examples of predisposing factors are rare in Western patients, they are evident in developing countries, where they often predispose to NPD and noma in children (Emslie 1963; Pindborg *et al.* 1966; Sheiham 1966; Pindborg *et al.* 1967; Enwonwu 1972, 1985). It is important to note that NPD is sometimes an early signal of impending serious illness (Enwonwu 1972), including agranulocytosis (Tewari *et al*. 2009). Also, chemotherapy in patients with acute leukemia may result in NPD (Santos *et al*. 2009).

HIV infection

In Africa, the general population shows a high HIV-seropositive prevalence rate, ranging up to 33% in some populations. In Europe, prevalences have been established for areas in Great Britain. The prevalence in patients attending London hospitals was below 0.7% in 1994 (Unlinked Anonymous HIV Surveys Steering Group 1996). In South Africa, NPD in otherwise systemically healthy individuals correlated with HIV infection, with a predictive value of 69.6% (Shangase *et al.* 2004). In industrialized countries, a significant proportion of patients with NPD are HIV infected, and no characteristics have been identified that distinguish NPD in HIV-seropositive from that in HIV-seronegative patients. A history of frequent relapses and poor response to traditional or drug therapy may be suggestive (Greenspan *et al*. 1986; Horning & Cohen 1995). Suspicion of HIV infection is also supported by the simultaneous presence of oral candidosis, "hairy leukoplakia", or Kaposi's tumor, but these lesions are far from always present in HIV-infected patients.

HIV infection attacks T-helper cells, causing a drastic change in the T-helper (CD4 positive)/T-suppressor (CD8 positive) ratio with severe impairment of the host's resistance to infection. Depleted peripheral helper T-lymphocyte counts correlate closely with the occurrence of NG, as demonstrated in a study of 390 US HIV-seropositive soldiers (Thompson *et al*. 1992), and an inverse correlation

between NPD and CD4-positive T-cell counts was recently found among patients who had not started HAART (Ranganathan *et al*. 2012). On the other hand, no correlation was found between CD4-positive T-cell count or neutrophil count and extent and severity of NPD in studies of South African patients (Phiri *et al*. 2010; Wood *et al*. 2011). Furthermore, a complete absence of T cells in gingival tissue of HIV-infected patients with periodontitis has been reported (Steidley *et al*. 1992). The lack of local immune effector and regulatory cells in HIV-seropositive patients could in fact explain the characteristic and rapidly progressive nature of periodontitis in these patients. Moreover, a protective effect against NPD has been encountered with HAART of the HIV infection (Tappuni *et al*. 2001), as well as against HIV-associated gingivitis and periodontitis (Masouredis *et al*. 1992). NP has been revealed as a marker for immune deterioration, with a 95% predictive value that CD4-positive cell counts were below 200 cells/mm^3, and, if untreated, a cumulative probability of death within 24 months (Glick *et al*. 1994). As a consequence of this finding, a test for HIV infection, if possible, may be recommended for all NPD patients.

Malnutrition

In developing countries, malnutrition has often been mentioned as a predisposing factor for NPD (Enwonwu 1972; Osuji 1990). Malnutrition results in lowered resistance to infection and protein malnutrition has been emphasized as the most common public health problem affecting underprivileged Nigerian children who are most often affected by NPD (Enwonwu 1985, 1994). In response to periodontal pathogens, phagocytes elaborate destructive oxidants, proteinases, and other factors. Periodontal damage may occur as the result of the interaction between these factors, the antioxidants, and the host-derived antiproteinases. Malnutrition is characterized by marked tissue depletion of the key antioxidant nutrients and impaired acute-phase protein response to infections. This is due to impairment in the production and cellular action of the cytokines. Other features of malnutrition include an inverted helper-to-suppressor T-lymphocyte ratio, histaminemia, hormonal imbalance with increased blood and saliva levels of free cortisol, and defective mucosal integrity. Malnutrition usually involves concomitant deficiencies of several essential macro- and micro-nutrients, and therefore has the potential to adversely influence the prognosis of periodontal infections (Enwonwu 1994).

Poor oral hygiene, pre-existing gingivitis, and history of previous necrotizing periodontal diseases

Many of the early studies of NPD showed that a low standard of oral hygiene contributed to the establishment of the disease (Johnson & Engel 1986). This has been supported by later studies in the US and Nigeria (Taiwo 1993; Horning & Cohen 1995). Consequently, NPD is usually established on the basis of pre-existing chronic gingivitis (Pindborg 1951b). It should be emphasized, however, that plaque accumulation as seen in NPD patients may also be enhanced by the discomfort experienced with oral hygiene practices due to the disease.

Based on questionnaires and personal interviews, 28% of NPD patients have been found to have a history of previous painful gingival infection and 21% had gingival scars suggestive of previous NPD (Horning & Cohen 1995).

Psychological stress and inadequate sleep

Just as other ulcerative gastrointestinal conditions have been shown to have psychogenic origins, psychological stress has often and for many years been mentioned as a predisposing factor for NPD (Johnson & Engel 1986). Epidemiologic investigations seem to indicate a more frequent occurrence of necrotizing diseases in periods when individuals are exposed to psychological stress (Pindborg 1951a, b; Giddon *et al.* 1963; Goldhaber & Giddon 1964). New recruits and deployed military personnel, college students during examination periods, patients with depression or other emotional disorders, and patients feeling inadequate to handle life situations are more susceptible to NPD (Pindborg 1951a, b; Moulton *et al*. 1952; Giddon *et al*. 1963; Cohen-Cole *et al*. 1983). Urine levels of corticosteroids have been used as a physiological measure of stress, and increased free cortisol levels in the urine of NPD patients as compared with controls have been encountered. The NPD patients showed significantly higher levels of trait anxiety, depression, and emotional disturbance than did control individuals (Co-hen-Cole *et al.* 1983). The role of anxiety and psychological stress in the pathogenesis of NG has been borne out by both psychiatric and biochemical investigations (Moulton *et al.* 1952; Shannon *et al*. 1969; Maupin & Bell 1975). There are several ways in which psychological stress factors may interfere with host susceptibility. Host tissue resistance may be changed by mechanisms acting through the autonomic nervous system and endocrine glands, resulting in elevation of corticosteroid and catecholamine levels. This may reduce gingival microcirculation and salivary flow and enhance nutrition of *P. intermedia*, but also depress neutrophil and lymphocyte functions, which facilitates bacterial invasion and damage (Johnson & Engel 1986; Horning & Cohen 1995).

Inadequate sleep, often as the result of lifestyle choices or job requirements, has been mentioned by many patients with NPD (Horning & Cohen 1995).

Smoking and alcohol use

Smoking has been listed as a predisposing factor for NPD for many years and presumably predisposes to other types of periodontitis as well (American Academy of Periodontology 1996).

Two studies from the 1950s found that 98% of patients with NPD were smokers (Pindborg 1951a; Goldhaber 1957). Later data have confirmed this by finding that among patients with NPD only 6% were non-smokers, in contrast to 63% in a matched control group (Stevens *et al*. 1984). The amount smoked also appears important since 41% of subjects with NG smoked >20 cigarettes daily, whereas only 5% of controls smoked that much (Goldhaber & Giddon 1964).

The relationship between tobacco usage and NPD appears to be complex. It has often been stated that smokers in general have poorer oral hygiene than non-smokers, but studies have shown that there is little difference in the level of plaque accumulation in smokers versus non-smokers. Also, there have been no conclusive studies to show that smoking adversely affects periodontal tissues by altering the microbial composition of plaque (American Academy of Periodontology 1996). Smoking could lead to increased disease activity by influencing host response and tissue reactions. As examples, smokers have depressed numbers of T-helper lymphocytes, and tobacco smoke can also impair chemotaxis and phagocytosis of oral and peripheral phagocytes (Eichel & Shahrik 1969; Kenney *et al*. 1977; Ginns *et al*. 1982; Costabel *et al*. 1986; Lannan *et al*. 1992; Selby *et al*. 1992). Among further effects of tobacco, nicotine-induced secretion of epinephrine resulting in gingival vasoconstriction has been proposed as one possible mechanism by which smoking may influence tissue susceptibility (Schwartz & Baumhammers 1972; Kardachi & Clarke 1974; Bergström & Preber 1986). The exact mechanism by which tobacco smoking predisposes to NPD, however, remains to be determined.

Social or heavy drinking has been admitted by NPD patients and its role as a predisposing factor can be explained by its numerous physiologic effects which add to other factors as general sources of debilitation (Horning & Cohen 1995).

Caucasian ethnicity

A number of American studies have demonstrated a 95% preponderence of Caucasian patients with NPD, including a study in which the referring population was 41% African–American (Barnes *et al*. 1973; Stevens *et al*. 1984; Horning & Cohen 1995), but a proportion of 49% of African–Americans in another study casts doubt on race as a predisposing factor alone, and the mechanism for this factor is unknown.

Young age

In industrialized countries, young adults appear to be the most predisposed to NPD. While the disease can occur at any age, the reported mean age for NPD is between 22 and 24 years. This may reflect a number of factors such as military population age and wartime stress, and probably is related to the involvement of other factors such as smoking (Horning & Cohen 1995).

Treatment

The treatment of the NPD is divided into two phases: acute and maintenance phase treatment.

Acute phase treatment

The aim of acute phase treatment is to eliminate disease activity as manifest by ongoing tissue necrosis laterally and apically. A further aim is to avoid pain and general discomfort which may severely compromise food intake. Among patients suffering from systemic diseases resulting in loss of weight, further weight loss due to reduced food intake should be avoided by rapid therapeutic intervention.

At the first consultation, scaling should be attempted as thoroughly as the condition allows. Ultrasonic scaling may be preferable to the use of hand instruments. With minimal pressure against the soft tissues, ultrasonic cleaning may accomplish the removal of soft and mineralized deposits. The continuous water spray combined with adequate suction usually allows good visibility. How far it is possible to proceed with debridement at the first visit usually depends on the patient's tolerance of pain during instrumentation. Obviously, toothbrushing in areas with open wounds does not promote wound healing. Therefore, patients should be instructed in substituting toothbrushing with chemical plaque control in such areas until healing is accomplished.

Hydrogen peroxide and other oxygen-releasing agents also have a long-standing tradition in the initial treatment of NPD. Hydrogen peroxide (3%) is still used for debridement in necrotic areas and as a mouth rinse (equal portions of 3% H_2O_2 and warm water). It has been thought that the apparently favorable effects of hydrogen peroxide may be due to mechanical cleaning and the influence on anaerobic bacterial flora of the liberated oxygen (Wennström & Lindhe 1979; MacPhee & Cowley 1981). Further adjunctive local oxygen therapy of NPD showed a more rapid clinical restitution with less periodontal destruction than in a group without oxygen therapy (Gaggl *et al*. 2006).

