The chief complaint is the reason the patient is seeking care. It is usually documented in the patient's words, or in the case of a young minor, the parent's or guardian's words. This verbal description of the problem is often aided by hand gestures and the patient pointing to a general area of discomfort. After obtaining the **chief complaint**, the examination process is continued by obtaining a dental history of the **present illness**. This helps establish the correct diagnosis. Treatment should not be rendered unless the clinician is certain of the diagnosis. Patients suffering excruciating pain often have difficulty in cooperating with the diagnostic procedures, but until a diagnosis has been made, treatment must not be started. Nonodontogenic pains need to be managed appropriately, which usually does not involve endodontic treatment (see Chapter 11, "Nonodontogenic Toothache and Chronic Head and Neck Pains").

PRESENT DENTAL ILLNESS

A history of the present illness should help determine the severity and the urgency of the problem. When questioning the patient regarding the problem, questions should be put forth in a manner that leaves them open for patient discussion. Closed questions that allow the patient to respond with "yes" or "no" are of less help than open-ended questions. Start asking questions with words such as "how," "when," "where," or "what." Questions of this type encourage even the poor historian to verbalize more specifically problems that persist.

In obtaining information regarding the present illness, certain areas should be covered, such as whether there has been any recent dental treatment. This information may help localize a particular problem or give an impression of how frequently the patient seeks dental care. A history of trauma is important in determining the course of examination as well as treatment. Discomfort, and what triggers it, is also very important in determining severity and urgency. Questions should be posed in regard to the character of pain, its location, what initiates or relieves the symptoms, the duration of the symptoms, and what medications the patient is taking to alleviate the symptoms. Not only will this help determine the pain intensity level, but analgesic ingestion can interfere with testing results.⁶⁻⁸

MEDICAL HISTORY

Patients need to share their medical problems with their clinicians so the data can be used in planning treatment.⁹ Today, with patients on so many medications, it is essential to communicate properly with patients. Health history is one of the most important

steps in diagnosis and treatment planning. What are the patient's medical conditions, concerns, and contraindications? Technology facilitates communicating with the patient's physician by telephone, fax, and/or the Internet. An almost instantaneous access to concerns by the physician is an improvement over past methods.

To begin the medical history, one needs to provide patients with a standard medical history form for them to fill out (such as the one in Table 1). This can be done in the reception room and with the help of office staff.

In the past, patients often felt uncomfortable revealing their medical history to staff, let alone the clinician. Fortunately, today patients are much more open to completing a detailed medical history form or discussing a "condition" with the clinician in the presence of staff. However, in those instances in which a patient does feel uncomfortable, it is the clinician's duty to thoroughly review with the patient the health treatment as certain aspects can result in adverse reactions with treatment.

In reviewing the medical history, particular emphasis must be placed on **illnesses, history of bleeding, and medications**. **Illness** often means hospitalization to patients; consequently, they may not list weight changes, accidents, or problems related to stress and tension. Patients of African American heritage should be questioned about sickle cell anemia; there is a report of pulp necrosis occurring in patients with this distressing condition.¹⁰ The term **bleeding** is usually interpreted by the patient to mean frank blood and seldom elicits answers related to bruising or healing time. Chronic use of aspirin¹¹ (not considered a drug by many people) or a history of liver disease should be of concern to the clinician. These should all be specifically mentioned in the medical history form. **Medication** means to many people only those items obtained by written prescription. Clinicians must also ask about "pills" and "drugs." Many people are self-medicating with diet pills, sleep inducers, and vitamins, as well as "recreational drugs," to mention only a few.

Investigating self-administered medication is also important to find out what "over-the-counter" medications the patient is actually taking. Women should be asked if they are pregnant or nursing, or if they have menstrual or menopausal problems.

Positive answers to these questions must be weighed and evaluated along with the other responses to determine the risk of treatment against the risk of nontreatment. When the history uncovers a serious problem, and a review of the systems involved (e.g., cardiac, respiratory) does not explain the problem, the patient's physician must be consulted. Then it is important to obtain the patient's physician's written permission to perform any dental treatment.

During these interviews, the clinician-patient relationship tends to crystallize. Patients feel more confident in the relationship. This is the time when high-strung patients may be calmed and reassured, although they may not be completely at ease until the first treatment is completed. Kindness and attention to their concerns or problems (chief complaint) during the history taking will greatly reduce most patients' emotional trauma and stress.

Clinical Examination

In general, the clinical examination should follow a logical sequence, from the general to the specific, from the more obvious to the less obvious, from the external to the internal. The results of the examination, along with information from the patient's history, will be combined with the clinical testing to establish the diagnosis, formulate a treatment plan, and determine the prognosis.

VITAL SIGNS

The first step in an examination is to obtain and record the patient's vital signs. These include blood pressure, pulse, respiratory rate, and temperature. Establishing a baseline or a "norm" for each patient is considered standard of care. Patients with test values well outside the range of acceptable norms are at risk, as is the clinician who treats them.⁹ Common sense suggests that this risk should be shared with the patient's physician. Communication with the physician and the information received should be recorded in the chart and dated.

The vital signs may be recorded by any trained member of the office team. However, abnormal values must be evaluated and signed by the doctor. Any additional observations of abnormalities such as breathlessness, color change, altered gait, or unusual body movements observed during the initial meeting must be recorded.

Blood Pressure (normal: 120/80 mm Hg for persons under age 60 years; 130/90mm Hg for persons over age 60 years)

The Joint National Committee on Prevention, Detection, Evaluation, of High Blood Pressure recently added a new category, prehypertension, for patients with blood pressure of 120 to 139/80 to 89 mm Hg (see Chapter 23). Routine use of the sphygmomanometer not only establishes a baseline blood pressure but also occasionally brings to light unsuspected cases of hypertension in patients who are not regularly seeing a physician or are not maintaining prescribed regimens of therapy. Some ethnic groups are predis-

posed to hypertension. Halpern reported that only 18% of the dental clinic patients attending Temple University Dental School "were seeing their physicians."⁹ At times, however, elevated blood pressure is caused only by the stress and anxiety of the moment and can be dealt with by reassurance or, if necessary, pretreatment sedation.

The emphasis of this procedure stresses the importance of the examination. Both the patient and the doctor are inclined to be more serious in their questions and answers when the examination begins with blood pressure records. It must be stressed that no patient, with or without a dental emergency, should be treated when the **diastolic** blood pressure is over 100 mm Hg.¹²

Blood Pressure, Pulse Rate and Respiration (normal: pulse 60 to 100 beats per minute; respiration 16 to 18 breaths per minute)

Blood Pressure When these examinations are added to the recording of blood pressure, the clinician increases the opportunity to know the patient better. These examinations also show the patient, by physical contact, how further examination will proceed—deliberately, gently, and completely. Pulse and respiration rates may also be elevated owing to stress and anxiety; in fact, these elevated signs may be even better indicators of stress than is blood pressure. Tests with markedly positive findings should be repeated later in the appointment or at a subsequent appointment.

Temperature (normal body temperature, 98.6°F [37°C])

The taking and recording of body temperature is a simple, significant procedure. An elevated temperature (fever) is one indication of a total body reaction to inflammatory disease. If the body temperature is not elevated, one can assume that the body is "managing" its defenses well, whatever the local signs (pain, swelling of an abscess formation). Systemic treatment with antibiotics, with its attendant risks, will likely not be required. A temperature above 98.6°F but less than 100°F indicates localized disease.¹³ Localized disease can usually be treated by removing the cause (e.g., cleaning and disinfecting the root canal) and/or incision and drainage.

Cancer Screen (soft tissue examination: lumps, bumps, white spots)

Every new patient must be routinely screened for cancer and other soft tissue non-odontogenic conditions as part of the examination and informed of the results.

Table 2 Oral Cancer Warning Signals*

Swelling, lump, or growth anywhere in or about the mouth
White, scaly patches inside the mouth
Any sore that does not heal
Numbness or pain anywhere in the mouth area
Repeated bleeding in the mouth without cause

*"Open Wide." Reproduced with permission from the American Cancer Society, New York.

This examination should include a survey of the face, lips, neck, and intraoral soft tissues. When such examinations are made routinely, without secrecy, they will usually dispel the unstated fears of the cancerphobe and add to the confidence and rapport of all patients with their clinicians. The sooner this examination is completed the better. It is sometimes argued that clinicians are liable if they inform patients that they are performing an examination and then miss finding disease when it is present. In fact, clinicians are more liable if they miss reporting the disease because they have not made an examination. Extraorally, a cancer survey includes palpation of the floor of the mouth for masses, and examination for asymmetry and color changes. Intraorally, this examination is repeated with the additional care of directed lighting and of moving the tongue in such a manner so that all areas can be clearly seen (Table 2).

EXTRAORAL EXAMINATION

Inflammatory changes originating intraorally and observable extraorally may indicate a serious, spreading problem.¹⁴ The patient must be examined for asymmetries, localized swelling, changes in color or bruises, abrasions, cuts or scars, and similar signs of disease, trauma, or previous treatment. Positive findings, combined with the chief complaint and information about past injuries or previous treatment to teeth or jaws, will begin to clarify the extent of the patient's problem. The extraoral examination includes the face, lips, and neck, which may need to be palpated if the patient reports soreness or if there are apparent areas of inflammation. Painful and/or enlarged lymph nodes are of particular importance. They denote the spread of inflammation and possible malignant disease. The extent and manner of jaw opening can provide information about possible myofascial pain, neuralgia, and dysfunction.¹⁵ The temporomandibular joint should be examined during function for sensitivity to palpation, joint noise, and irregular movement.¹⁶ (See Chapter 11 for more details on this topic.)

INTRAORAL EXAMINATION

The intraoral examination begins with a general evaluation of the oral structures. The lips and cheeks are retracted while the teeth are in occlusal contact, and the oral vestibules and buccal mucosa are examined for localized swelling, sinus tract, or color changes. With the patient's jaws apart, the clinician should evaluate in a similar manner the lingual and palatal soft tissues. Also, the presence of tori should be noted. Finally, as part of the general inspection, carious lesions, enamel fractures, discolorations, and other obvious abnormalities associated with the teeth, including loss of teeth and the presence of supernumerary or retained deciduous teeth, should be noted. Often the particular tooth causing the complaint is readily noted during this visual examination if it has not already been pointed out by the patient. Complaints associated with discolored or fractured teeth or with enamel crack lines could involve not only enamel but dentin as well. Teeth with extensive caries or large restorations, or teeth restored by full coverage, are, for the most part, readily located. Sinus tracts should be traced to the origin of lesions. True "puzzlement" begins when the complaint centers on teeth fully crowned and/or are part of extensive bridges or splints, or when only a few teeth are restored, and then only with minimal restorations.

Transillumination with a fiber-optic light, directed through the crowns of teeth, can add further information.¹⁷ By this method, a previously treated tooth, not noticeably discolored, may show a gross difference in translucency when the shadow produced on a mirror is compared with that of adjacent teeth. Transillumination may also locate teeth with vertical cracks or fractures (see Chapter 19, "Infractures and Vertical Root Fractures," for more information).