Twice-daily rinsing with a 0.2% chlorhexidine solution is a very effective adjunct to reduce plaque formation, particularly when toothbrushing is not performed. It also assists self-performed oral hygiene

Fig. 22-17 Necrotizing periodontitis with severe pain. The entire gingival margin is the seat of a necrotic ulcer. (a) Facial aspect; (b) palatal aspect. (c, d) The patient was treated with scaling supplemented with metronidazole and the next day was free of symptoms and the clinical features were significantly improved.

during the first weeks of treatment. Its effect is discussed in Chapter 37. For an optimal effect of this medicament, it should be used only in conjunction with and in addition to systematic scaling and root planing. The chlorhexidine solution does not penetrate subgingivally and the preparation is readily inactivated by exudates, necrotic tissues, and masses of bacteria (Gjermo 1974). The effectiveness of chlorhexidine mouth rinses therefore is dependent upon simultaneous, thorough mechanical debridement.

In some cases of NPD, the patient's response to debridement is minimal or his/her general health is affected to such an extent that the supplementary use of systemic antibiotics or chemotherapeutics is indicated. This also applies to patients with malaise, fever, and lassitude. The choice of drug aims at a direct action on bacteria which are the cause of the inflammatory process in NPD.

Supplementary treatment with metronidazole 250 mg t.i.d. has been found to be effective against spirochetes and appears to be the first choice in the treatment of NPD (Proctor & Baker 1971; Shinn 1976; Loesche *et al*. 1982). The adjunctive use of metronidazole in HIV-associated NPD is reported to be extremely effective in reducing acute pain and promoting rapid healing (Scully *et al*. 1991). Acute pain usually disappears after a few hours (Fig. 22-17).

Antibiotics such as penicillins and tetracyclines are also effective. Penicillin 1 mIU t.i.d should be used as an adjunct to scaling, as for metronidazole, until the ulcers are healed. Topical application of antibiotics is not indicated in the treatment of NPD, because intralesional bacteria are frequent, and topical application does not result in a sufficient intralesional concentration of antibiotics.

It is important to emphasize that many HIV-seropositive patients with NPD at their initial visit are not aware of their serostatus. If HIV infection is a suspected predisposing factor, the patient can be referred to his/her physician for further examination. Some patients may prefer referral to a hospital department. Information on HIV serostatus is frequently not available at initiation of therapy, but the lack of information has no serious implications for the choice of treatment or for the handling of the patient. As a consequence of a lack of information on HIV-serostatus of patients seeking dental treatment in general, all procedures in the dental office must always include precautions to protect against transmission of the virus to the dentist, to the dental auxiliaries, and to other patients.

If the dentist asks the patient about his/her possible chance of having contracted HIV infection, this should be done with great care, because HIV infection

has serious implications for the patient. Consequently, a successful outcome depends on a confidential relationship between patient and dentist. In the case of a new patient, such a relationship is only established after at least a couple of appointments in the clinic.

Usually, in HIV-infected patients antibiotic prophylaxis as an adjunct to scaling does not appear to be necessary. Bacteria recovered from venipuncture 15 minutes after scaling were not detectable in samples obtained at 30 minutes (Lucartoto *et al*. 1992). Neither does removal of sequestra always appear to require antibiotic cover (Robinson 1991). HIV-infected patients are susceptible to candidal infections (Holmstrup & Samaranayake 1990) and if oral candidosis is present or occurs throughout the period of antibiotic treatment, treatment with appropriate antimycotic drugs such as miconazole may be necessary.

Patients with NPD should be seen almost daily as long as the acute symptoms persist. Appropriate treatment alleviates symptoms within a few days. Thereafter the patient should return in approximately 5 days. Systematic subgingival scaling should be continued with increasing intensity as the symptoms subside. Correction of restoration margins and polishing of restorations and root surfaces should be completed after healing of the ulcers. When the ulcerated areas are healed, the local treatment is supplemented with oral hygiene instruction and patient motivation. Instruction in gentle but effective toothbrushing and approximal cleaning is mandatory. In many cases the extensive tissue destruction results in residual soft tissue defects that are difficult for the patient to keep clean. Oral hygiene in these areas often requires the use of interproximal devices and soft, smaller brushes. Sometimes healing is delayed in HIV-infected patients and intensive professional control may be necessary for prolonged periods of time.

Patients with NPD are not always easily motivated to carry out a proper program of oral hygiene. They frequently have poor oral hygiene habits and possibly a negative attitude to dental treatment in general. As a result, some patients discontinue treatment as soon as pain and other acute symptoms are alleviated. Motivation and instruction should be planned to prevent this from happening, and should be reinforced during later visits. Patients with severely impaired immune functions, for instance due to HIV infection, may suffer from other infections or diseases during the period of treatment. This may complicate the treatment, because patients may be hospitalized.

Maintenance phase treatment

When the acute phase treatment has been completed, necrosis and acute symptoms in NPD will have disappeared. The formerly necrotic areas are healed and the gingival craters are reduced in size, although some defects usually persist. In such areas, bacterial plaque readily accumulates and the craters, therefore, predispose to recurrence of NPD or to further destruction because of a persisting chronic inflammatory process, or both. These sites, therefore, may require surgical correction. Shallow craters can be removed by simple gingivectomy, while the elimination of deep defects may require flap surgery. Treatment of NPD has not been completed until all gingival defects have been eliminated and optimal conditions for future plaque control have been established. If possible, elimination of predisposing factors is also very important to prevent recurrence. Due to delayed healing in HIV-infected patients, periodontal surgery is not recommended in these patients. Instead, intensive approximal cleaning is necessary to prevent recurrence of disease.

Chapter 23

Effect of Periodontal Diseases on General Health

Panos N. Papapanou and Evanthia Lalla

Division of Periodontics, Section of Oral and Diagnostic Sciences,
Columbia University College of Dental Medicine, New York, NY, USA

Introduction

The concept that oral and general health are interrelated is far from new. Writings from ancient civilizations including the Assyrians, Hebrews, Greeks, and Romans corroborate the notion that "strong teeth" reflect good health, but also that various systemic ailments can be attributed to poor oral health (O'Reilly & Claffey 2000). In more modern times, a 1891 publication titled "The human mouth as a focus of infection" by the American dentist W.D. Miller (1891), followed by influential articles by the London physician William Hunter (1900, 1910) in the *British Medical Journal* and the *Lancet* at the turn of the 20th century, established the belief that "oral sepsis" (the term used to describe oral infections) played an etiologic role in the development of a number of diverse pathologic conditions, including "chronic dyspepsias, intestinal disorders, ill health, anemias and nervous complaints". The concept of "oral sepsis" evolved to that of "focal infection" (Billings 1912), according to which a circumscribed area of tissue infected with pathogenic organisms could lead to hematogenous dissemination resulting in infection of contiguous or non-contiguous organs. These beliefs translated into drastic treatment decisions, and scores of patients were edentulated in order to cure (or even prevent) multiple diseases. As is usually the case, empirical evidence gradually revealed that these radical practices were unsound (Cecil & Angevine 1938), the purported associations were increasingly refuted, and more conservative approaches to the treatment of oral pathologic conditions finally prevailed.

Interestingly, during the past two decades, and with the increased understanding that inflammation is at the heart of several pathologic conditions that were traditionally viewed as non-inflammatory, the potential effects of oral infection/inflammation on general health outcomes has regained attention and has been the focus of intense investigation. A new field of periodontal research has emerged, commonly referred to as "periodontal medicine", which explores the epidemiologic evidence related to these associations, as well as the potential pathobiologic mechanisms that may account for such links. This chapter will primarily review the biologic plausibility and epidemiologic evidence related to the association between periodontitis and (1) atherosclerotic vascular disease; (2) adverse pregnancy outcomes, and (3) diabetes mellitus, as these are the three most studied conditions thus far. Emerging data on associations with chronic renal disease and pulmonary infections will be discussed briefly as well.

Clinical Periodontology and Implant Dentistry, Sixth Edition. Edited by Niklaus P. Lang and Jan Lindhe.

Atherosclerotic vascular disease

Biologic plausibility

A wealth of data originating from diverse areas of investigation have implicated chronic, low-level inflammation as an important factor in atherosclerotic vascular disease (AVD) (Ross 1999). Supporting studies stemming from a variety of disciplines such as cell biology, epidemiology, clinical trials, and experimental animal research have consistently revealed that atherosclerotic lesions involve an inflammatory component. Cellular interactions involved in atherogenesis are fundamentally similar to those in chronic inflammatory–fibroproliferative diseases, and atherosclerotic lesions represent a series of highly specific cellular and molecular responses that can best be described, in aggregate, as an inflammatory disease (Ross 1993, 1999).

As discussed in other chapters of this textbook, periodontal diseases represent mixed infections of the periodontal tissues in which several, primarily anaerobic, Gram-negative bacteria have a prominent role (Haffajee & Socransky 1994). Likewise, as reviewed in Chapter 7, the prevalence of these infections, especially those of mild or moderate severity, is substantial in most populations. The deepening of the periodontal sulcus occurring during the course of these infections is concurrent with a marked bacterial proliferation, resulting in levels reaching 10^9 or 10^{10} bacterial cells within a single pathologic periodontal pocket. The ulcerated epithelial lining of the periodontal pocket may constitute a substantial surface area in cases of generalized periodontitis (Hujoel *et al*. 2001) and is in constant contact with the biofilm of the subgingival dental plaque. Thus, the ulcerated pocket epithelium provides a gate through which lipopolysaccharide (LPS), bacterial outer membrane vesicles, fimbriae, and other antigenic structures of bacterial origin may challenge the immune system and elicit a local and systemic inflammatory host response (Ebersole & Taubman 1994). Importantly, a number of pathogenic species involved in periodontal infections display tissue invasion properties (Meyer *et al*. 1991; Sandros *et al*. 1994; Lamont *et al*. 1995). Further, frequent transient bacteremias occurring as a result of daily activities such as toothbrushing or chewing (Silver *et al*. 1977; Kinane *et al*. 2005; Forner *et al*. 2006; Crasta *et al*. 2009), as well as during invasive oral therapeutic procedures (Heimdahl *et al*. 1990; Lockhart *et al*. 2008) may confer a significant systemic bacterial challenge. Similarly, a number of pro-inflammatory mediators, including several interleukins, are produced locally in the inflamed gingival tissues (Salvi *et al*. 1998) and can also be disseminated systemically through the blood stream. Circulating levels of the same mediators also have been found to be higher during the course of several non-oral infections (Otto *et al*. 1999; Humar *et al*. 1999; Endo *et al*. 1992), and have been identified as important biomarkers of cardiovascular disease (CVD) (Hackam & Anand, 2003; Hansson 2005).

Central to the role of periodontal infection/inflammation as a risk factor for atherosclerosis is the concept of *vascular endothelial activation*. Figures 23-1, 23-2, and 23-3 summarize a number of potential biologic mechanisms through which periodontal bacteria or periodontitis-associated inflammatory mediators may initiate and perpetuate different well-described steps in atherogenesis. As shown in Fig. 23-1, circulating bacterial products such as LPS, outer membrane vesicles, and fimbriae, or inflammatory cytokines and chemokines result in an up-regulation of cell-surface receptors and in expression of adhesion molecules on the endothelial lining of the vasculature. As a result, peripheral blood monocytes are recruited and adhere to the activated endothelium. In addition, in a process collectively referred to as "molecular mimicry", antibodies targeted against specific bacterial proteins (such as the so-called "heat-shock" proteins that are evolutionarily well-conserved and highly homologous to host proteins), partly act as autoantibodies and induce apoptotic damage in the vascular endothelium. In a next step, outlined in Fig. 23-2, monocytes migrate into the subendothelial space, transform into tissue macrophages, take up oxidized low density lipoprotein cholesterol (LDL), and become foam cells. Apoptosis of LDL-laden macrophages results in the accumulation of lipids in the subendothelial space, that is in the formation of *atheromatic plaques*. Furthermore, invasive periodontal pathogens induce smooth muscle cell proliferation in the intima and neointima formation. Extracellular matrix build-up and extravasation of T cells result in the formation of a fibrous cap covering the atheroma. Finally, Fig. 23-3 outlines the maturation of atheromatic plaques that may ultimately lead to plaque rupture. The fibrous cap and its prothrombotic components are exposed after endothelial cell apoptosis. Enzymatic degradation of the extracellular matrix results in plaque rupture, exposure of prothrombotic plaque components, and subsequent thrombus formation that leads to the occlusion of the vessel. This manifests as a clinical event, for example as a myocardial infarction (MI) in the case of an occluded coronary artery, or as stroke in the case of an occluded cerebral vessel.

A number of studies have examined the presence of oral bacteria in atheromatic plaque lesions. Chiu (1999) investigated the relationship between the presence of multiple infectious agents in human carotid endarterectomy specimens and pathoanatomic features of the corresponding carotid plaques, and reported positive immunostainings for *Porphyromonas gingivalis* and *Streptococcus sanguis* in several carotid plaque specimens. The bacteria were immunolocalized in plaque shoulders and within a lymphohistiocytic infiltrate, associated with ulcer and thrombus formation, and adjacent to areas of strong labeling for apoptotic bodies. A similar study, using the polymerase chain reaction (PCR) to detect the presence of bacterial DNA in carotid endarderectomy specimens

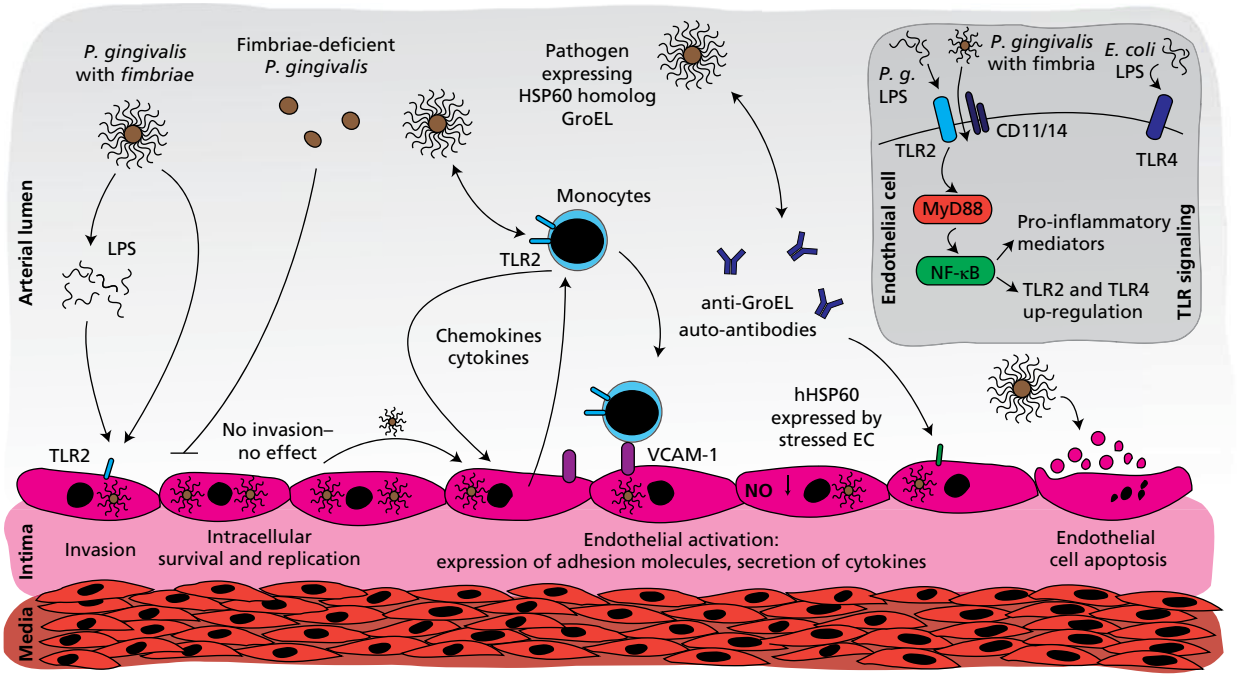

Fig. 23-1 Schematic overview of potential mechanisms linking periodontal infections and endothelial dysfunction/incipient atherosclerosis. Vascular endothelial cells are invaded by fimbriated pathogens, for example *P. gingivalis*. These pathogens can persist and multiply intracellularly. Activation of Toll-like receptor 2 (TLR2) by fimbriated bacteria or lipopolysaccharide (LPS) results in release of pro-inflammatory mediators and up-regulation of cell adhesion molecules. Monocytes are recruited by a gradient of chemotactic cytokines, such as monocyte chemoattractant protein 1 (MCP-1). Antibodies against bacterial heat-shock proteins, such as HSP60-related GroEL, autoreact with human HSP60 (hHSP60) expressed by activated endothelium, resulting in cell destruction. Further, *P. gingivalis* induces apoptosis of endothelial cells. (NO, nitrogen oxide; NF-κB, nuclear factor κB; VCAM-1, vascular cell adhesion protein 1; MyD88, myeloid differentiation primary response protein 88; TLR4, Toll-like receptor 4) (Source: Kebschull *et al.* 2010. Reproduced with permission from Sage.)

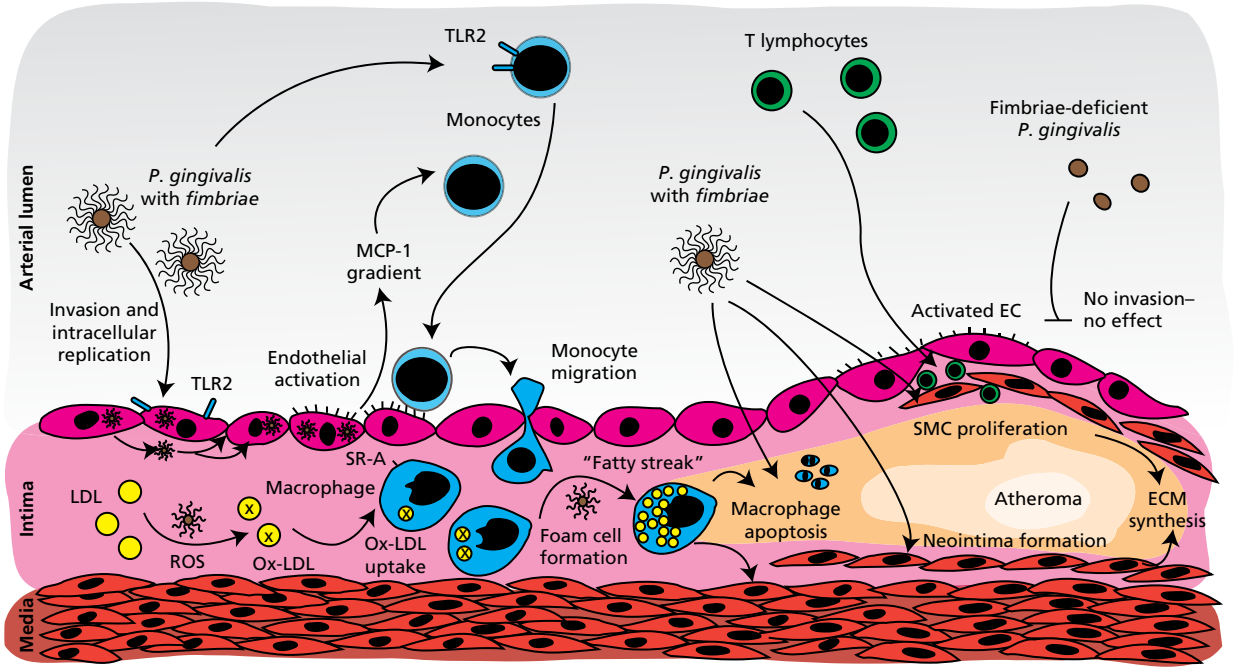

Fig. 23-2 Potential mechanisms linking periodontal infections and fatty-streak formation/plaque maturation. Monocytes activated by periodontal pathogens chemotactically migrate into the subendothelial space, transform into macrophages, and subsequently into foam cells after uptake of oxidized low density lipoprotein (oxLDL). Apoptosis of LDL-laden macrophages results in accumulation of lipids in the subendothelial space. Furthermore, periodontal pathogens induce smooth muscle cell proliferation in the intima and neointima formation. Extracellular matrix (ECM) build-up and extravasation of T cells consummate the formation of a fibrous cap covering the plaque. (MCP-1, monocyte chemoattractant protein 1; TLR2, Toll-like receptor 2; SR-A, macrophage scavenger receptor; ROS, reactive oxygen species; SMC, smooth muscle cell; EC, endothelial cell.) (Source: Kebschull *et al.* 2010. Reproduced with permission from Sage.)