CORONAL EVALUATION

The most obvious tooth is examined first, particularly when the patient, the history, or the general examination calls attention to a certain tooth. Using a mouth mirror and an explorer, and possibly a fiber-optic light, the clinician carefully and thoroughly examines the suspected tooth or teeth for caries, defective restorations, discoloration, enamel loss, periodontal problems, or defects that allow direct passage of stimuli to the pulp. Sometimes sealing off such leakage with temporary cements or periodontal dressings can be diagnostic. Vertical and horizontal fractures, located by transillumination, should be further investigated by having the patient bite on a firm object such as the Tooth Slooth (Professional Results Inc., Laguna Nigel, CA) or a wet cotton roll.¹⁸ Occlusal

wear facets and parafunctional patterns are also sought out, as is tooth mobility. Since the use of the operating microscope, diagnosis of crack lines has improved since many of these lines are not visible to the naked eye.

Pulpal Diagnosis

For convenience, diagnosis has been divided into two areas, pulpal and apical. The diagnostic terminology for both the pulp and the periapex is consistent with the terms recommended by the American Board of Endodontics. Pulpal diagnosis is addressed first (Table 3).

PULPALGIA

In the first edition of *Endodontics*, Ingle introduced the term *pulpalgia*.¹⁹ Pulpalgia (pulpal pain) had numerous classifications that described its degree of severity and pathologic process. Today this term is not often used, and the terms *reversible* and *irreversible pulpitis* are the generally accepted clinical diagnostic terms. Clinicians, however, must deal with patients suffering from pulpalgia and have an understanding of the role of pulpal pain. Pulpal pain (toothache) is the symptom that brings patients into the clinician's office. It comes in many forms, rising from mild discomfort to raging pain, and then disappears, but the pulp is left in a worsening condition. Histologically, the pulp ranges from normal, to severely inflamed, to becoming totally necrotic. Prior

Table 3 Endodontic Diagnostic Terminology*

PULPAL

Normal pulp: a clinical diagnostic category in which the pulp is symptom free and normally responsive to vitality testing

Reversible pulpitis: a clinical diagnosis based on subjective and objective findings indicating that the inflammation should resolve and the pulp return to normal

Irreversible pulpitis: a clinical diagnosis based on subjective and objective findings indicating that the vital inflamed pulp is incapable of healing

Additional descriptions:

Symptomatic: lingering thermal pain, spontaneous pain, referred pain

Asymptomatic: no clinical symptoms but inflammation produced by caries, caries excavation, trauma, etc.

Hyperplastic pulpitis (pulp polyp): growth of an exposed pulp into occlusal surfaces

Internal resorption: the pulp has dentinoclastic activity

Pulp necrosis: a clinical diagnostic category indicating death of the dental pulp

Previously treated: a clinical diagnostic category indicating that the tooth has been endodontically treated and the canals are obturated with various filling materials, other than intracanal medicaments

Previously initiated therapy: a clinical diagnostic category indicating that the tooth has been previously treated by partial endodontic therapy (e.g., pulpotomy, pulpectomy)

Additional pulpal terms:

Calcific metamorphosis: a pulpal response to trauma characterized by rapid deposition of hard tissue within the canal space

Dystrophic calcification: diffuse foci of calcification frequently found in the aging pulp; usually described as being perivascular or perineural

APICAL (PERIAPICAL)

Normal apical (periapical) tissues: Teeth with normal periradicular tissues that will not be abnormally sensitive to percussion or palpation testing. The lamina dura surrounding the root is intact and the periodontal ligament space is uniform.

Symptomatic apical periodontitis (acute apical periodontitis): inflammation, usually of the apical periodontium, producing clinical symptoms including a painful response to biting and percussion. It may or may not be associated with an apical radiolucent area.

Additional descriptions:

Lateral or **furcal** for additional spatial clarification

Asymptomatic apical periodontitis (chronic apical periodontitis): inflammation and destruction of apical periodontium that is of pulpal origin, appears as an apical radiolucent area, and does not produce clinical symptoms

Additional descriptions:

Lateral or **furcal** for additional spatial clarification

Table 3 Continued from Page 526

Acute apical (periapical) abscess: an inflammatory reaction to pulpal infection and necrosis characterized by rapid onset, spontaneous pain, tenderness of the tooth to pressure, pus formation, and eventual swelling of associated tissues

Additional descriptions:

Lateral or **furcal** for additional spatial clarification

Chronic apical (periapical) abscess (suppurative periapical abscess): an inflammatory reaction to pulpal infection and necrosis characterized by gradual onset, little or no discomfort, and the intermittent discharge of pus through an associated sinus tract

Additional descriptions:

Lateral or **furcal** for additional spatial clarification

Additional periradicular terms:

Apical scar: dense collagenous connective tissue in the bone at or near the apex of a tooth with a distinctive radiolucent presentation; a form of repair usually associated with a root that has been treated surgically and usually associated with a perforation of both the facial and lingual osseous cortices

Cellulitis: a symptomatic edematous inflammatory process associated with invasive microorganisms that spread diffusely through connective tissue and fascial planes.

Condensing osteitis (focal sclerosing osteomyelitis, periradicular osteosclerosis, sclerosing osteitis, sclerotic bone): a diffuse radiopaque lesion believed to represent a localized bony reaction to a low-grade inflammatory stimulus, usually seen at the apex of a tooth (or its extraction site) in which there has been a long-standing pulp pathosis

*The diagnostic terminology for both the pulp and the periapex is consistent with the terms recommended by the American Board of Endodontics, 2007.

to opening into the pulp, one must make a diagnosis based on the signs and symptoms with which the patient presents. In some cases, no treatment will be needed, only advice and reassurance.

Pulpal pain can be classified as hyperreactive, acute, or chronic. *Acute* and *chronic* refer to the timing of the pain, not to its intensity. Hyperreactive pulpalgia, also known as dentinal sensitivity, is non-inflammatory, yet a remarkable number of patients present with this condition, brought on by heat or cold, sweet or sour foods, or touch to the tooth. They consider it toothache, not realizing that the pain from eating ice cream is not pathologic. Today it can be quite easily controlled with desensitization or sealant application by the clinician or with special toothpastes.

Acute pulpalgia ranges from incipient, to moderate, to advanced and reflects the degree of inflammation the pulp is suffering. Incipient pulpalgia is rarely irreversible. Some moderate pulpalgias are reversible and some are irreversible. This is where many diagnostic mistakes are made.

Incipient pulpalgia is the mild discomfort experienced following cavity or crown preparation or, in some patients, incipient caries. It could be gone in a day or two. Histologically, one would find a marginal increase in leukocytes and some edema causing pressure. When the edema subsides, the discomfort disappears. But it still causes patients to return for assurance, and, of course, incipient caries should be removed if that is the cause.

Moderate acute pulpalgia is a true but tolerable toothache; however, now there is true inflammation of the pulp. The pulp may not yet be infected by bacteria but is reacting to their acidic output. The symptoms may be “nagging” but mild and of short duration. Pulpalgia may be spontaneous but more likely is precipitated by an irritant such as hot or cold fluid. Mild analgesics may control the pain, and the pulp condition is still reversible.

If bacteria have invaded and infected the pulp, the patient may initially have symptoms that he or she can “live with” and does live with, even though the pain is more intense and longer lasting once it begins. Temperature tests result in lingering pain, pointing to irreversible pulpitis. “Watchful waiting” may lead to the next level of pulpalgia, excruciating pain. That pain comes from advanced acute pulpalgia, the **ultimate toothache**. It is deemed irreversible. The patient may be in exquisite agony, at the point of hysteria. Relief can often be achieved temporarily with cold water or an ice cube. The patient may report to the office with a jar of ice water. Histologically, the coronal pulp is necrotic and gas has formed, causing the pressure that can be relieved by the cold. Testing with heat gives an immediate explosive response, so one must be prepared to immediately bathe the tooth with ice water. Immediate pulp extirpation is required.

Chronic pulpalgia is associated with irreversible pulpitis. The pain is not severe, and some patients have lived with it for months or even years,

suppressing the pain with analgesics. They may not even have had any overt symptoms. Eventually, the tooth starts to ache at night. Radiographically, there may be resorption of the roots and condensing osteitis of the surrounding bone. Pulp testing results may be inconclusive. There is usually no pulpalgia with a totally necrotic pulp because the pulp tissue, including its sensory nerves, is destroyed.

Today these terms are not often used, and the terms *reversible* and *irreversible pulpitis* are the generally accepted clinical diagnostic terms. Clinicians, however, must deal with patients suffering from pulpalgia, and an understanding of the role pulpal pain—pulpalgia—plays can assist in developing a correct diagnosis necessary for proper treatment.

NORMAL PULP

This is a clinical diagnostic category in which the pulp is symptom free and normally responsive to vitality testing. Temperature sensitivity will disappear once the stimulus, such as ice cream, has been removed. The normal pulp may exhibit a strong response but is not painful. (see Table 3)

REVERSIBLE PULPITIS

Reversible pulpitis is a clinical diagnosis based on subjective and objective findings, indicating that the inflammation should resolve and the pulp return to normal. Signs of reversible pulpitis often include a normal periapical diagnosis but an increased response to cold that is nonlingering in nature (disappearing within seconds). The term *lingering* is often a confusing term to some, but it is used on an individual basis. If the patient response is equal in duration on all teeth, it would be nonlingering. If one tooth (or more) stands out above the rest of the teeth in terms of a variation or duration of symptoms, that is classified as lingering. Reversible pulpitis is commonly related to recent restorations, root scaling, traumatic brushing techniques, incipient caries, and small infractions in the tooth crown. Patients who complain of symptoms related to sweets also are typically exhibiting a reversible pulpitis. The patient who is undergoing vital bleaching may develop reversible pulpitis.²⁰ Pohjola et al. mentioned this sensitivity as the most frequently reported side effect.²¹ Whatever the reason for the reversible pulpitis, stopping the irritation typically allows the pulp to return to normal. However, if the stimulus is not stopped, resolved, or treated, and the pulp is sufficiently irritated, pulpitis will progress into an irreversible state.

IRREVERSIBLE PULPITIS

Irreversible pulpitis, like reversible pulpitis, is a clinical diagnosis based on subjective and objective findings. It is defined as the point where an inflamed pulp is no longer capable of healing and returning to normal. This type of pulpitis exhibits many forms and symptoms. Lingering painful thermal responses, particularly to cold, are the classic form of irreversible pulpitis. This pain is intensified by a stimulus but can be spontaneous. It is typically episodic in nature initially but may progress into a constant intense pain or toothache.

Because the pulp is considered a deep tissue, it can be very difficult to isolate and pinpoint the exact tooth. Referred pain is common. Pulp testing needs to be thorough and methodical. Irreversible pulpitis, although commonly associated with its symptomatic form, also presents in numerous other ways. Many times, an asymptomatic tooth may have an irreversible pulpitis. Lin and Langeland showed that when caries invaded the pulp space, bacteria were present, and a root canal filling is the appropriate treatment.²² The exception to this will be the young patient who still exhibits open apices or incomplete root development. For further discussion of this, see Chapter 34 on vital pulp therapy.

Another form of irreversible pulpitis is hyperplastic pulpitis.²³ Also referred to as a pulp polyp, this is a growth of pulp tissue from the pulp chamber that is usually covered with epithelium. This is typically seen again in a younger population and can be found in both primary and permanent dentition.