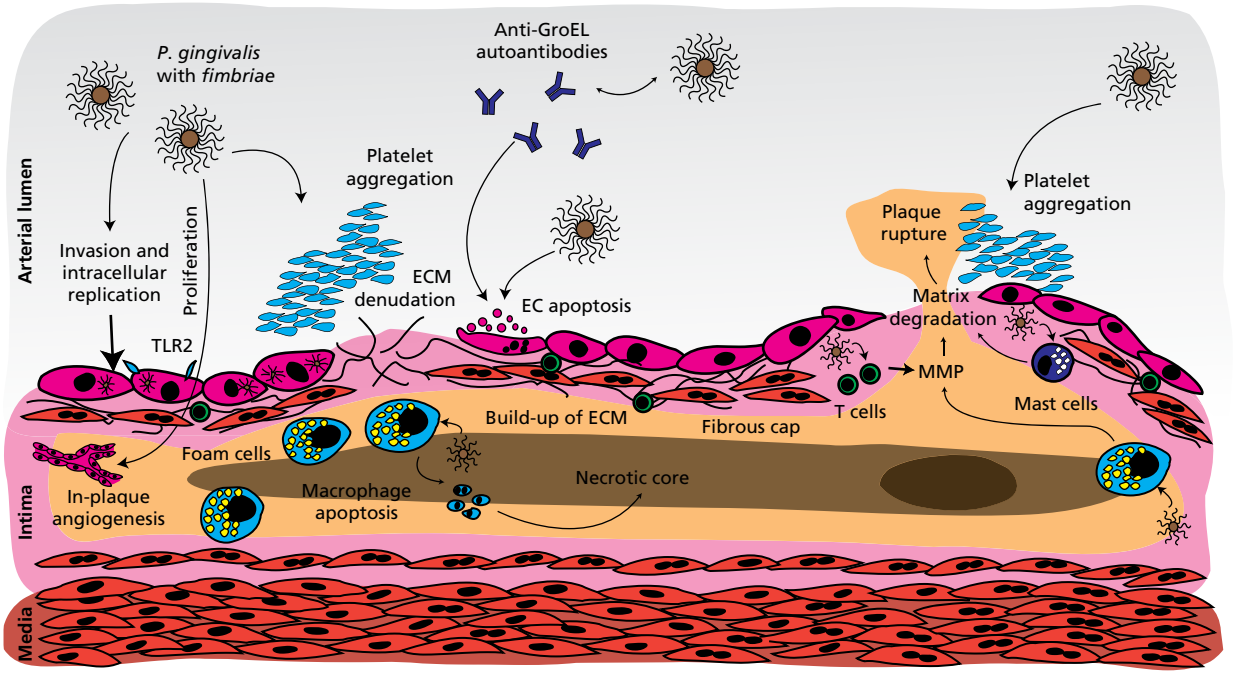

Fig. 23-3 Potential mechanisms linking periodontal infections to mature atherosclerotic plaques and plaque rupture. Pathogen-mediated in-plaque angiogenesis is a hallmark of plaque organization. Denudation of the fibrous cap and its prothrombotic components occurs after endothelial cell (EC) apoptosis mediated by whole periodontal pathogens, or antiendothelial autoantibodies. Plaque rupture is induced by pathogen-mediated extracellular matrix (ECM) degradation by EC, plaque macrophages, T cells, and plasma cells, leading to exposure of prothrombotic plaque components, and subsequent vessel occlusion. (MMP, matrix metalloproteinases; TLR2, Toll-like receptor 2.) (Source: Kebschull *et al.* 2010. Reproduced with permission from Sage.)

(Haraszthy *et al*. 2000), reported that 30% of the specimens examined were positive for *Treponema forsythia*, 26% for *P. gingivalis*, 18% for *Aggregatibacter actinomycetemcomitans*, and 14% for *Prevotella intermedia*. The validity of these data were confirmed by other investigators (Stelzel *et al*. 2002; Fiehn *et al*. 2005) and extended by Kozarov *et al*. (2005) who demonstrated that viable and invasive *A. actinomycetemcomitans* and *P. gingivalis* could be recovered from human atheromatic plaques. These observations were further corroborated by experimental animal studies that demonstrated that oral infection of atherosclerosis-prone (apolipoprotein-E deficient) mice with *P. gingivalis* resulted in accelerated atherosclerosis and in the concomitant presence of *P. gingivalis* DNA in their aortic tissue (Lalla *et al*. 2003). For a comprehensive review of the literature on the potential biologic mechanisms of periodontitis-induced atherogenesis, the reader is referred to the review by Kebschull *et al*. (2010).

Epidemiologic evidence

Epidemiologic evidence on the association between periodontitis and AVD has been generated by three different types of studies: (1) *association studies* (cross-sectional, case–control or longitudinal cohort studies) focusing on *surrogate markers* of AVD; (2) *association studies* focusing on *clinical AVD-related events* [i.e. coronary heart disease (CHD), MI, cerebrovascular disease, peripheral artery disease]; and (3) *intervention studies*, examining the effects of *periodontal therapy on AVD-related outcomes (surrogate markers or events)*. In the following text, we will summarize the data accordingly. We want to draw the attention of the reader to two fundamental issues that are important for the correct interpretation of the data: First, it must be realized that the *exposure variable*, in this case periodontitis as a potential risk factor for AVD, has been defined in these studies using a variety of measures that reflect poor periodontal status. Thus, studies have used traditional clinical or radiographic parameters, such as probing pocket depth, attachment level, and presence of gingival inflammation, but also surrogate markers of poor oral health such as tooth loss or edentulism. The latter two, although related to poor periodontal status, are clearly not synonymous with periodontitis. Furthermore, as discussed in detail in the Chapter 7, the definition of a "periodontitis case" using clinical variables or radiographic assessments of alveolar bone loss is dependent on threshold values of extent and severity, and these have varied greatly across studies. To further complicate the matter, a number of epidemiologic studies have used subgingival microbial profiles or levels of serum antibodies to periodontal bacteria, which reflect the infectious nature of periodontitis rather than its clinical phenotype, as the exposure variable. As discussed in Chapter 7, there is no universally acceptable appropriate definition of periodontitis, and there is a need for additional methodologic research in order to define the optimal exposure

variable to be used in the study of the association between periodontitis and systemic health outcomes such as AVD. The last point that needs to be emphasized, and which is a key determinant of the quality of an epidemiologic study, is whether the association between the exposure under investigation (i.e. periodontitis) and the outcome (i.e. AVD) has been adjusted for *additional exposures* that are known to affect AVD status (e.g. hyperlipidemia, hypertension, or physical activity), as well as for potential *confounders*, in other words, factors that are associated with both periodontitis and AVD (e.g. diabetes mellitus or smoking). Thus, it must be recognized that both the diverse exposure definitions across studies and the variable degree of adjustment for additional risk factors may underlie some of the non-concordant findings in the literature.

Associations with surrogate markers of AVD

Periodontitis patients have been shown to display higher white blood cell counts (Kweider *et al*. 1993; Loos *et al*. 2000) and C-reactive protein (CRP) levels (Ebersole *et al*. 1997; Slade *et al*. 2000; Loos *et al*. 2000) than periodontally healthy controls. Wu *et al*. (2000b) examined the relation between periodontal health status and serum total and high density lipoprotein (HDL) cholesterol, CRP, and plasma fibrinogen in the third National Health and Nutrition Examination Survey (NHANES III). Based on an analysis of a total of 10 146 subjects with available cholesterol and CRP levels and 4461 subjects with available fibrinogen levels, poor periodontal status was significantly associated with increased CRP and fibrinogen levels. Slade *et al*. (2000) explored the same database and reported that people with extensive periodontal disease had an approximately one-third increase in mean CRP and a doubling of the prevalence of elevated CRP compared with periodontally healthy people. Similarly, raised CRP levels were observed in edentulous subjects. Based on data obtained from 2973 participants in the second phase of NHANES III, aged ≥40 years, Dye *et al*. (2005) showed that a high serum IgG antibody level to *P. gingivalis* was significantly related to elevated serum CRP. In a sample comprising 5552 subjects aged 52–75 years from the Atherosclerosis Risk in Communities (ARIC) study (Slade *et al*. 2003), participants with extensive periodontal disease (≥30% of sites with a pocket depth of ≥4 mm) had 30% higher CRP levels than participants with an extent of periodontal disease between 0% and 30%. In a multivariate analysis stratified for body mass index (BMI), extensive periodontal pocketing remained associated with CRP levels when adjusted for age, sex, diabetes mellitus, cigarette use, and use of non-steroidal anti-inflammatory medications. In a meta-analysis of ten cross-sectional studies reporting levels of high sensitivity CRP (hsCRP) in periodontitis, Paraskevas *et al*. (2008) reported a statistically significant weighted mean difference for hsCRP between periodontitis patients and periodontally healthy controls of 1.56 mg/L. Given that an hsCRP level between 1 and 2 mg/L is currently considered to be associated with intermediate risk for CVD, and a level exceeding 3 mg/L with high risk (Ridker 2003), the above difference appears to be highly significant from a clinical point of view. Finally, Schwahn *et al*. (2004) reported on associations between periodontitis, edentulism, and high plasma fibrinogen levels (>3.25 g/L) in 2738 participants in the Study of Health in Pomerania (SHIP), aged 20–59 years. After adjustments for multiple co-variates (age, sex, BMI, education, use of alcohol, aspirin, and other medications, LDL levels, smoking, and other pathologic conditions including gastritis, bronchitis, and diabetes), presence of ≥15 pockets with a probing depth of ≥4 mm was significantly associated with high plasma fibrinogen levels with an odds ratio (OR) of 1.9 (95% CI 1.2–2.8). Less extensive pocketing or edentulism was not associated with high plasma fibrinogen levels.

Another group of studies has investigated the association between periodontitis and subclinical atherosclerosis, commonly measured by means of carotid artery intima–media thickness (IMT) assessments. Increased IMT has been documented to be directly associated with increased risk of MI and stroke (O'Leary *et al*. 1999). Beck *et al*. (2001) provided the first evidence that periodontitis may be linked to subclinical atherosclerosis. These authors analyzed cross-sectional data from 6017 participants in the ARIC study, and demonstrated that severe periodontitis conferred increased odds for higher carotid artery intima–media wall thickness (OR 2.09; 95% CI 1.73–2.53 for IMT of ≥1 mm). A couple of years later, the Oral Infection and Vascular Disease Epidemiology Study (INVEST), a prospective population-based cohort study of randomly selected subjects in a triethnic population comprising a total of 1056 subjects aged ≥55 years with no baseline history of stroke, MI, or chronic inflammatory conditions, investigated the relationship between carotid artery plaque and IMT with tooth loss and measures of periodontitis. In a first report based on data from 711 subjects (Desvarieux *et al*. 2003), loss of 10–19 teeth was associated with increase in prevalence of atherosclerotic plaques in a model adjusted for age, sex, smoking, diabetes, systolic blood pressure, LDL, HDL, ethnicity, education, toothbrushing, social isolation, physical activity, and years of residence in the US (OR 1.9; CI 1.2–3.0). Since in this cohort a higher number of lost teeth paralleled an increased severity of periodontal disease at the remaining teeth, it was assumed that tooth loss reflected, in part, current or cumulative periodontal disease. In a subsequent publication, Engebretson *et al*. (2005) reported on a subsample of 203 subjects from the INVEST cohort with available panoramic radiographs. In a logistic regression model, severe bone loss was defined as a whole-mouth average bone loss of ≥50% of the root length and was associated with the presence of carotid

atherosclerotic plaque after adjustment for age, sex, hypertension, coronary artery disease (CAD), diabetes, smoking, HDL, and LDL. In addition, log-transformed mean carotid plaque thickness increased over tertiles of periodontal bone loss, suggesting a dose-dependent association. A third INVEST report (Desvarieux *et al*. 2005) included 657 patients with available dental and medical variables as described above, as well as data on the prevalence and level of ten bacterial species, assessed by checkerboard DNA–DNA hybridization (Socransky *et al*. 1994) in up to eight subgingival plaque samples per subject. In this study, "etiologic bacterial burden" was defined as the aggregate colonization per subject by *A. actinomycetemcomitans*, *P. gingivalis*, *T. forsythia*, and *Treponema denticola*. The data revealed that IMT and white blood cell counts increased significantly over tertiles of "etiologic" periodontal bacterial burden in a fully adjusted model including age, BMI, sex, race/ethnicity, smoking, systolic blood pressure, education, diabetes, HDL, and LDL. Importantly, the association was exclusively observed for "etiologic bacteria", as increased colonization by putative pathogens of the "orange complex" or a number of health-associated bacteria was not associated with increased IMT. A similar association was observed between "etiologic" bacterial burden and both diastolic and systolic blood pressure as well as prevalent hypertension (Desvarieux *et al*. 2010).

Interestingly, serum IgG antibody levels to specific periodontal pathogens were associated with carotid IMT of ≥1 mm in an ARIC-based subject sample of 4585 participants (Beck *et al*. 2005b). The strongest association emerged when the combined titer against *Campylobacter rectus* and *Micromonas micros* was used. Similarly, a research group from Finland reported on the association between serum titers to periodontal pathogens and IMT in a sub-sample of 1023 men aged 46–64 years from the Kuopio Ischemic Heart Disease Risk Factor study (Pussinen *et al*. 2005). Incident IMT thickening, assessed 10 years post baseline in participants with no prior CHD, increased significantly across tertiles of IgA titer levels to *A. actinomycetemcomitans* and *P. gingivalis*. Lastly, a report from the INVEST study based on 430 participants followed up over a median of 3 years demonstrated that progression of carotid IMT varied inversely across quartiles of longitudinal improvement in clinical and microbial periodontal status (Desvarieux *et al*. 2013).

Associations with clinical events

Tables 23-1, 23-2, and 23-3 summarize data from selected epidemiologic studies with a sample size of at least 1000 participants that have used periodontal status as an exposure and have reported OR, hazard ratios (HR) or relative risk (RR) for clinical AVD outcomes. Table 23-1 summarizes studies focusing on CHD, CAD or CVD, Table 23-2 studies on MI or acute coronary syndrome (ACS), and Table 23-3 studies on stroke. In these studies, periodontal disease has been broadly defined using a variety of measures that include self-reported assessments of tooth loss or periodontal status; clinically and/or radiographically assessed gingival inflammation, and extent and severity of pathologic periodontal pockets or clinical attachment loss; bacterial colonization by specific periodontal species; and serum IgG and IgA antibody titers to periodontal pathogens or specific bacterial antigens. The tables largely reflect the variability of the findings across studies, with many – but clearly not all – publications reporting statistically significant associations after adjustments for co-variates and potential confounders. At least three meta-analyses have been published summarizing the association between periodontal disease and clinical cardiovascular outcomes (Janket *et al*. 2003; Mustapha *et al*. 2007; Humphrey *et al*. 2008), consistently concluding that the available evidence suggests a moderate, positive association between periodontal diseases and AVD. This conclusion was corroborated by two recent narrative reviews (Kebschull *et al*. 2010; Lockhart *et al*. 2012). Interestingly, the effect of periodontitis on AVD events appears to differ with age. As shown in two publications from the Normative Aging Study (NAS) cohort, periodontitis was more strongly associated with incident CHD (Dietrich *et al*. 2008) and stroke (Jimenez *et al*. 2009) in younger versus older (>60 years) men. Another issue that has been vigorously debated in the literature is whether the association between periodontitis and AVD events can be attributed to the confounding effect of smoking (Hujoel *et al*. 2002; Spiekerman *et al*. 2003) or may be entirely spurious (Hujoel *et al*. 2003, 2006). However, recent studies have consistently reported positive associations between periodontal infections and AVD in never smokers. For example, a Korean case–control study reported an OR of 3.3 (95% CI 1.7–6.7) for non-fatal stroke among never smokers (Sim *et al*. 2008). Finnish data from a nested case–control study observed an OR for incident stroke among male never smokers of 3.31 (95% CI 1.31–8.40), while the OR among female never smokers was 2.36 (95% CI 1.44–3.88) (Pussinen *et al*. 2007). US data obtained from the Behavioral Risk Factor Surveillance Survey including 41 891 participants from 22 states showed that, among never smokers, the respective OR for CHD among participants missing 1–5 or 6–31 teeth were 1.39 (95% CI 1.05–1.85) and 1.76 (95% CI 1.26–2.45), respectively (Okoro *et al*. 2005). Thus, although adjustment for smoking is critically important when studying the role of periodontitis on AVD outcomes, the available evidence suggests that it is wrong to conclude that smoking alone, particularly residual confounding by smoking or environmental tobacco smoke, can completely explain the reported associations in observational epidemiologic studies.

Table 23-1 Selected epidemiologic studies with sample size >1000, associating periodontal status with coronary heart disease (CHD), coronary artery disease (CAD) or cardiovascular disease (CVD).

Study	n	Country	Age range (years)[a]	Design	Exposure[b]	Outcome	Adjustments[c]	Measure of association
Beck *et al*. (2005a)	5002	USA (subset of the ARIC study)	45–64	Cross-sectional	Periodontitis (clinical) Serum IgG to 17 periodontal species	CHD	1–9	No association with clinical periodontal status OR for high vs low IgG in ever smokers: *Td* 1.7 (1.2–2.3) *Pi* 1.5 (1.1–2.0) *Co* 1.5 (1.1–2.1) *Vp* 1.7 (1.2–2.3); OR for high vs low IgG in never smokers: *Pn* 1.7 (1.1 –2.6) *Aa* 1.7 (1.2–2.7) *Co* 2.0 (1.3–3.0)

Intervention studies

Intervention studies, in other words studies that examine the effects of periodontal therapy on AVD-related outcomes, can provide critical information on the role of periodontal infection/inflammation as a risk factor for AVD and its sequelae. Data from intervention studies are of particular importance from a public health standpoint, as they reveal whether targeting a particular exposure by means of prevention or therapy translates into tangible benefits in terms of incidence reduction of the disease in question. Ideally, the value of the interventions should be assessed using randomized, placebo-controlled clinical trials that provide the highest level of evidence and minimize bias. In the case of the periodontitis–AVD association, the design and conduct of such studies is unfortunately particularly challenging, primarily due to the extended time course of evolution of AVD, the relatively low incidence of AVD-related clinical events, which necessitates the inclusion of large subject samples in order to obtain adequate power, as well as ethical considerations related to the follow-up of untreated periodontal disease over prolonged time periods. Therefore, intervention trials conducted to date have been largely limited to the study of the effects of periodontal therapy on surrogate markers of risk for AVD or on pathways related to the pathobiology of the disease. For example, D'Aiuto *et al*. (2004b) reported on 94 systemically healthy patients with generalized severe periodontitis who received non-surgical therapy and extractions. In logistic regression analysis, the reduction of CRP levels 6 months after periodontal therapy was significantly associated with the number of extracted teeth (OR 1.4; CI 1.1–1.8) and median probing depth reduction in pockets initially of ≥5 mm (OR 4.7; CI 1.4–15.8). In subsequent publications (D'Aiuto *et al*. 2005; D'Aiuto & Tonetti, 2005), non-surgical periodontal therapy with and without adjunctive local antibiotics resulted in a reduction of median CRP levels at 2 months, with a more pronounced effect in non-smokers than smokers. Circulating interleukin-6 (IL-6) levels were significantly reduced only in the group that received adjunctive local antibiotics (intensive treatment), but no significant changes were observed in LDL and HDL cholesterol and triglyceride levels. The same group (D'Aiuto *et al*. 2006) reported 6-month data on the effect of standard versus intensive therapy. In comparison to baseline levels, a significant reduction in white blood cell counts, CRP levels, IL-6 levels, total cholesterol, LDL, and systolic blood pressure were observed in the intensive treatment group, whereas an increase in HDL levels was observed in the standard treatment group. Similarly, Taylor *et al*. (2006) reported that patients undergoing full-mouth extractions who had at least two teeth with probing depths of ≥6 mm, attachment loss and bleeding on probing, showed a significant reduction in CRP levels from 2.5 mg/L to 1.8 mg/L, and this effect was more pronounced in non-smokers. The most recent meta-analysis of intervention studies that examined the effect of periodontal therapy on hsCRP levels (Paraskevas *et al*. 2008) concluded that there is modest evidence that treatment results in a statistically significant weighted reduction of 0.50 mg/L (95% CI 0.08–0.93; $P = 0.02$). Exploring further the apparent heterogeneity in the short-term post-treatment responses in the level of serologic inflammatory markers, Behle *et al*. (2009) used a composite score ("Summary Inflammatory Score") to represent the aggregate post-treatment response to a panel of 19 individual biomarkers. These investigators demonstrated that approximately one-third and one-fourth, respectively, of the treated patients showed a marked reduction or a pronounced increase in systemic inflammation, while the remainder remained seemingly unchanged. Interestingly, periodontal therapy resulted in significant differential regulation of multiple genes expressed in peripheral blood monocytes, especially in genes related to innate immunity, apoptosis, and cell signaling, in a manner compatible with the promotion of an antiatherogenic phenotype (Papapanou *et al*. 2007). Thus, although it appears that the above studies indicate a general trend towards a periodontal treatment-induced suppression of systemic inflammation, the effects of such treatment on specific markers are not entirely consistent across studies and their sustainability over time is not convincingly established.