Aerodontalgia or barodontalgia has often been referred to as an irreversible pulpitis. This was first documented in World War II pilots when they were flying at elevations of 5,000 to 38,000 feet. In 1945, Urban and Ritchey published a research article in which they placed pilots into a decompression chamber and simulated different altitudes and flights.²⁴ They found that the healthy pulps were asymptomatic, but irreversible pulpitis that was “sealed” in the tooth elicited intense pain when barometric pressure decreased with altitude. This phenomenon also occurs when traveling in high mountainous countries.

PULP NECROSIS

This is a clinical diagnostic category, indicating partial or complete death of the dental pulp. This could be due to persisting inflammation of pulp tissue. The pulp is nonresponsive to vitality testing and is often pain free, although it can often be very painful to heat stimulation. Apical inflammatory response is

primarily caused by a bacterial invasion from the infected pulp but may also be due to trauma or continual chemical irritation.

PREVIOUSLY TREATED

A clinical diagnostic category indicating that the tooth has been endodontically treated and the canals are obturated. Obturation may occur with various filling materials, including hard and soft pastes and resins, gutta-percha, and many other materials. Intracanal medicaments, such as calcium hydroxide, are not considered completely treated. They would fall into the category of previously initiated treatment.

PREVIOUSLY INITIATED THERAPY

This is a relatively new term that is being introduced to clarify the clinical scenarios encountered. This clinical diagnostic category indicates that the tooth has been previously treated by partial endodontic therapy (e.g., pulpotomy, pulpectomy), but no definitive treatment has been done.

Apical Diagnosis

The second part in determining a comprehensive diagnosis is apical diagnosis. In the past, various other terminologies have been used and sometimes referred to as periapical or periradicular diagnosis. For a description of a tooth's signs and symptoms, the diagnostic terminology is divided into five main categories. As these topics have already been extensively described in Chapter 13, they are mentioned here briefly for the purpose of completeness in the diagnosis.

NORMAL PERIAPICAL TISSUES

Teeth with normal apical tissues are asymptomatic. They will not be abnormally sensitive to percussion, or palpation, or thermal or electric testing. Radiographically, the lamina dura surrounding the root is intact and the periodontal ligament space is uniform. There is no sign or symptom of a pathologic change evident from either a clinical or a radiographic examination.

SYMPTOMATIC APICAL PERIODONTITIS

When the term *symptomatic* is used, it is done so to describe a clinical scenario representing some form of altered sensation for the patient. Inflammation, usually in the apical periodontium, produces clinical symptoms ranging from mild discomfort to an exquisitely painful response to biting and/or percussion. It

may or may not be associated with an apical radiolucent area. These symptoms usually are of shorter onset but may exhibit mild discomfort. If a radiographic image reveals a radiolucency, the terms *lateral* or *furcal* may be used for additional spatial clarification of the lesion.

ASYMPTOMATIC APICAL PERIODONTITIS

Asymptomatic is a term used to describe a clinical scenario in which there is noted radiographically, inflammation and destruction of the apical periodontium with possible root and bone resorption but not necessarily producing clinical symptoms. Again, the terms *lateral* and *furcal* may be used to give additional clarification as to the position of the lesion.

ACUTE APICAL ABSCESS

The term *abscess* is used when signs of swelling or exudate are present or believed to be occurring. The term *acute* is used when an inflammatory reaction to pulpal infection and necrosis is characterized by rapid onset, spontaneous pain, and exquisite tenderness of the tooth to pressure. These patients are typically in moderate to severe discomfort owing to the sudden onset. Often few, if any, changes to the apical periodontium will be noted radiographically. The most commonly noted change is a widened periodontal ligament (PDL). As with all apical diagnoses, the terms *lateral* and *furcal* may be used to give additional clarification as to the position of the lesion or widened PDL.

CHRONIC APICAL ABSCESS

Chronic apical abscess is usually characterized by a gradual onset, with little or no discomfort to the patient. An intermittent discharge of pus through an associated sinus tract is commonly found. Radiographically, a large periapical lesion may be present. As with all endodontic abscess formations, it is an inflammatory reaction to pulpal infection and necrosis.

CELLULITIS

This is another form of abscess characterized by a symptomatic edematous inflammatory process. Invasive microorganisms spread diffusely through the connective tissue and fascial planes, to create various degrees of swelling and discomfort. It can be very rapid in its spread and requires close observation in its treatment.

APICAL SCAR

The apical scar is a dense collagenous connective tissue "scar" in the bone with a distinctive

presentation. It is a dark radiolucency found at or near the apex of a tooth that has been surgically treated. It is a form of repair but is commonly associated with lesions that have been involved with the destruction of both the facial and lingual osseous cortical plates.

CONDENSING OSTEITIS

Condensing osteitis is a diffuse radiopaque lesion noted usually at the apex of a tooth or extraction site. It is believed to be associated with a low-grade inflammatory stimulus. It is a localized bony reaction commonly found in cases of long-standing pulpal pathosis.

PROGNOSIS AND INFORMED CONSENT

Today patients are demanding to be more informed and to actively participate in the choices available to them when it comes to treatment. This area must be divided into two parts: prognosis and informed consent.

Prognosis, as described by *Stedman's Medical Dictionary*, "is a forecast of the probable course and/or outcome of a disease."²⁵ The ability to accurately prognosticate is a major factor and a key to obtaining positive outcomes. One clinician's view of success or a positive outcome may differ from another's depending on the factors used to define success. Chapter 31, "Outcomes of Endodontic Treatment," explores in detail many aspects of treatment outcomes. It is important to remember when discussing treatment options with a patient that one does not omit the prognosis. Some patients may choose to "gamble" more than others when it comes to saving their teeth, but it is ultimately their choice after having received a detailed informed consent.

Informed consent consists of the risks, benefits, alternatives, and consequences associated with these choices. (See Chapter 3, "Ethics and the Law," for more details.) These areas need to be explored completely. Patients do not understand dental terminology for the most part, and it is important to relate these items in lay terms so as to reduce confusion for the patient. It is not necessary to explain every miniscule detail of the procedure or risk, but it is important to relay a general overview and the most likely complications that might ensue. Patients should feel comfortable and participatory in their treatment.³ It is also of the utmost importance to have a written informed consent that patients sign at the end of this explanation, acknowledging that they were informed of the risks, benefits, and alternatives to treatment and that they had the option to have any questions they

had, answered prior to treatment. From a medico-legal perspective, this will not stop litigation, but it will show due diligence to the attorneys that the patient was involved in the treatment choices. In today's litigious society, one cannot be too careful in protecting oneself.

B. DIAGNOSTIC TESTING

JAMES C. KULILD

An accurate diagnosis is the cornerstone of any subsequent endodontic therapy. To achieve the critical goal of this accurate diagnosis, a clinician must follow a systematic diagnostic evaluation process. This process must assess all possible orofacial areas that could have an influence on decision making and subsequent possible endodontic treatment, or referral, if the chief complaint is not of endodontic origin.

The overall goal of diagnostic testing is two-fold. The first is to gain objective data from the patient's signs and symptoms as well as from the results of diagnostic testing. The second is to reproduce the patient's chief complaint, if the patient has had past painful episodes. If the chief complaint cannot be reproduced during the evaluation, the practitioner should be weary of providing any treatment that might be well-intentioned but might result in a poor outcome, as that treatment may not be related to the chief complaint and may not, in fact, have been necessary.

At the present time, the capabilities of diagnostic testing are well short of the objective science needed to definitively determine the health or disease status of the pulp. This is because pulp tissue is contained in the noncompliant environment of the root canal system that does not allow direct visual inspection, histological, or other direct evaluation techniques. Van Hassel¹ stated that the unique encasement of the pulp in a low-compliance environment directly affects its ability to respond to injury and/or disease. However, within these limitations, the clinician must still attempt to determine the health or disease status of the pulp so that appropriate treatment decisions can be made.

The clinician must clearly understand that any, and all, diagnostic tests are merely adjuncts in the decision-making process that leads to both pulpal and periapical diagnoses. Treatment decisions should not be made on the basis of one piece of diagnostic data. There must be corroborating data from at least one other test before treatment is recommended. In 1937, Stephen² reported a poor correlation between diagnostic data, clinical signs and symptoms and actual histological findings. Mitchell and Tarplee³ attempted a similar in vivo experiment in 1960 and also could

not identify consistent findings in teeth with painful pulpitis. Seltzer et al.^{4,5} reported a poor correlation between diagnostic data and actual histological findings in their exhaustive studies. They stated that a history of previous pain was an important diagnostic sign of pulp inflammation. They also found that the presence of large deposits of tertiary dentin did not result in delayed responses to pulp testing, but surprisingly generated responses more quickly. They also stated that inflammation was not necessarily irreversible and that the pulp may have the capability to repair itself. Conversely, the pulp may become necrotic without ever manifesting pain. Johnson et al.⁶ stated that false-positive pulp testing results were obtained in half of the teeth that were histologically necrotic. Conversely, negative pulp testing results had a much greater chance of indicating histological pulp necrosis. In 1973, Garfunkel et al.⁷ reported the correlation between a clinical diagnosis and the histological status of the pulp that was about 50%. Bhaskar and Rappaport⁸ reported on 25 anterior teeth, that had been previously traumatized and reacted negatively to conventional pulp testing, all contained vital pulps when examined histologically. Hyman and Cohen⁹ concluded that it was possible to erroneously reason that a tooth contained a pulp with irreversible pulpitis when, in fact, it contained either a normal or irreversibly involved pulp. They also stated that a diagnosis of irreversible pulpitis should be substantiated by multiple tests to prevent unnecessary endodontic treatment. In 1945, Herbert¹⁰ attempted to correlate clinical signs and symptoms with the histological condition of the pulp in an in vivo experiment and determined that the results were not always consistent.

However, if a clinician has performed the correct diagnostic procedures and performed them correctly with clear results, he should put his faith in them in spite of apparent conflicting data or signs. For example, a tooth that has been treated previously with nonsurgical root canal treatment (NS RCT) can still illicit a positive response to pulp vitality tests.^{11,12} Adjacent teeth that seem to manifest two separate and distinct

 †L = lingual, measurements go from mesial to distal.

periapical radiolucencies may, in fact, reflect pathology of only one of those teeth if pulp vitality tests indicate a normal pulp in one of the teeth.^{11,12}

Practically speaking, a diagnostic table for recording diagnostic testing results can be easily created for each clinically tested tooth. It can include responses for a variety of tests (Table 1). The information should be recorded and placed in the patient's dental record. The information can also be recorded in an electronic record with the help of a dental assistant as the tests are being performed. Both pulpal and periapical diagnoses should be recorded based on the documented clinical findings (see Table 1 in section 14A in this chapter).

Caring, competent, and capable clinicians must be confident enough to tell the patient that the diagnosis is based on the best available evidence. There are many physiological and psychological processes occurring that could cloud any diagnostic testing results that might be performed.^{13–25} Patients must understand that diagnostic testing is not pure science and that ultimate treatment recommendations may be based on not only the tests themselves but on the clinical judgment of the clinician formed by a variety of factors: education and training, updating current information by reading appropriate literature, attending related continuing education courses, and always giving each and every patient full attention and expertise. A variety of various pulp testing methodologies and techniques have been used in the past with and without consistent success.^{14,23,25}

Visual Oral Examination and Review of Systems

A clinician should perform a thorough general visual examination that evaluates the entire orofacial region.

This soft and hard tissue exam avoids “tunnel vision” that can occur by examining only the single tooth or the specific area in question. A cancer screening exam should always be conducted particularly in the danger areas on the ventral and/or lateral surfaces of the tongue and the floor of the mouth. A visual exam is also helpful in determining any facial asymmetries that may or may not be helpful in subsequent determination of the patient's chief complaint.

Croll et al.²⁶ published a guide for a rapid neurological assessment and initial management for the patient with traumatic dental injuries that could require immediate referral, as well as prevent significant second- and third-order effects from neurological damage. It is important to point out that pain appearing to be of endodontic origin may in fact be referred from another source, particularly when evaluating teeth in the mandibular left quadrant. A patient may be experiencing either a coronary insufficiency or a myocardial infarct.^{27,28} If the pain does not resolve, vital signs should be repeated and the patient should be questioned on any other possible symptoms, for example, chest pain, pain radiating down the left arm, nausea, or sweating. When in doubt, it is always prudent to activate the emergency response system, prepare to administer cardiopulmonary resuscitation if needed, and have a staff member ready the office automated external defibrillator for any possible eventuality. Never assume “everything is OK” until the facts provide substance for that assumption.

Thermal Tests

Thermal tests are commonly employed diagnostic pulpal tests. If properly done, they have proven to be reasonably effective and generally cause no

irreversible negative effects on either soft or hard tissues. Any thermal test, at best, merely identifies the presence of pulp nerve tissue that is capable of responding to a change in temperature. Reiss and Furedi²⁹ stated, back in 1933, that dentists should not be interested in just the condition of the nerves in the pulp but in the condition of the pulp itself.

Mullaney et al.³⁰ reported that only 2 of 48 pulps that had not responded to either the electric pulp tester (EPT) or cold thermal tests exhibited a normal histological appearance. However, every patient in the study had a painful response when the pulpal tissue in the canal was broached, indicating remaining neural innervation. The authors attributed the response to the movement of the necrotic tissue putting pressure on the periapical tissues.

England et al.³¹ histologically examined 30 human pulps, in which clinical diagnostic testing indicated the pulps had either irreversible pulpitis or were necrotic. The nerve fibers of both types of pulps were compared with those of normal pulps. Functioning nerve tissue was reported in the pulps with irreversible pulpitis. In the necrotic pulps, only the connective tissue sheaths remained. They were incapable of transmitting any neural impulses. The nerve fibers in pulps with irreversible pulpitis resisted degeneration longer than the surrounding tissue.³¹ A thermal test may provide information that suggests whether the pulp is reversibly or irreversibly inflamed or necrotic.

Ice has been used for cold thermal tests as it is readily available and inexpensive. However, ice is not as cold as some other available materials and has many shortcomings that limit its effectiveness. The primary shortcoming is that melted ice water can spread to either soft tissue or another tooth and cause a false-positive result. A false positive is defined as the patient responding to a pulp test, when in fact the pulp tissue in the tooth being examined is necrotic, or another tooth is responding, not the tooth being examined. A false negative is defined as the patient not responding to a pulp test when in fact the pulp tissue in the tooth being examined is vital. Cold tests are most likely to give a positive response in the cervical area compared to the occlusal surface.³² Cold response seems to be

related to the thickness and type of tooth structure between the source of the cold and the pulp. It is important to emphasize that just because the pulp tissue in the tooth being tested responds “positive,” it does not necessarily indicate that the pulp is either healthy or diseased. The pulp could be either normal or suffering from reversible or irreversible pulpitis. A normal pulp is a clinical diagnostic category in that the pulp is symptom free and normally responsive to vitality testing.³³ Reversible pulpitis is a clinical diagnosis based on subjective and objective findings indicating that the inflammation should resolve and the pulp return to normal.³³ Irreversible pulpitis is a clinical diagnosis based on subjective and objective findings indicating that the vital inflamed pulp is incapable of healing.³³ Seltzer et al.³⁴ tried to simplify the previously complicated pulpal diagnostic terminology by coining earlier similar terms, treatable or non-treatable. The fact that a tooth responds quickly and dramatically does not, in and of itself, indicate that endodontic treatment is indicated. If the sensation remits relatively “quickly,” the pulp can reasonably be presumed to be either normal or suffering from reversible pulpitis. However, if the sensation “lingers,” it may indicate that the pulp is irreversibly involved and NS RCT is indicated. The time periods represented by the words “quickly” and “lingers” are relative and can vary from patient to patient. Generally, “quickly” implies that the sensation returns to normal within a few seconds. The term “lingers” implies that the sensation lasts much longer extending perhaps 30 seconds or more. Materials with temperatures colder than ice include skin refrigerant, Endo Ice, carbon dioxide snow (CO₂) and Spray and Stretch (Gebauer Co., Cleveland, OH).

White and Cooley³⁵ compared in vitro the temperature changes in a human tooth when skin refrigerant (ethyl chloride), an ice water bath, and an ice stick were applied to the crown of an extracted canine tooth. They reported that skin refrigerant produced a greater thermal change (58.4°F) than ice water (69.2°F) or an ice stick (75.4°F).

Tetrafluoroethane (Endo-Ice, Hygenic Corp., Akron, OH) is approximately -50°F.³⁶ It is available in a convenient spray that can be used to apply the liquid material to a medium- or large-sized cotton pellet held

Figure 1 Endo-Ice (Hygenic Corp., Akron, OH) is tetrafluoroethane, can be applied to teeth with cotton forceps and large cotton pellets.

in a pair of cotton forceps (Figure 1). During the testing procedure, the patient is shown the cold test materials to help alleviate any anxiety they may have about the procedure. The patient is told to raise their hand when they feel any cold, burning, or tingling sensation and at that time the pellet will be immediately removed from the tooth being tested. They are told to warm the tooth with their tongue and cheek and keep their hand up until the sensation returns to normal. After testing control teeth, the clinician can then move the testing process to the tooth (teeth) in question and determine their response.

Jones³⁷ reported that a large cotton pellet produced the largest temperature change in the pulp chamber compared to a small cotton pellet, a cotton-tipped applicator, and/or cotton roll. Jones et al.³⁸ reported that Endo-Ice and CO₂ produced similar results in determining pulpal response, but the Endo-Ice elicited faster response. Miller et al.³⁹ conducted an in vitro experiment to determine whether ice, 1,1,1,2-tetrafluoroethane (the new formulation for Endo-Ice), or CO₂ produced the greatest temperature change in teeth restored with full coverage. They

reported that Endo Ice produced the greatest temperature reduction in intact teeth and those restored with gold, porcelain fused to metal, and porcelain crowns, when tested for less than 15 seconds.

Fuss et al.³⁶ evaluated the in vivo effectiveness of the EPT, CO₂, dichlorodifluoromethane, (Spray and Stretch), ethyl chloride, and ice in producing a response in patients during pulp testing. They reported that the EPT, CO₂, and dichlorodifluoromethane were more dependable in producing a response than ethyl chloride or ice. However, in young patients, they reported that CO₂ and dichlorodifluoromethane were the most dependable. They also reported in the same study that CO₂ and dichlorodifluoromethane were more effective in lowering the internal temperature of the tooth than ethyl chloride or ice.

Carbon dioxide snow, more commonly known as dry ice, became popular because it was predictable as a cold thermal material in diagnostic testing. Ehrmann⁴⁰ popularized the use of the CO₂ pencil (−78°C) that had been previously introduced by Obwegeser and Steinhauser in 1963. A small amount of the CO₂ is expressed through the end of the syringe that is then placed on the crowns of the teeth being evaluated. Figure 2A shows the solid CO₂ being extruded from the syringe in the form of a pencil, that can then be applied to the tooth (Figure 2B). In order to avoid the danger involved if a tank of this type falls to the floor breaking the regulator in the top of the tank and turning it into a potential lethal missile, the tank should be secured with a chain or in a box (Figure 3) Despite the very cold temperature, numerous investigations have demonstrated the safety of CO₂ on both the enamel and the pulp. Augsburger and Peters⁴¹ reported that a 5-second application of CO₂ resulted in a statistically significantly greater temperature decrease on the crowns of extracted teeth compared to ice or skin refrigerant. Peters et al.⁴² reported that CO₂ produced no cracks or fissures in the enamel of human teeth in vitro after being subjected to it for 15, 45, and 60 seconds on the same spot on the enamel, a time that is significantly longer than that used clinically. A follow-up in vivo scanning electron microscope and histological investigation using canine teeth as the experimental model resulted in no damage to either the enamel or the pulp.⁴³ Using the scanning electron microscopy, Peters et al.⁴⁴ evaluated the effects of 2 minutes of exposure of CO₂ on human teeth scheduled for extraction and reported that there was no subsequent damage to the enamel surface. An in vivo investigation showed

Figure 2 **A**, Solid CO₂ being extruded from the syringe in the form of a pencil. **B**, The pencil is held with a gauze pad and applied to the tooth.

Figure 3 The CO₂ tank is stored securely in a box.

that a 5-minute application of CO₂ to the surface of a tooth had no effect on intact human pulps.⁴⁵

Warm thermal testing is not employed as frequently as cold testing as most patients are more sensitive to cold stimuli and the fact that warm thermal tests have been traditionally more difficult to perform. Some traditional ways to apply warm thermal testing include the following: a heated ball burnisher, a rotating Burlew rubber wheel, heated base plate gutta-percha (GP), or warm water. White and Cooley³⁵ evaluated the temperature changes in a human tooth when hot water from the tap, hot GP stopping material, a hot burnisher, or a Burlew wheel were applied to the crown of an extracted canine tooth. The hot GP stopping material, hot burnisher, and Burlew wheel produced temperature rises within 2°F of each other after an 8-second application. However, flooding the tooth with water at 136°F produced a temperature rise approximately 7°F higher. The authors preferred the Burlew wheel because of its convenience and because of the inherent difficulties involved in isolating each individual tooth with a rubber dam before the warm water is applied.³⁵ The warm thermal test can be accomplished by isolating an individual tooth, filling a syringe with very warm water from the tap, applying the water to the tooth, and then quickly suctioning the water from the site if the patient demonstrates a severe response. The practitioner must be prudent when using a heated ball burnisher or a Burlew wheel as there is no way to gauge the temperatures being

Figure 4 System B Hot Pulp Test Tip (Sybron Endo, Orange, CA).

produced on the surface of a tooth or within the pulp chamber, and possible irreversible damage to either the enamel or the pulp can occur.