Another set of studies has focused on the effects of periodontal therapy on endothelial dysfunction, a marker of vascular disease (Verma *et al*. 2003). Endothelial dysfunction is defined as the reduced vasodilator capability of peripheral blood vessels and is assessed by measuring the difference in the diameter of a peripheral artery prior to and after reactive hyperemia induced through occlusion of blood flow (Celermajer *et al*. 1992). Two earlier studies established that endothelial dysfunction is more pronounced in patients with periodontitis than periodontally-healthy controls (Amar *et al*. 2003; Mercanoglu *et al*. 2004). Three small-sized, single arm intervention studies (i.e. studies that assessed the same individuals before and after periodontal therapy) have reported positive effects of periodontal therapy on endothelial dysfunction: one study involved non-surgical periodontal therapy (Mercanoglu *et al*. 2004), the second study employed adjunctive systemic antibiotics (Seinost *et al*. 2005), and the third study (Elter *et al*. 2006) provided periodontal therapy according to the principle of "full-mouth disinfection" (a treatment modality that includes full-mouth scaling and root planing in two visits within 24 hours in combination with adjunctive oral rinsing/pocket irrigation with an antiseptic solution). Likewise, a single-arm study conducted on 35 patients with mild-to-moderate periodontitis showed that non-surgical periodontal therapy resulted in diminished IMT thickness at 6 and 12 months after

treatment completion (Piconi *et al*. 2009). A larger randomized controlled trial involving a total of 120 patients with severe periodontitis, 61 of whom received full-mouth subgingival debridement completed within a single session and accompanied by extensive application of local antibiotics in all deep periodontal pockets (Tonetti *et al*. 2007), demonstrated a significant improvement in endothelium-dependent dilatation (EDD) in the treatment group at a 6-month follow-up examination. Notably, this intense intervention resulted in a transient deterioration of EDD and a significant increase in multiple inflammatory mediators in the plasma immediately after the intervention.

To date, only a single, multicenter pilot study has examined the effects of periodontal therapy on cardiac events. The Periodontitis and Vascular Events (PAVE) study (Beck *et al*. 2008; Offenbacher *et al*. 2009b) randomized patients with periodontitis and a history of severe CVD to either community care or a study protocol that consisted of oral hygiene instruction and mechanical periodontal therapy. Over a 25-month follow-up period, cardiovascular adverse events occurred with similar frequency in the community control and the periodontal treatment groups. However, the administered periodontal therapy resulted in a rather limited improvement of periodontal status at 6 months after the intervention, and these positive effects were not sustainable at the 1-year follow-up. The interpretation of the findings of this study is further complicated by the fact that a substantial proportion of the individuals randomized in the community care group did receive some form of preventive or periodontal care outside the study. Lastly, obesity appeared to nullify the ability of periodontal treatment to reduce CRP levels. Important lessons were thus learned from this pilot trial that will inform the design of future randomized controlled trials with respect to (1) the required intensity of the protocol-provided periodontal intervention in order to result in clinically and biologically meaningful and sustainable positive effects on the periodontal status; (2) the role of coexisting risk factors for AVD that may negate the treatment-induced positive modulation of systemic inflammation; and (3) the overall feasibility of the study design.

Adverse pregnancy outcomes

Definitions and biologic plausibility

Preterm infants are born prior to the completion of 37 weeks of gestation. An estimated 11–12.5% of pregnancies end in preterm birth (PTB), and this rate appears to be on the rise in several developed countries, despite significant advances in obstetric medicine and improvements in prenatal care utilization (Goldenberg & Rouse 1998; Shapiro-Mendoza & Lackritz 2012). Of particular interest are the *very preterm infants*, born prior to 32 gestational weeks, the majority of whom require neonatal intensive care due to their increased perinatal mortality, primarily due to impaired lung development and function. The overall contribution of PTB to infant mortality and morbidity is substantial and includes a number of acute and chronic disorders, including respiratory distress syndrome, cerebral palsy, pathologic heart conditions, epilepsy, blindness, and severe learning disabilities (McCormick 1985; Veen *et al*. 1991).

Preterm infants often weigh less at birth and *low birth weight* (LBW) (i.e. <2500 g) has been used as a surrogate for prematurity in cases where the exact gestational age at birth is difficult to assess. Birth weight is further classified as *very low* (<1500 g) or *moderately low* (1500–2500 g). An additional term used is "*small for gestational age*", defined as birth weight within the 10th percentile of normal weight at a particular gestational age, and may, thus, affect even full-term infants as a result of intrauterine growth retardation (Ashworth 1998).

A number of risk factors for PTB have been identified (Goldenberg *et al*. 2000). These include young maternal age (Wessel *et al*. 1996; Lao & Ho 1997; Scholl *et al*. 1988), multiple gestation (Lee *et al*. 2006b), small weight gain during pregnancy (Honest *et al*. 2005), cervical incompetence (Althuisius & Dekker 2005), smoking, alcohol, and drug abuse (Myles *et al*. 1998), black race (Kleinman & Kessel, 1987; David & Collins 1997), and a number of maternal infections (uterine track infections, bacterial vaginosis, chorioamnionitis) (Romero *et al*. 2001). Obstetric history of PTB is a robust marker of future PTB (Mutale *et al*. 1991). Importantly, approximately 50% of the variance in the incidence of PTB remains unexplained (Holbrook *et al*. 1989).

Despite the established role of genitourinary tract infections in the pathobiology of PTB, women with preterm labor do not invariably present with positive amniotic fluid cultures (Romero *et al*. 1988), leading to the hypothesis that PTB may be indirectly mediated through *distant* infections resulting in translocation of bacteria, bacterial vesicles or LPS in the systemic circulation. The possibility that periodontal infections may constitute such maternal infections that adversely influence birth outcomes was raised for the first time in the late 1980s (McGregor *et al*. 1988). Transient bacteremias occur commonly in subjects with inflamed gingiva (Ness & Perkins 1980; Kinane *et al*. 2005; Forner *et al*. 2006) and may conceivably reach the placental tissues, providing the inflammatory impetus for labor induction (Offenbacher *et al*. 1998). An interesting publication in this context by Hill (1998) reported that amniotic fluid cultures from women with vaginosis rarely contained bacteria common to the vaginal tract, but frequently harbored Fusobacteria of oral origin, which are common constituents of the periodontal microbiota. Thus, these authors proposed that oral bacteria may reach amniotic fluids and influence maternal fetal tissues via a hematogenous spread resulting in a

chorioamniotic challenge. In line with these observations, experimental evidence on the role of oral infections on pregnancy outcomes was first provided in a series of studies by Collins *et al*. (1994a, b) who demonstrated that injection of the pregnant hamster with *P. gingivalis* resulted in intrauterine growth retardation, smaller fetuses, and an increase in pro-inflammatory mediators such as IL-1β and prostaglandin E_2 (PGE_2) in the amniotic fluid. Subsequent studies in pregnant mice and rabbits (Boggess *et al*. 2005) confirmed and expanded these observations to include experimental infections by *C. rectus*.

Epidemiologic evidence

Association studies

The first study that reported an association between adverse pregnancy outcomes and poor periodontal conditions was a case–control study (Offenbacher *et al*. 1996) that included 124 mothers, of whom 93 ("cases") gave birth to children with a birth weight of <2500 g or prior to 37 weeks of gestation. Forty-six mothers who delivered infants of normal birth weight at term served as controls. Assessments included a broad range of known obstetric risk factors, such as tobacco use, drug use, alcohol consumption, level of prenatal care, parity, genitourinary infections, and nutrition. The data showed a small, albeit statistically significant, difference in attachment loss between cases and controls (3.1 versus 2.8 mm). Multivariate logistic regression models, controlling for other risk factors and co-variates, demonstrated that periodontitis, defined as ≥60% of all sites with attachment loss of ≥3 mm, conferred adjusted OR of 7.9 for preterm, LBW babies. Several case–control studies have since been published, most of which reported a positive association between periodontitis and adverse pregnancy outcomes (Offenbacher *et al*. 1996; Dasanayake *et al*. 2001; Canakci *et al*. 2004; Goepfert *et al*. 2004; Mokeem *et al*. 2004; Radnai *et al*. 2004; Jarjoura *et al*. 2005), although a number of studies failed to document an association (Davenport *et al*. 2002; Buduneli *et al*. 2005; Moore *et al*. 2005). A systematic review and meta-analysis of case–control studies (Corbella *et al*. 2012) included 17 studies and a total of 10 148 women, and reported statistically significant OR for periodontitis and both PTB (OR 1.78; 95% CI 1.58–2.01) and LBW (OR 1.82; 95% CI 1.51–2.20), although the authors cautioned that uncontrolled or inadequately reported confounders may have affected the association demonstrated by the pooled data.

Non-uniform data were also generated by cohort studies – studies that evaluated the periodontal status of pregnant women prior to the completion of the second trimester and compared prospectively the incidence of adverse pregnancy outcomes in women with and without periodontitis. In the first prospective cohort study reporting a positive relationship between periodontitis and prematurity, Jeffcoat *et al*. (2001) assessed the periodontal condition of 1313 primarily African–American pregnant women at 21–24 weeks of gestation and reported that in women with generalized periodontitis, defined as ≥90% of all sites with attachment loss of ≥3 mm, adjusted OR were 4.45, 5.28, and 7.07 for delivery prior to 37, 35, and 32 weeks of gestation. Corroborating data were reported in additional cohorts in the US (Offenbacher *et al*. 2001), Chile (Lopez *et al*. 2002a), and Switzerland (Dortbudak *et al*. 2005). Similar positive associations were reported for very preterm deliveries (Offenbacher *et al*. 2006), small-for-gestational-age infants (Boggess *et al*. 2006a), pre-eclampsia (Boggess *et al*. 2003; Contreras *et al*. 2006; Herrera *et al*. 2007; Nabet *et al*. 2010), and antepartum vaginal bleeding and risk for premature delivery prior to 35 gestational weeks (Boggess *et al*. 2006b). In contrast, four cohort studies (Romero *et al*. 2002; Holbrook *et al*., 2004; Moore *et al*. 2004; Rajapakse *et al*. 2005) failed to document such associations. Of particular interest is the study by Moore *et al*. (2004) who reported data on 3738 women recruited when presenting for an ultrasound scan at approximately 12 weeks of pregnancy. Regression analysis indicated no significant relationships between the severity of periodontal disease and either PTB or LBW, although a positive correlation was reported between poorer periodontal health and late miscarriage.

Nevertheless, a recent systematic review of all available association studies (cross-sectional, case–control, and prospective cohort studies) by Ide and Papapanou (2013) concluded that maternal periodontitis is modestly, but significantly, associated with PTB, LBW, and pre-eclampsia.

Intervention studies

Contrary to the logistical difficulties associated with the conduct of intervention studies of periodontal therapy and atherosclerosis-related outcomes described above, testing whether treatment of periodontal disease in pregnant women results in a reduction of adverse pregnancy outcomes is feasible. The first published intervention study (Mitchell-Lewis *et al*. 2001) examined a cohort of 213 young, predominantly African–American women with respect to clinical periodontal status, and analyzed the available birth outcome data for 164 women, 74 of whom received oral prophylaxis during pregnancy and 90 who received no prenatal periodontal treatment. In this cohort with a particularly high incidence of PTB/LBW of 16.5%, no differences in clinical periodontal status were observed between women with normal and adverse birth outcomes ("cases"). However, cases harbored statistically significantly higher levels of *T. forsythia* and *C. rectus* in their subgingival plaque and had consistently elevated counts for a number of species examined. Interestingly, PTB/LBW occurred in 18.9% of the women who did

Table 23-4 Intervention studies with sample size >200, examining the effect of periodontal therapy during pregnancy on adverse pregnancy outcomes.

Study	N	Country	Sample characteristics	Periodontal disease definition	Interventions	Outcomes
Lopez *et al*. (2002b)	Tx group: 200 Ctr group: 200	Chile	Low SES	≥4 teeth with PD ≥4 mm and with CAL ≥3 mm	Tx group: SRP during gestation Ctr group: SRP after delivery	RR for PLBW: 0.18 (0.05-0.6) RR for PTB: 0.19 (0.04-0.85) RR for LBW: 0.16 (0.02-1.33)

not receive periodontal intervention, and in 13.5% of those who received such therapy, reflecting a substantial, although statistically non-significant, incidence reduction of approximately 30%. The small sample size in combination with the fact that the participants were not randomly assigned to the two treatment groups were important shortcomings of the study design.

Several additional intervention studies have been published since, and the key features and main findings from studies involving a sample size of >200 women are summarized in Table 23-4. Six of the seven studies assigned randomly the enrolled pregnant women with periodontitis to treatment and control groups, while the control group in the study by Gazolla *et al*. (2007) consisted of women who "dropped out" of treatment. Of note, the study by Jeffcoat *et al*. (2003) involved two "active" treatment groups, one that received scaling and root planning and a placebo pill, and a second that received adjunctive systemic metronidazole as well. Five of the seven studies, and actually the ones of higher methodological quality (Jeffcoat *et al*. 2003; Michalowicz *et al*. 2006; Offenbacher *et al*. 2009a; Newnham *et al*. 2009; Macones *et al*., 2010), failed to detect any positive effect of periodontal therapy on pregnancy outcomes, including PTB at <37 or <35 gestational weeks, or LBW of <2500 g or <1500 g. Interestingly, adjunctive use of systemic metronidazole did not enhance the effect of periodontal therapy on gestational outcomes, a finding which is in line with an earlier multicenter trial that suggested that systemic metronidazole used in the treatment of asymptomatic bacterial vaginosis does not reduce the occurrence of PTB (Carey *et al*. 2000).

Thus, despite the biologic plausibility of the link between maternal periodontal infections and adverse pregnancy outcomes, and the promising data of the early association studies, the findings summarized in Table 23-4, as well as meta-analyses presented in recent systematic reviews (Polyzos *et al*. 2010; Baccaglini 2011; Chambrone *et al*. 2011; Michalowicz *et al*. 2013), indicate that periodontal therapy during gestation does not result in improved obstetric outcomes. It must be emphasized, however, that the failure of the trials to demonstrate an effect of therapy on PTB or LBW should not be interpreted as evidence indicating that periodontal infection/inflammation is unrelated to adverse pregnancy outcomes. There are several reasons why interventions targeting a true risk factor may still fail: these may include inappropriate timing of the intervention, failure of the intervention to adequately change the level of exposure to the presumed causative/contributory factor, as well as the possibility that the risk factor may have resulted in irreversible damage that is no longer modifiable through intervention. In the case of treatment of maternal periodontitis during pregnancy, we must note that the periodontal status of the pregnant women did not improve dramatically after therapy in most studies. In addition, the transient bacteremias that are induced during therapy may counteract the potential beneficial effects of treatment. Thus, although treatment of periodontitis during gestation was shown to be safe for the mother and the fetus (Michalowicz *et al*. 2008), the second trimester of pregnancy may not be the most appropriate time for the delivery of periodontal treatment. The potential effects on obstetric outcomes of therapy delivered before conception are unknown and may be entirely different (Xiong *et al*. 2011). Likewise, the potential beneficial effects of periodontal therapy on subgroups with excessive risk for prematurity have not yet been assessed and warrant further investigation in future studies (Kim *et al*. 2012).

Diabetes mellitus

Biologic plausibility

The role of diabetes mellitus as a risk factor for periodontitis is reviewed in detail in Chapters 7 and 14. However, accumulating evidence suggests the presence of an inverse association as well, in other words, that periodontitis may affect the diabetic state. As reviewed above, periodontal infections result in an elevation of serum pro-inflammatory cytokines and prothrombotic mediators (Loos 2005; Kebschull *et al*. 2010) which, in turn, may result in insulin resistance, may adversely impact metabolic control, and, long-term, may lead or contribute to the development of diabetic complications. In an experimental animal study, ligature-induced periodontitis in Zucker fatty rats was associated with deterioration of glucose metabolism (Pontes Andersen *et al*. 2007). A study in adults with type 2 diabetes demonstrated a dose–response relationship between severity of periodontitis and plasma levels of tumor necrosis factor-alpha (TNF-α) (Engebretson *et al*. 2007), a cytokine known to promote insulin resistance (Hotamisligil *et al*. 1993; Gupta *et al*. 2005; Shoelson *et al*. 2006). Further support for a potential effect of periodontitis on the diabetic state comes from evidence that periodontal treatment in non-diabetic individuals results in a reduction of systemic inflammation (D'Aiuto *et al*. 2004a; 2006; Paraskevas *et al*. 2008). Interestingly, periodontal therapy in patients with type 2 diabetes suppressed serum TNF-α (Iwamoto *et al*. 2001), whereas treatment of periodontitis in individuals with type 1 diabetes resulted in lower TNF-α secretion by peripheral blood-derived macrophages and reduction in serum CRP and E-selectin (Lalla *et al*. 2007). A number of studies have further demonstrated that periodontal therapy can reduce circulating inflammatory mediators, such as CRP, TNF-α, IL-6, and fibrinogen, and increase the levels of adiponectin in individuals with diabetes (O'Connell *et al*. 2008; Katagiri *et al*. 2009; Matsumoto *et al*. 2009; Correa *et al*. 2010; Sun *et al*. 2010). These effects may result in improved insulin sensitivity, and eventually lead to improved glycemic control and overall diabetes outcomes.

Epidemiologic evidence

Association studies

Table 23-5 provides a summary of longitudinal studies that examined the association between baseline periodontal status and development of diabetes complications or incident diabetes. In one of the first studies that demonstrated that periodontitis entails higher risk for diabetic complications, Thorstensson *et al*. (1996) followed 39 pairs of patients with type 1 diabetes, each consisting of a person with severe periodontitis, matched with respect to age, sex, and diabetes duration with a person with no or only mild periodontal disease. After a median follow-up of 6 years, a significantly higher incidence of proteinuria and cardiovascular complications, including angina, intermittent claudication, transient ischemic attack, MI, and stroke was found in the patients with severe periodontitis. Three prospective studies of Pima Indians in the Gila River community in Arizona, a population with a high prevalence of type 2 diabetes, extended these findings. Taylor *et al*. (1996) were the first to demonstrate that severe periodontitis at baseline entailed increased risk for poor glycemic control [glycated hemoglobin A1c (HbA1c) >9%] at follow-up. Saremi *et al*. (2005) demonstrated a significantly increased adjusted relative risk for cardiorenal mortality (3.2; 95% CI 1.1–9.3) over a median follow-up of 11 years in patients with type 2 diabetes and severe periodontitis, when compared to a group comprising patients with diabetes but with no, mild or moderate periodontitis. Lastly, periodontitis and edentulism were found to predict incident microalbuminuria and end-stage renal disease in patients with type 2 diabetes (Shultis *et al*. 2007).

More recently, two cohort studies explored the association between periodontitis in diabetes-free individuals and the development of type 2 diabetes over time. The first (Demmer *et al*. 2008) used data from 9296 non-diabetic participants in NHANES I and its Epidemiologic Follow-Up study. Periodontal disease was recorded at baseline by means of a no longer utilized clinical index system (Periodontal Index), or by using tooth loss as its surrogate. In adjusted analyses, participants with severe tooth loss at baseline had an OR of 1.7 (P <0.05) for incident diabetes when compared to those least affected, and those in the upper three quintiles of the Periodontal Index had elevated OR ranging from 1.50 to 2.08, although no dose–response association could be established. Limitations of this study include the rather imprecise method of assessment of periodontitis and the lack of laboratory data to exclude undiagnosed diabetes at baseline. In contrast, no association between baseline periodontitis and incident diabetes could be demonstrated after adjustments in a 7-year prospective study of 5848 non-diabetic individuals in Japan (Ide *et al*. 2011), despite significant positive associations in the unadjusted analyses. Of note, periodontal conditions were not assessed with adequate precision in this study either.

Intervention studies

As discussed earlier, systemic inflammation promotes insulin resistance and dysregulates glycemia (Hu *et al*. 1990; Pradhan *et al*. 2001; Shoelson *et al*. 2006). Since periodontitis contributes to systemic inflammation (Kebschull *et al*. 2010), it is conceivable that treatment of periodontal infections may result in improved glycemic control. Table 23-6 summarizes the design and findings of a selection of recent intervention studies that examined the effect of periodontal therapy on the level of HbA1c, one of the key indicators of metabolic control in diabetes. As shown in Table 23-6, most of these studies have a modest sample size, have not included patients with type 1 diabetes, and have a follow-up time that ranged between 3 and 18 months. Three studies (Stewart *et al*. 2001; Kiran *et al*. 2005; Koromantzos *et al*. 2011) provided only mechanical, non-surgical periodontal therapy in the treatment arm, three studies (Promsudthi *et al*. 2005; Yun *et al*. 2007; Jones *et al*. 2007) used adjunctive systemic antibiotics, and one study (Katagiri *et al*. 2009) also included topical application of an antibiotic ointment to all deep pockets. On the other hand, a recent 6-month multicenter randomized controlled trial that included 514 participants with type 2 diabetes and periodontitis (Engebretson *et al*. 2013) showed no positive effect of scaling and root planing on HbA1c levels. Limitations of the above study include the suboptimal control of periodontal inflammation in the treatment arm, the high levels of obesity in the patient sample that may have counteracted the systemic anti-inflammatory effects of periodontal therapy, and the relatively good metabolic control of diabetes before the initiation of the intervention, with a mean HbA1c at baseline of 7.8%.