Selden⁴⁶ reported a warm thermal technique whereby the patient rinses their mouth with extremely warm water, and then ice is applied to the most likely tooth to determine if the pain is diminished by the application of ice. Using heated GP is an adequate testing procedure if a suitable lubricant is placed on the buccal surface of the tooth to prevent the GP from sticking to it. One investigation showed that after 10 seconds of exposure to heated GP on the enamel of a tooth that there was no evidence of injury.⁴⁵

The System B (Sybron Endo, Orange, CA) allows the dentist to set specific temperatures for warm thermal testing. After the surface of the tooth has been lubricated, a hot pulp test tip can be attached to the handle of the System B and the temperature set at 150°F. The tip is placed on the surface(s) of the tooth, and the patient's response is evaluated (Figure 4). This temperature is used as it represents the temperature of very warm tap water. This can be done without fear of damage to either the hard or soft tissues of the tooth.

Electric Pulp Testing

The EPT gauges the ability of nerves in the pulp to respond to electrical stimulation. The patient generally does not feel a true “electrical” stimulation but feels a warm, “tingly,” burning, or pain sensation. This is because the nerves in the pulp responding to EPT are A-delta nociceptors and do not transmit electric, thermal, touch, or proprioceptive sensations

to the central nervous system, but only pain. The EPT also causes the patient some anxiety knowing the instrument passes an electrical current through their teeth. False-positive responses can also occur just as in thermal tests in adjacent teeth.⁴⁷ The EPT gives the clinician no information on the status of inflammation in the pulp or the health or disease of the vasculature system. Reynolds⁴⁸ accurately stated this fact when he reported after getting accurate EPT readings that those results still could not distinguish between various states of vitality. The clinician should evaluate contralateral teeth as control teeth. Chilton and Fertig⁴⁹ reported that there was no significant difference in the pulp test results of contralateral vital teeth.

Jacobson⁵⁰ reported that the optimal placement of the probe tip in vitro was the occlusal two-thirds on the labial or buccal surfaces of teeth. Other investigators have reported that the incisal edge was the optimal placement site to achieve the lowest possible threshold for an EPT response.^{32,51} The threshold increased as the probe tip was moved toward the gingival margin.

Van Hassel and Harrington⁵² reported that precautions needed to be taken during pulp testing procedures to prevent electrical current from spreading to adjacent teeth, especially those with contacting metal fillings, and that multirooted teeth had the greatest chance of giving false readings.

Historically, EPT relied on direct or indirect current applied directly to the tooth. In 1909, Tousey⁵³ described the faradic current that was suitable for pulp testing through enamel and dentin. Early EPT instruments were not well calibrated, and the design sometimes allowed a tooth to receive full power on the first application causing the patient needless discomfort. In 1953, Taylor⁵⁴ reported on the capabilities of the Burton Vitalometer that used frequencies between 2 and 3,000 cycles. The instrument had a manual sliding device that would increase the current on a scale from 1 to 14.

Mumford⁵⁵ reported that the shape of the area produced by the current emitted during use of the EPT was triangular in shape, with the base of the triangle at the interface between the pulp tester tip and the enamel. The apex was oriented toward the pulp. He further stated that teeth with incompletely formed root apices require a stronger current to illicit a response, because the pulp has a greater cross-sectional area and requires greater current density.

Fulling and Andreasen⁵⁶ reported a higher EPT threshold value for teeth with immature root apices. They also reported that the CO₂ pencil provided

Figure 5 The Analytic Technology pulp tester (Sybron Endo, Orange, CA) was the first digital pulp tester marketed in the 1980s.

similar pulp test reactions regardless of status of root formation.

Newer instruments introduced since the 1980s use either battery or AC power that is applied logarithmically and automatically to the tooth being tested (Figure 5). This design precludes the chance of a patient receiving a full charge on the first application. The clinician can adjust the speed of delivery of the small amount of electric current based on personal preference. Cooley et al.⁵⁷ reported that the Analytic Technology pulp tester (Sybron Endo) included some technological advances that improved both performance, comfort to the patient, and ease of operation for the dentist. These enhancements included the following: the ability to turn on automatically when the probe made contact with the tooth, the ability to turn off automatically when the probe tip was removed from the tooth surface, a numerical digital display, a red light on the probe handle indicating to the clinician that a good contact with the tooth was made, and voltage was electronically stabilized. Kitamura et al.⁵⁸ reported similar positive results when evaluating the Analytic Technology pulp tester both *in vitro* and *in vivo*. Wahab and Kennedy⁵⁹ reported in an investigation that more accurate results were obtained with the EPT if there was a slower rate of current increase.

Martin et al.⁶⁰ investigated various conductive media to transmit current used during use of the EPT. They reported that petroleum jelly or a water-based jelly was the most conductive of the materials evaluated including toothpaste, saline pads, prophylaxis paste, and direct contact with no media. The type of media was not significant except for direct contact with no media. Michaelson et al.⁶¹ reported no difference between toothpastes, water, or Electrocardiogram (EKG) paste. Dry contact did not evoke a response. Before the

Figure 6 Patient placing finger lightly on the metal part of the probe handle.

routine use of gloves in the dental clinic, the circuit between the EPT instrument was closed by contact of the clinicians' ungloved hands or a lip clip in contact with the patients lips, cheek, or gingival. Anderson and Pantera⁶² reported on a modified EPT technique that not only allows the use of gloves and predictably accurate measurements, but also puts the patient "in charge" of the procedure alleviating much of the anxiety many patients feel when told a small amount of electric current will be used on their tooth. The technique consists of placing the probe tip of the EPT on the tooth, asking the patient to place their finger lightly on the metal part of the probe handle and informing them to remove their finger from the probe handle when they feel a warm, tingling sensation (Figure 6). Cailleteau and Ludington⁶³ reported a similar technique, but also stated that the lip clip may still be necessary if a patient has limited or restricted ability to control their hand movements, for example, physically debilitated or handicapped patients.

A clinician may need to use EPT on a tooth with full coverage. This may preclude using a pulp tester probe tip because its relatively large size would contact either the gingival tissue or the metal of the restoration. Pantera et al.⁶⁴ reported that small metal endodontic instruments such as files, explorers, or the like could be used in a bridging procedure. The tip of a small bridging instrument is coated with a contact medium and placed on the enamel or dentin of the tooth being evaluated. The probe tip is then placed on the metal of the bridging instrument.

Some have questioned the use of dental electrical diagnostic or treatment equipment applying current to a patient with an embedded cardiac pacemaker that could potentially interfere with its function.⁶⁵ This

includes the EPT, electric desensitizing equipment, ultrasonics, electrosurgical instruments, and related equipment. Using an animal model, the authors reported that the magnitude of currents used in those type of instruments could modify pacemaker function and cautioned against their use in patients with artificial pacemakers. However, Simon et al.⁶⁶ in an exhaustive in vitro and in vivo investigation reported that three dogs with implanted artificial pacemakers were unaffected by short or sustained stimulation with pulp vitality testers. Wilson et al.⁶⁷ recently demonstrated no effect on implanted cardiac pacemakers or cardioverters/defibrillators with either the EPT or electronic apex locators. Investigators do recommend contacting the patient's physician or cardiologist for specific guidance regarding the use of electrical devices.

Percussion

Percussion is one of the oldest pulp vitality tests used because it requires no armamentarium. Generally, patients who have a tooth sensitive to mastication have already percussed the tooth in question with their own finger tip(s) and informed the dentist which teeth are sensitive. Percussion is an indirect means of testing pulp vitality because teeth that are sensitive to percussion often have existing periapical lesions associated with a necrotic pulp. However, this is not always the case, and false positives can result if the clinician is evaluating a cracked tooth or a "high" restoration. If a crack has developed in the crown of a tooth with a vital pulp, the tooth can still be exquisitely sensitive, because of the crown segments, moving microscopically causes pain due to the movement of fluid in the odontoblastic tubules. The tooth is sensitive to thermal stimuli as the pulp is vital. These mutually exclusive diagnostic findings, pain to percussion/mastication and thermal sensitivity, are pathognomonic for a cracked tooth.

Sometimes, the solution to percussion sensitivity might be as simple as performing an occlusal adjustment. Periapical lesions cause discomfort to the patient because when the tooth is compressed in the socket during percussion, pressure is added to the bone and periodontal ligament (PDL) causing discomfort. Clinicians should move cautiously when percussing a tooth known to be sensitive to mastication. Although the standard instrument used to percuss teeth by many clinicians has been the end of the mirror handle, there is another way to employ this test that causes minimal discomfort but still achieves

Figure 7 Clinician grasping a tooth between his thumb and forefinger at the level of the middle third of the crown.

the desired results. To begin with, control teeth and then the tooth to be tested are compressed into the socket with increasing force until the clinician is assured the tooth is not sensitive to percussion (Figure 7). If the clinician is not confident with the pressure findings, one can gently tap with the end of the mirror handle to determine percussion sensitivity. One of the advantages of using digital pressure to assess percussion sensitivity is that the mobility of the tooth can be assessed simultaneously as discussed in "Mobility." A calibrated percussion instrument has been suggested that can more objectively identify the percussion test.⁶⁸

Mobility

The advantage of performing both mobility and percussion testing simultaneously makes the testing process more tolerable for the patient while decreasing the number of separate diagnostic tests. The following Miller Index⁶⁹ is an objective system to use, and the results can be easily communicated:

- Class I: First distinguishable sign of movement greater than normal.
- Class II: Movement of the tooth as much as 1 mm in any direction.
- Class III: Movement of the tooth more than 1 mm in any direction and/or depression or rotation of the tooth.

Palpation

Manual digital palpation of the soft and hard tissues around or adjacent to the tooth in question can be

extremely helpful in identifying areas that are either sensitive to touch or altered due to developmental reasons, disease, or trauma. The clinician should always bilaterally palpate both the area in question and the contralateral side. Bilateral palpation is important for several reasons. The first is that subtle changes in anatomy often cannot be detected unless both ipsilateral and contralateral areas are evaluated simultaneously. The second is that a swelling on the ipsilateral side may appear to be significant until the contralateral side is palpated at the same time. A bilateral swelling could be *toris mandibularis*. The third is that the clinician can much better assess the consistency of either a neoplastic or inflammatory swelling by palpating bilaterally, for example, fluctuant or indurated. Absence of discomfort during palpation does not mean that disease is not present or that the tissues are healthy. For example, the swelling might be a painless ameloblastoma. Conversely, the presence of discomfort does not mean that disease is present, for example, palpating over the mental foramen.

Transillumination

Diagnostic use of transillumination was reported in 1927 when Cameron⁷⁰ reported its use for diagnostic procedures. Friedman and Marcus⁷¹ reported that it

was a useful test for detection of caries, calculus, and soft tissue lesions. It is a vital and extremely effective tool in the evaluation process and one that is frequently overlooked. It is primarily used to help determine the presence of a crown or root fracture. It can also be used to aid in the determination of pulp vitality. When a bright light is projected through the tooth being tested, the transmitted light can be interrupted by cracks present as well as changes in the color of the pulp. There are many devices available for transillumination. These include specifically designed fiberoptic lights, a high speed handpiece with the fiberoptic-activated or other bright point light sources. Inexpensive alternatives are also available.⁷²

To evaluate a tooth for a crown fracture, the dental unit light should be turned off and only the fiberoptic light used. The fiberoptic light is placed sequentially on all sides of the tooth. If a crack is present in the dentin, the light will be interrupted at that crack and the clinician will see a dark line marking its location. The dentin on the opposite side of the crack from the light source will be darker in color (Figure 8). If a crack of this type is observed in a tooth, the tooth may also exhibit symptoms such as sensitivity to thermal stimulation and mastication and/or percussion.⁷³ Ritchey et al.⁷⁴ previously described these defects as incomplete tooth fractures and discussed the diagnostic frustrations

Figure 8 Photo of crown of tooth with crack located using a transilluminator.

they presented to the clinician. If multiple signs and symptoms are observed, endodontic treatment is indicated followed by a full coverage restoration. Frequently, the sensitivity to mastication occurs when the pressure is released after it is applied.⁷⁵ These fractures have been referred to as greenstick fractures.^{76,77}

Fiberoptic illumination is also a helpful adjunct to evaluate pulp vitality in anterior teeth after trauma. Loss of tooth translucency is reported to be an accurate indication of pulpal health or disease.⁷⁸ The dental unit light should be turned off, and the fiberoptic light is placed on the lingual surfaces of the anterior teeth. The color of a tooth with normal uninfamed pulp has yellow, white, and pink hues indicating a combination of the yellow dentin, the white enamel, and the pink healthy pulp. The color of a tooth with a necrotic pulp often exhibits a darker brown or black color indicating the change in color of the necrotic pulp. These color changes are often subtle and not observable when using only the dental unit light.

Periodontal Probing

Periodontal probing is an essential part of the diagnostic process, but it is also one that is frequently omitted by practitioners, particularly if the patient does not have generalized periodontal disease. A periodontal probe should always be readily available. Double-ended instruments are available with an explorer on one end and a periodontal probe on the other (Figure 9). The tooth should be evaluated interproximally as well as in at least three locations on both the buccal and the lingual surfaces. In addition, each furcation should also be explored with a periodontal probe. Periodontal defects could be a sign of either an endodontic or a periodontal problem. Simon et al.⁷⁹ described a classification of endodontic/periodontal presentations that can aid in not only diagnosis but also determination of an acceptable treatment plan and prognosis. Harrington et al.⁸⁰ reported diagnostic criteria to aid the practitioner in

Figure 9 Instrument with periodontal probe on one end and number 23 explorer on the other end.

Figure 10 Methylene blue dye (Sullivan-Schein, Melville, NY).

determining whether a periodontal defect is of periodontal or endodontic origin. If the periodontal probe sinks abruptly into an isolated periodontal defect, the level of suspicion for a vertical root fracture (VRF) increases (see Chapter 19). Conversely, if the periodontal probe steps down into a periodontal defect, the level of suspicion of a generalized periodontal condition increases. This is particularly true if a similar situation exists on the contralateral side of the arch. If a VRF is suspected but cannot be visualized, with or without magnification, a dye can be used to help in identifying a crack. Methylene blue has also been used to stain cracks (Figures 10).

Although the presence of a furcation defect does not directly imply pulp necrosis, it is extremely important in the health or disease status of the tooth. Furcation canals have been reported to be a portal of exit for necrotic pulp tissue by-products and/or bacteria from a necrotic pulp into the adjacent periodontal ligament.⁸¹ The following Glickman Classification System is commonly used⁸²:

- Grade I: Incipient lesion when the pocket is supra-bony involving soft tissue and there is slight bone loss.
- Grade II: Bone is destroyed on one or more aspects of the furcation but a probe can only penetrate partially into the furcation.
- Grade III: Intraradicular bone is completely absent but tissue covers the furcation.
- Grade IV: A through-and-through furcation defect.

The practitioner, using furcation probing as well as other endodontic diagnostic results, must also make a reasonable determination whether any furcation lesion is the result of periodontal disease, endodontic disease, or a true combined endodontic/periodontal lesion.

Test Cavity

A test cavity has been advocated for pulp vitality testing after all other diagnostic evaluation tests

have been inconclusive, and the practitioner has a high level of suspicion that the pulp is necrotic. The technique starts with fully informing the patient of the exact procedure so there are no surprises because this procedure has the potential to be uncomfortable for the patient. The patient is told that a bur will be used to drill into the tooth without anesthesia to determine the vitality of the pulp tissue. Air water coolant should be used to avoid injury to a vital pulp. If the patient does not respond to the bur, once the dentin is exposed, the tooth can be tested with an EPT or a cold thermal test. A tooth with calcification producing pulpal obliteration may still not give clear test results. If the pulp is vital, the test cavity should be restored with a bonded restoration.

Anesthetic Test

When other appropriate diagnostic tests have been inconclusive, the anesthetic test may be performed by injection of local anesthesia into a painful area with an end toward making a diagnosis. Administration of the local anesthesia could be by block, infiltration, or intraosseous injection. A diagnostic block anesthetic test can be used effectively if the practitioner desires to evaluate the effects of anesthetizing large areas when a patient reports a vague location(s) for the pain. For example, a patient explains that the discomfort covers the entire left cheek and associated hard and soft structures. If a left inferior alveolar (IA) nerve block is successful and the pain remits, the practitioner can feel confident that the chief complaint is associated with pathosis within the distribution of the IA nerve (V3) and its branches. A second example is a patient who reports vague and intense pain in the mandibular left arch that contains teeth that are carious or have faulty restorations. After a successful IA nerve block, the intense pain does not remit but remains constant. This block anesthetic test may have identified the chief complaint as being a myocardial infarct, as there was no decrease in the pain after the nerve block. Cardiac pain may be referred to the left mandible and occasionally to the maxilla or the right mandible and can easily mimic pain of dental or orofacial origin.^{27,28}

The infiltration anesthetic test may be used in an area suspected of being the source of the patient's chief complaint, and then waiting to see if the pain remits. It

can be a useful test, particularly in the maxillary arch, in differentiating pain between the maxillary and mandibular arches. An example would be a patient who reports sharp and lingering pain to hot coffee on the left side of the face, but cannot narrow it down to either an individual tooth or even which arch. Thermal pulp tests are inconclusive, but the patient is now experiencing the same pain once again and cannot narrow the location to either arch. If the clinician believes the pain emanates from the posterior maxillary arch, he can inject local anesthesia in that area to see if the pain remits. If the pain remits, the practitioner can be reasonably sure the pain is due to pulpitis in the maxilla. If the pain does not remit, the practitioner may conclude that the pain source is in the mandibular arch and now administer a mandibular block with a reasonable assurance that the pain should abate. If after all the above have been accomplished and the pain does not abate, the practitioner may draw the conclusion that the pain is not of endodontic origin and refer the patient to the appropriate healthcare practitioner for further evaluation. The pain could be referred from the heart or the thyroid.

The PDL injection may be helpful in identifying a source of pulpally related pain. However, a common misperception is that the anesthetic remains in the PDL and does not diffuse into the surrounding bone and to adjacent teeth. Studies have shown that the PDL injection is an intraosseous injection with the local anesthetic passing into the surrounding cancellous bone and anesthetizing adjacent teeth.⁸³ Thus, PDL anesthesia provides the same type diagnostic information as the infiltration of anesthetic but on a more localized basis.

Magnification

Magnification allows the clinician to visualize what cannot be observed using only the unaided eye. Chapter 25F provides an extensive description of the use of aids in magnification in endodontics.

Dyes

Dyes can aid greatly in the diagnosis of either caries or fractures. Caries detector dyes have been used effectively to identify caries not otherwise evident with either visual inspection methods or traditional

Figure 11 Caries indicator solutions can highlight tooth cracks; shown here is Sable-Seek (Ultradent, South Jordan, UT).

hand instruments (Figure 11)... Caries can contribute to the patient's chief complaint and perhaps require conservative pulp therapy. Methylene blue dye and India ink have been very effective dyes used to diagnose the presence of crown or root fractures (see Figure 10). A very small amount of the dye is placed on a small cotton pellet and the crown/root is coated with it. Any dye remaining on the surface is washed away and, if a fracture is present, the dye remains within the crack and can be observed through loupes or a dental operating microscope.

Measurement of Tooth Surface Temperatures

Even though not widely used, measurement of tooth surface temperatures could represent another testing technique. Fanibunda⁸⁴ reported that the pulp circulation was much more efficient than supporting tissue circulation in maintaining the temperature of the crown in vitro. His results indicate that measurement of crown surface temperatures may be a step in the right direction in determining whether vital tissue or necrotic tissue fills the pulp chamber. However, even the most sensitive temperature measurement device may not be able to distinguish whether a vital pulp is reversibly or irreversibly involved.

Cholesteric liquid crystals are a possible vehicle for measuring the surface temperature of a tooth. Howell et al.⁸⁵ experimented with various liquid crystals until they arrived at a combination that would indicate temperatures in 30° to 40°C range. They used cholesteric compounds that were in a

10% solution in a chlorinated hydrocarbon solvent. When applied to the tooth surface, the crystals went through color changes that were compared with adjacent or contralateral teeth. Although their reported results were equivocal, this diagnostic test might be helpful when taken into consideration with other diagnostic information.

Banes and Hammond⁸⁶ evaluated the ability of a thermistor to accurately measure the surface temperatures of teeth with vital pulps and contralateral teeth that had previously received NS RCT both with and without full gold crowns. They reported that the surface temperatures of the endodontically treated teeth without full gold crowns were statistically significantly lower than those of the contralateral teeth with vital pulps. There was no temperature difference, however, between those two groups when restored with full gold crowns. Stoops and Scott⁸⁷ used thermistors in vivo to determine the surface temperature of contralateral teeth and reported thermistors to be extremely consistent in recording the temperatures of teeth with both necrotic and vital pulps. They stated that there was a statistically significant difference between the surface temperatures recorded for teeth with vital pulps and those that were pulpless. They also reported that the thermistors, like any other sensitive temperature measuring devices, were affected by a small amount of saliva on the tooth or a current of air in the room.

Electronic thermography produces color images of the body that indicate relative differences in temperature in both superficial and deep areas. Components include an infrared sensor, control unit, thermal image computer, software, a color monitor, and printer. A review of the literature reports that current technology is not sensitive enough to identify periapical lesions deep within the bone that would indicate a necrotic pulp or irreversible pulpitis.⁸⁸

The use of the Hughes Probeye 4300 thermal video system (Hughes Aircraft Co., Carlsbad, CA) was reported to be sensitive enough to measure temperature differences of as little as 0.1°C.⁸⁹ The authors conducted their investigation on 20 human subjects and measured the surface temperatures on maxillary incisor teeth after they had been isolated with a rubber dam. The teeth had a variety of restorations with some containing normal pulps and others containing necrotic pulps or prior root canal-filling materials. They reported no difference in the surface temperatures between those categories of teeth. However, when the teeth were cooled by air spray to approximately 22°C and then allowed to re-warm to their original resting

temperature of approximately 29°C, the teeth containing normal pulps took about 5 seconds to re-warm whereas the others containing necrotic pulps or prior root canal-filling materials took about 15 seconds to re-warm. The investigators suggested that electronic thermography could be a useful adjunct to other pulp diagnostic tests if the prohibitive expense of the current system could be reduced and if an alternative could be found to the requirement for routine isolation of the effected teeth with a rubber dam.

Measurement of Pulpal Blood Flow

It is recognized that measuring pulpal blood flow can aid in determining pulpal healthy; to that end efforts using laser Doppler flowmetry and pulse oximetry are currently investigated (see Chapter 14C).