Obviously, no unanimous conclusion can be drawn from the listed studies on the ability of periodontal therapy to significantly improve metabolic control in diabetes. However, two systematic reviews (Simpson *et al*. 2010; Teeuw *et al.* 2010) that combined evidence from intervention trials concluded that there is a statistically significant effect of periodontal therapy on HbA1c levels, amounting to a reduction of 0.40% (P = 0.03 and P = 0.04, respectively). This estimate is fairly similar to the one produced by an earlier meta-analyses (0.46%) (Darré *et al*. 2008). Importantly, the magnitude of the effect appears to be significant from a clinical standpoint: Data generated by the United Kingdom Prospective Diabetes Study (Stratton *et al*. 2000) indicate a 35% reduction in the risk of microvascular complications for every percentage point decrease in HbA1c. In addition, an average 0.20% reduction in HbA1c was associated with a 10% reduction in mortality in the general population (Khaw *et al*. 2001). Additional larger clinical trials are obviously needed to confirm the validity of the findings available so far, as well as to clarify issues such as (1) the effect of periodontal therapy on metabolic

Table 23-5 Longitudinal studies examining the association between periodontal status and diabetes complications or incident diabetes.

Study	n	Country	Diabetes type	Follow-up time	Findings
Thorstensson *et al.* (1996)	39 case–control pairs matched for age, gender, and diabetes duration	Sweden	1	Median of 6 years	Significantly higher incidence of proteinuria (P <0.05), stroke (P <0.01), TIA (P <0.05), angina (P <0.001), MI (P <0.01), heart failure (P <0.01), and intermittent claudication in cases vs controls
Taylor *et al.* (1996)	88 individuals with radiographic assessments of bone loss (80 with clinical periodontal data)	USA	2	Median of 2 years	Severe periodontitis at baseline was significantly associated with increased risk for HbA1c ≥9% at follow-up, after adjustments for age, baseline level of glycemic control and complications, diabetes duration, and smoking
Saremi *et al.* (2005)	628 individuals	USA	2	Median of 11 years	Severe periodontitis at baseline had a significant effect on death from cardiorenal disease: death rate ratio 4.5 (95% CI 2.0–10.2), adjusted for age, gender, and diabetes duration; death rate ratio was 3.5 (95% CI 1.2–10.0), adjusted for age, gender, and BMI
Shultis *et al*. (2007)	529 individuals with no MAU and GFR ≥60 mL/min/1.73 m^2 at baseline	USA	2	Median of 9.4 years for MAU; 14.9 years for ESRD	Severe periodontitis at baseline was associated with a 2.1 increase in incidence of MAU (P=0.01) and a 3.5 increase in incidence of ESRD (P=0.02) when compared to no/mild periodontitis, after adjustments for age, gender, diabetes duration, BMI, and smoking
Demmer *et al.* (2008)	9269 individuals with available periodontal data at baseline	USA (NHANES I and its follow-up study)	Diabetes-free	Mean of 17 years	Among the three highest quintiles of baseline periodontitis severity, adjusted OR for incident diabetes were 2.08 (95% CI 1.51–2.87), 1.71 (1.19–2.45), and 1.50 (0.99–2.27) when compared to individuals without periodontitis
Ide *et al*. (2011)	5848 civil service officers with available periodontal data at baseline	Japan	Diabetes-free	Mean of 7.5 years	Incident diabetes was significantly associated with severe periodontitis after adjustment for age and sex (hazard ratio 1.49; 95% CI 1.03-2.14), but not after adjustment for additional variables including smoking, BMI, hypertension and triglyceride levels (hazard ratio 1.28: 95% CI 0.89-1.86)

BMI, body mass index; HbA1c, hemoglobin A1c; MAU, microalbuminuria; ESRD, end-stage renal disease; GFR, glomerular filtration rate; MI, myocardial infarction; NHANES I, First National Health and Nutrition Examination Survey; TIA, transient ischemic attack, OR, odds ratio.

control in type 1 diabetes patients; (2) whether the effect differs according to pretreatment levels of metabolic control and/or pretreatment severity of periodontitis and other co-morbidities; and (3) the extent to which adjunctive antibiotics account for the observed improvement in glycemic control.

Other associations

Chronic renal disease

Renal function is commonly measured by means of the glomerular filtration rate (GFR), which is estimated on the basis of an equation that incorporates the patient's serum creatinine concentration, age, sex, and race (Levey *et al*. 2006). In a healthy adult, GFR ranges between 100 and 120 mL/min/1.73 m^2 body surface area. Functional loss of renal glomeruli caused by renal interstitial disease results in the retention of toxic compounds that are normally excreted by the kidney, disturbances in blood electrolytes and acid–base balance, anemia, renal osteodystrophy secondary to hypocalcemia, hyperphosphatemia and resulting hyperparathyroidism, hypertension, and growth retardation in younger patients. Chronic kidney disease (CKD) is classified on the basis of GFR into five stages, ranging from stage 1 that signifies incipient CKD to stage 5 that represents end-stage renal disease (ESRD), a fatal condition in the absence of renal replacement therapy (hemodialysis, peritoneal dialysis, or renal transplantation).

Common causes of CKD include diabetes mellitus, glomerulonephritis, and chronic hypertension. As discussed earlier, the increased incidence of diabetes complications in individuals with severe periodontal disease (Thorstensson *et al*. 1996; Saremi *et al*. 2005), the evidence demonstrating an adverse effect of periodontitis on endothelial function (Amar *et al*. 2003; Tonetti *et al*. 2007), and the recently reported contributory effects of periodontitis to hypertension (Desvarieux *et al*. 2010), all support the biologic plausibility of an association between periodontitis and CKD that can be mediated by means of periodontitis-induced systemic inflammation.

The first publication suggesting an association between periodontitis and CDK was a cross-sectional analysis of data from 5537 participants in the ARIC study that showed a statistically significantly elevated OR for GFR of <60 mL/min/1.73 m^2 in individuals with either moderate or severe periodontal disease when compared to those with no periodontal disease or only gingivitis (Kshirsagar *et al*. 2005). In a more recent cross-sectional analysis of 6199 participants in the 2001–2004 NHANES study, Grubbs *et al*. (2011) defined CKD as a GFR of <60 mL/min/1.73 m^2 or a urinary albumin-to-creatinine ratio of ≥30 mg/g and reported that periodontitis was associated with a greater than two-fold higher risk of CKD. This association was only moderately attenuated after adjustments for age, sex, race/ethnicity, tobacco use, hypertension, diabetes, educational attainment, poverty index ratio, and dental care use. A dose–response relationship between periodontitis severity, incident macroalbuminuria, and ESRD was demonstrated in patients with type 2 diabetes (Shultis *et al*. 2007). Additional publications reported an association between serum IgG antibody levels to specific periodontal pathogens and impaired renal function in the ARIC (Kshirsagar *et al*. 2007b) and NHANES III datasets (Fisher *et al*. 2008). Nevertheless, several reports have failed to document an association between periodontitis and CKD, although they generally originate from limited-sized studies that specifically focus on dialysis patients (Gavalda *et al*. 1999; Castillo *et al*. 2007; Garcez *et al*. 2009; Vesterinen *et al*. 2011). Furthermore, studies carried out in patients with ESRD undergoing hemodialysis demonstrated that periodontitis was associated with hypoalbuminemia (Kshirsagar *et al*. 2007a), which is a strong predictor of death in these patients (Lowrie & Lew 1990), as well as with increased cardiovascular disease-associated mortality (Kshirsagar *et al*. 2009; Chen *et al*. 2011). Finally, a small exploratory single cohort trial suggested that non-surgical periodontal treatment in subjects with generalized chronic periodontitis may positively affect renal function as indicated by surrogate measures of GFR (Graziani *et al*. 2010).

Pulmonary infections

Emerging evidence suggests that poor oral status may influence lung function and contribute to the development of bacterial pulmonary infection (pneumonia). High-risk groups for acquisition of pneumonia of oral bacterial origin are residents of nursing homes, hospitalized individuals, as well as patients requiring mechanical ventilation due to respiratory failure. A comprehensive review of the role of periodontal infections in pneumonia in these groups was provided by Raghavendran *et al*. (2007).

In general, the pathogenesis of pneumonia involves aspiration of bacteria-containing secretions of oropharyngeal origin and inadequate clearance of the bacteria by host defense mechanisms. Frail, elderly individuals or subjects with compromised immunity are particularly susceptible, as are individuals with endotracheal tubes that may facilitate the seeding of oropharyngeal microbiota into the lower airway. Given the complexity of the microbiota associated with periodontitis (Paster *et al*. 2006), and the enhanced pathogenicity of polymicrobial inocula when compared to mono-infections in experimental pneumonia models (Kimizuka *et al*. 2003; Okuda *et al*. 2005), an association between periodontitis and pulmonary infections is plausible. Interestingly, in a prospective study of 697 80-year-old subjects in Japan (Awano *et al*., 2008), the adjusted mortality due to pneumonia over a 5-year period was approximately four times higher in individuals with ≥10 teeth with probing depth of >4 mm, than in those with fewer teeth and shallower pockets.

Finally, a number of trials have examined whether oral antimicrobial interventions may contribute to a reduction in incident pulmonary infections. These have included studies focusing on the prevention of ventilator-associated pneumonia (Pugin *et al*. 1991; Bergmans *et al*. 2001), nosocomial pneumonia (DeRiso *et al*., 1996; Fourrier *et al*. 2000; Houston *et al*. 2002; Fourrier *et al*. 2005), or pneumonia in elderly residents of nursing homes (Yoneyama *et al*. 1996, 2002). Although the studies were not uniformly successful in reducing the incidence of the respective outcomes, the data are generally supportive of the notion that oral antibacterial interventions are valuable in the control of pulmonary infections.

Concluding remarks

Somewhat provocatively, it has been stated that modern science has a tendency to recycle original discoveries made a long time ago. The notion certainly applies to some extent to the association between periodontitis and systemic diseases. Our views have certainly evolved since the times when the "focal infection" theory prevailed, and our reaction to the potential threat that oral infections may pose to general health are more measured and are geared towards prevention and anti-infective/anti-inflammatory approaches rather than indiscriminate extraction therapy. As discussed in this chapter, the proposed associations are biologically plausible, and the magnitude of the biologic effects of periodontal diseases on general health outcomes is gradually being defined. In addition, it is increasingly evident that periodontal treatment results in lower levels of systemic inflammation. Nevertheless, we cannot yet draw any conclusions on whether periodontal diseases constitute causative exposures for any of the discussed conditions, neither are there sufficient data available that demonstrate that treatment of periodontitis may prevent the incidence of specific *clinical* adverse events. Ongoing research will hopefully clarify these issues in the near future. Importantly, the studies reviewed underscore that the oral cavity is an integral part of the human body, and that "health" must encompass oral – and periodontal – health as well. Last, but certainly not least, these studies have provided a unique opportunity for oral health researchers to expand their investigative sphere, interact fruitfully with colleagues in medicine, and acquire more knowledge. Irrespective of the definitive conclusions of these research efforts, their byproducts may prove to be just as important as the elucidation of the research task *per se*.