Ultraviolet Light

Some objects possess the unusual feature of being able to emit light of a higher wavelength when illuminated with ultraviolet (UV) light. That principle is called fluorescence. Foreman⁹⁰ reported that teeth with necrotic pulps and teeth with endodontic treatment did not fluoresce when exposed to UV light while teeth with vital pulps fluoresced normally. He cautioned that lighting in the operatory needed to be suppressed to fully observe any changes in the tooth color. Moreover, the patient and staff need to wear suitable goggles to protect them from the harmful effects of UV light on their eyes.

Patient Temperature

The importance of obtaining a baseline temperature as well as follow-on readings at subsequent appointments cannot be underestimated. Patients frequently state they do not have a fever when, in fact, they have not taken their temperature before they came in for the evaluation appointment. A temperature over 100°F indicates a systemic response to an infection. Having a baseline temperature gives the clinician one more diagnostic tool that can be used to determine whether the patient's condition is either improving or worsening.

Communication with other practitioners must employ an objective and understandable language so the facts can be conveyed clearly about a patient's current condition. Otherwise, poor treatment deci-

sions will be made based on false or faulty diagnostic information. Misinformation may lead to misdiagnosis and result in mistreatment.

C. LASER DOPPLER FLOWMETRY

ASGEIR SIGURDSSON

Having information about the blood flow, or re-establishment of circulation, in the pulp can be of great value, particularly in situations in which teeth have been traumatized. All traumas to developing teeth have the potential to cause irreversible damage that ultimately may lead to pulpal necrosis. In many situations, there is the possibility of revascularization of the injured pulp, a development that is most desirable for the continued development of the tooth. The risk in waiting for revascularization is that bacteria may enter the damaged pulp leading to inflammatory root resorption.¹ However, if the endodontic treatment is initiated while blood vessels are attempting to re-grow through the apical opening, healing of the pulp is arrested and there is no further growth or development of the root structure. It is therefore very desirable to have a reliable method for assessing blood flow in the pulp.

The usual diagnostic instruments like the electric pulp tester (EPT) and various temperature tests have been shown to be not at all reliable in diagnosing the pulpal status of teeth following a traumatic injury, especially for teeth with immature root formation and open apex.²⁻⁵ Compounding the problem with these testing methods is that they all are very subjective, dependent on cooperation and understanding of the situation by the patient, something which can lead to further difficulty in cases involving young children. It is important to note that the usual pulp tests provide information only about the presence or absence of nerve receptors in the pulp and not about pulpal blood supply.

Current efforts to assess pulpal circulation involve the use of laser Doppler flowmetry (LDF) and pulse oximetry. Both methods are in their infancy and are not ready for general clinical application yet, but hopefully before long, these technologies can become part of dentists' diagnostic armamentaria.

Technology

DEVELOPMENT AND PRINCIPLE OF THE LDF TECHNOLOGY

Laser Doppler Flowmetry (LDF) was first introduced in the early 1970s. Initially, it was suggested for use in measuring blood flow in the retina.⁶ Soon, other applications for this technology were suggested, such as measuring blood flow in skin and in renal cortex.⁶ The technology employs a beam of infrared (780 to 820 nm) or near infrared (632.8 nm) light, directed into the tissue by optical fibers. As light enters tissue, it is scattered by stationary tissue cells and moving blood cells (Figure 1).

Photons that hit stationary tissue cells are scattered, but their frequency is not shifted. Photons that hit moving blood cells are scattered, and the light frequency is shifted according to the Doppler principle. A small proportion of the light, containing both Doppler-shifted and transmitted light, is backscattered to a photodetector (or more commonly, in newer instruments, to two or more photodetectors) built into the probe from which the laser light is beamed. A signal is then calculated with a preset algorithm in the LDF machine (Figure 2A,B).

Because red blood cells represent the vast majority of objects moving within a tooth, measurement of the Doppler-shifted backscattered light from them could give an indication of pulpal blood flow. The outcome signal depends on the number and velocity of the illuminated red blood cells, most commonly termed flux; that is the number of moving red cells per second times their mean velocities. Most current laser Doppler instruments give a readout, in addition to the flux, in perfusion units (PUs). It is important to remember that these PUs are arbitrary and calculated by the software that accompanies each instrument. No current Laser

Figure 1 Red light is emitted from a light source; if the light beam is scattered off stationary tissue or cells, there is no shift in the light spectrum. If, however, the light hits a moving cell in a blood vessel, there is a shift in the light spectrum of the scattered light according to the Doppler principle.

Doppler instrument can present absolute perfusion values of blood flow (e.g., mL/min/100 gram tissue). Because of this, the PUs are never comparable between various types of instruments, and even for the same instrument they could vary at different times unless the instrument is calibrated frequently using special suspensions of particles in liquid that have a known inherent vibration.

Initially, there was some concern that the power of the laser light would be hazardous to living tissues and could possibly burn or cause other permanent damage. That fear has been shown to be unfounded as the laser light in all currently used medial instruments is far below the maximum limit permitted for clinical applications and temperature changes in the illuminated tissue.⁷

For many LDF instruments, it can be difficult to objectively analyze the output of the instrument. Therefore, earlier, it was suggested to use the so-called Fast Fourier Transform (FFT) analysis associated with the LDF measurements.⁸ Subsequently, numerous studies have confirmed its usefulness in evaluating blood flow in soft tissues. This analysis identifies the presence of consistency of time between peaks in pulses. For example, a peak at or around 1.3 Hz, which is equivalent to approximately 78 heartbeats per minute, would give an indication of vitality in a tooth pulp (Figure 3A–C).

Figure 2 A, Example of a laser Doppler setup. The machine is from Moor Instruments Ltd, Devon, UK and has two sets of probes, so it is possible to record two different sites or two teeth simultaneously. **B**, The two probes from the Moor laser Doppler flow meter. Note that for practical purposes a one-probe machine is sufficient for most clinical applications.

Figure 3 **A**, A typical readout of a laser Doppler machine. Even though there are several spikes, it is hard to determine if those represent heartbeats or just movement artifacts. **B**, When the readout in panel A is analyzed by Fast Fourier Transform analysis, it is clear that there is a constant amplitude spike of about 1.3 Hz or about 78 beats per minute indicating blood circulation in the pulp. **C**, A readout from a different tooth and analyzed by Fast Fourier Transform analysis indicates no vitality. There is no consistent amplitude spike and therefore the pulp is deemed to be necrotic.

To date, only few investigations of pulpal vitality have been done with the FFT analytical approach.^{9,10} A recent study investigating revascularization of tooth pulp in a dog model applied this analysis to readings from teeth with vital pulps. A peak appeared at or around 2 Hz, that is, at around 120 beats per minute of the dog's heart rate. When readings from teeth with non-vital pulps were analyzed, this dominant peak was absent. This method of analysis thereby established that the pulsatile reading is of similar frequency to the heart rate and is due to blood flow rather than of movement artifacts.¹⁰ It was of interest to note that the investigators found that two teeth had been classified as having non-vital pulps based on a net flux value of only 18% of the pre-extraction flux, a reading that indicated a very low if not absent blood flow. But the FFT analysis indicated that both teeth had the typical peak of 2 Hz, indicating vitality of the pulps. Based on the FFT analysis, the teeth were correctly categorized as having vital pulps. Histological evaluation later confirmed that revascularization had occurred in both teeth. Based on their experience, the authors suggested that FFT analysis might prove a more feasible method than net flux calculation if this method is to be used in dentistry.¹⁰ However, further research is warranted because only a few studies have used this analytical method in dental application of the LDF.

Initial Suggestions for Dentistry

The first study showing that LDF could differentiate between vital and non-vital pulps in humans was published in 1986 by Gazelius et al.¹¹ They confirmed in five human subjects that there was a correlation between their heart rates as measured by electrocardiograms and peaks of flow measured in healthy and responsive maxillary central incisors. In addition, they showed that local injection of lidocaine (20 mg/mL) with adrenaline (12.5 mg/mL) caused a pronounced and long-lasting reduction of the flowmetric values in the same pulps. In this initial report on use of LDF in dentistry, the authors also mentioned, but did not investigate any further, the fact that a tooth with history of trauma and that did not respond to traditional vitality tests also did not show typical flow characteristics of a healthy pulp.

Two years later, Gazelius et al.¹² reported a case history on four luxated mandibular incisors in an 11-year-old boy in which the LDF showed no flux 1 week after the traumatic injury. After 6 weeks, however, the LDF indicated partial restoration of the blood flow in

the pulps, and 9 months later the blood flow appeared normal. The same teeth were not responsive to EPT until 9 months to a year after the trauma.

Subsequently, there have been several studies investigating the accuracy and, more importantly, the usefulness of the LDF technology in dentistry. One of the first studies to confirm that it was actually blood flow that was being measured in the pulp with the LDF was by Kim et al. in 1990.¹³ In a dog model study, they compared blood flow measurements, gathered by LDF, to data from a ¹³³Xe washout method that enables the researcher to accurately calculate blood flow in real time. However, this requires injection of ¹³³Xe into the blood stream close to the tissue of interest. All measurements were done on the same teeth and conducted at the same time. During the experiment, they used an intra-arterial injection of norepinephrine to affect the blood flow to the pulps. They found a significant correlation between the two measurement approaches, and both followed the expected effect of the norepinephrine on the blood flow.

All these findings are promising; however, it was pointed out, earlier, that the position of the probe on the tooth crown had a significant effect on pulpal blood flow estimates. For example, measurements recorded have not been consistent across all the testing sessions.¹⁴ It has been suggested, therefore, that to achieve reliable and comparable readings at different times, an accurate repositioning of the light probe each time is mandatory. Custom-made stents have been found to ensure accurate and reproducible positioning of the measurement probe at each session.¹⁴

Another question that surfaced is with regard to the applicability of LDF technology for dental situations. As mentioned above, the initial use of LDF was exclusively for direct soft tissue blood flow measurements, without any interference of hard tissue like dentin and enamel. All the engineering of light sources and photodetectors was designed with that in mind. It first had to be confirmed that the commercially available machines could be used in clinical settings in dentistry. A study published in 1993 by Ingolfsson et al.¹⁵ reported an investigation on the influence of probe design on the LDF signal output from the dental pulp. Recordings were made from anterior teeth in humans with different probe designs. All tested instruments had in common one light source and two photodetectors, the variable was the distance between the photodetectors. They found that the probe with the largest separation of the fibers produced significantly higher output than the other probes.¹⁵ This observation may not, however,

be the solution, because in a more recent study it was found that the probe with the smallest separation of fibers was the most sensitive in distinguishing necrotic pulps from vital ones.¹⁶ In another study, the smallest of three investigated separations showed the best specificity, while the other two probes had better sensitivity but poor specificity. The best specificity and sensitivity was shown by the 0.5 mm probe/3.1 KHz bandwidth combination.⁹

It is not only the probe design that needs to be considered when measuring the blood flow in the pulp; the adjacent environment of the mouth has to be contended with as well. In a follow-up study by Ingolfsson et al.¹⁷ investigating the efficacy of LDF in determining pulp vitality of human teeth, they found that even teeth with necrotic pulps had some output signal. Background noise from the gingival tissues, as well as from the movement of teeth, is the most likely explanation for the recorded signals.^{14,17-21} They found that output signals from teeth with necrotic pulps were always significantly lower than from teeth with vital pulps. These findings have subsequently been confirmed in other studies, and suggestions have been made to attempt to block out the gingival tissue effect with dental dam or aluminum foil covering the gingival tissues prior to placement of the custom-made stent (Figure 4A).^{18,20,22}

As stated previously, several studies have investigated and confirmed the apparent efficacy of LDF in assessing pulpal vitality in healthy and traumatized teeth. These studies have indicated that the LDF gives a better indication of pulpal revascularization or vitality than more traditional vitality tests.^{11,16,18,23,24} However, it was not until 2001 that an attempt was made to correlate clinical LDF findings to histological findings in the same teeth. Yanpiset et al.¹⁰ used a dog model in which young puppies' teeth with open apices were extracted and then reimplanted. The teeth were followed weekly over 3-month period, both radiographically and with LDF assessment. After 3 months, the pulps were harvested and evaluated histologically by "blinded" evaluators for signs revascularization. This study confirmed previous findings that the LDF technology was very effective in determining revascularization or lack thereof. LDF readings correctly predicted the pulpal status (vital vs non-vital) in 83.7% of the teeth; 73.9% (17 of 23) were correct for the vital pulps and 95% (19 of 20) were correct for the non-vital pulps. It was of interest that in this dog model the flux value increased significantly from week 2 to week 4 in the revascularizing pulps indicating that the LDF could provide information about healing progress in the pulps earlier.

Figure 4 A, When recording a traumatized tooth pulp, effort must be taken to block out as much as possible of the gingiva and other soft tissues immediately surrounding the tooth. It is recommended to use a dental dam as opaque as possible. In this figure, a vinyl (non latex) dental dam is used. **B**, An individual bite stent is made for every patient. By using heavy dental impression putty the stent can be made quickly and inexpensively. To ensure consistency in measurements, a hollow cylinder is placed into the putty through which the laser Doppler probe is placed. That way, the same area of the tooth can be measured each time, and it is easier to control for needed spacing from the gingiva.

Current Applications of LDF in Dentistry

CLINICAL DENTISTRY

It appears that the LDF technology has a future in clinical dentistry. It is, if properly conducted, an objective way to assess pulpal blood flow. Tests like EPT and temperature stimulation rely on subjective responses by the patient and only measure the neurological status of the pulp, not the vitality. Additionally, the LDF technology has also been shown to work in primary incisors. In a clinical study, it was shown that the LDF readings were different for primary incisor teeth prior to pulpotomy or extraction compared to the same teeth at an earlier time.²⁵

There are some recognized drawbacks with the current application of the LDF technology in dentistry. Apart from the initial high setup cost, the other drawbacks can be fairly easily overcome. The main issue is ensuring consistent and accurate reading of the LDF assessment over time. To be able to obtain accuracy and consistency, certain critical steps need to be taken. First, because of the sensitivity to movement, it is not possible to hold the probe manually against a crown surface. A stabilizing stent, most easily made out of rubber impression material, needs to be fabricated individually for each patient (see Figure 4A,B). This will not only reduce the artificial movements that might be picked up by the photodetectors but also ensure that the tooth is always tested on the same part

of the crown. Prior to placing the stent, the gingiva should be covered with a dark dental dam or aluminum foil. Additionally, the patient should be in a similar, if not identical, position in the dental chair each time while the recording is done, as body position might affect the reading.²⁶ With commercially available equipment and computer technology storing and comparing the recorded data should not be any obstacle for using this technology.

DENTAL TRAUMA

The use of LDF in dental trauma has proven to be even more valuable than in assessing vitality in healthy pulps.^{27–29} The LDF test can, for example, be a useful diagnostic adjunct for luxated teeth showing signs of adverse outcomes. In a series of studies, it was suggested that a predictive modeling may provide opportunity to identify “at-risk” teeth early after the trauma. Treatment, therefore, could be initiated with confidence prior to the tooth being lost from pulpal necrosis and infection.^{30–32} There is also a good indication, in case of avulsion, the LDF can detect revascularization after a few weeks, and well in advance of other more traditional clinical tests.^{10,27}

Other Potential Modalities

Pulse oximetry is routinely used in medicine to assess blood oxygen saturation. This technology uses

a noninvasive and objective way to record the oxygen saturation, and, as with the laser Doppler technology, it requires no subjective response from the patient. This technology is based on the principles of spectrophotometry and optical plethysmography³³ rather than the law of light frequency shift in LDF technology. The machinery consists of a light source probe that emits simultaneously two light beams; one transmits red light (640 nm) and the other transmits infrared light (940 nm). The light has to pass through the tissue of interest and a photodetector on the opposite side to the light source captures whatever light gets through. Oxygenated hemoglobin and deoxygenated hemoglobin absorb different amounts of red and infrared light. After the light from the probe has passed through living tissue with circulating blood, the machine calculates how much light has been absorbed and then calculates the ratio of the two lights. The output is in percentages of oxygenated arterial blood.

Over the years, pulse oximetry has been suggested and tested for use in dentistry with reasonable good results.³⁴ However, all that work has been done using testing machines designed to be used on earlobes or fingers but not teeth. Some authors have concluded that the accuracy of these commercial instruments, adapted for dental use, has been disappointing and they did not have predictable diagnostic value.³⁵ Recently, a study was published that used a custom-made probe specifically made for dental application.³³ In that study, the accuracy rate of detecting vital and non-vital pulp was found to be 86% for the cold test, 81% for the electrical test, and 97.5% for the pulse oximetry test, indicating that this approach is more accurate than more traditional methods. The custom-made probe is, as of yet, not commercially available, but when it is, it should be considered as an important adjunct to pulpal evaluation.

Future Suggestions for Use and Development

Early research has indicated that there are no differences between various LDF machines.^{24,27} However, no recent work has been published on this matter. With the fast developments in computer technology and equipment, vigilance must be kept and new and supposedly improved machines need to be tested and compared. There are still some questions about the probe design, the effect of different wavelength, frequency, and intensity of the laser light not fully answered for dental application of this technology. And algorithms like FFT analysis should be investigated further and confirmed for use in dentistry.

CHAPTER 15

DIAGNOSTIC IMAGING

A. ENDODONTIC RADIOGRAPHY

RICHARD E. WALTON

Radiographs are the “eyes” of the dentist when performing many procedures. They are essential for diagnosis and treatment planning, determining anatomy, managing treatments, and assessing outcome. Now considered essential, the use of the X-ray was not available to the dental profession until early in the last century.

No single scientific development has contributed as greatly to improved dental health as the discovery of the amazing properties of cathode rays by Professor Wilhelm Konrad Roentgen in 1895. The significant possibilities of their application to dentistry were seized upon 14 days after Roentgen’s announcement. Dr. Otto Walkoff took the first dental radiograph in his own mouth.¹ In the United States, within 5 months, Dr. William James described Roentgen’s apparatus and displayed several radiographs. Three months later, Dr. C. Edmund Kells gave the first clinic in this country on the use of the X-ray for dental purposes. Three years later (1899), Kells was using the X-ray to determine tooth length during root canal therapy. “I was attempting to fill the root canal of an upper central incisor,” Kells later said. “It occurred to me to place a lead wire in this root canal and then take a radiogram to see whether it extended to the end of the root or not. The lead wire was shown very plainly in the root canal.”

One year later (1900), Dr. Weston A. Price “called attention to incomplete root canal fillings as evidenced in radiographs.” By 1901, Price was suggesting that radiographs be used to check the adequacy of root canal fillings.² Price is also credited with developing the bisecting angle technique, whereas Kells described what today is called the paralleling technique, made popular some 40 years later by Dr. Gordon Fitzgerald.

Although these early attempts were rarely of diagnostic quality, they were the beginning of a new era. For the first time, dentists could see the accumulation of past dental treatment—therapy done without knowledge of what lay beneath the gingiva. Yet even today, with all of the technical refinements, the sleekness of operation, and the reduction of hazards, a discouraging segment of our profession continues to deprive their patients by failing to use radiography to its full potential. Dentists often under use or over use, under interpret or over interpret radiographs or fail to use careful and appropriate techniques.

Application of Radiography to Endodontics

In endodontics, radiographs have several essential functions:

1. Aid in diagnosis of hard tissue alterations of the teeth and periradicular structures.
2. Determine the number, location, shape, size, and direction of roots and root canals.³
3. Estimate and confirm the length of canals.
4. Localize hard-to-find, or disclose unsuspected, pulp canals by examining the position of an instrument within the root (Figure 1).
5. Aid in locating a pulp space markedly calcified and/or receded (Figure 2).
6. Determine the relative position of structures in the facial–lingual dimension.
7. Confirm the position and adaptation of master cones.
8. Aid in the evaluation of obturation.

Figure 1 Disclosing canals by radiography. **A**, Right angle horizontal projection reveals four files in separate canals superimposed. **B**, Horizontal angulation varied 30° mesially reveals all four canals and file short of working length in mesiolingual canal (arrow).

Figure 2 Locating canal. **A**, Advanced calcification and receded pulp. **B**, Radiograph reveals angulation of preparation and canal (arrow) at mesial of cut. **C**, Canal, seen in radiograph, is discovered with a fine file.

Figure 3 Radiograph taken *after* suturing and developed after patient left the office. The patient had to return to the office for removal of the root tip.

9. Facilitate the examination of soft tissues for tooth fragments and other foreign bodies following trauma.
10. Aid in localizing a hard-to-find apex during root-end surgery.
11. Confirm, following root-end surgery and before suturing, that all tooth fragments and excess filling material have been removed from the apical region and the surgical flap (Figure 3).
12. Evaluate, in follow-up films, the outcome of treatment.

LIMITATIONS OF RADIOGRAPHS

Radiographs are two-dimensional shadows on a single film. They are suggestive only and are not the singular final evidence in judging a clinical problem. There must be correlation with other subjective and objective findings. The greatest fault with the radiograph relates to its physical state. As with any shadow, these dimensions are easily distorted through improper technique, anatomic limitations, or processing errors.

In addition, the buccal–lingual dimension is absent on a single film and is frequently overlooked, although techniques are available to define the third dimension. These techniques are described later in detail.

Radiographs are not infallible. Various states of pulpal pathosis are indistinguishable in the X-ray shadow. Neither healthy nor necrotic pulps cast an unusual image. Correspondingly, the bacterial status of hard or soft tissue is not detectable other than by inference. Only bacteriologic evidence can determine this. Furthermore, periradicular soft tissue lesions cannot be accurately diagnosed by radiographs; they require histologic verification.⁴ Chronic inflammatory tissue cannot, for example, be differentiated from healed, fibrous, “scar” tissue, nor can a differential diagnosis of periradicular radiolucencies usually be made on the basis of size, shape, and density of the adjacent bone.^{3–7} A common misconception is that an inflammatory lesion is present only when there is at least a perceptible “thickening” of the periodontal ligament space. In fact, investigators have demonstrated that lesions of the *medullary bone* often go undetected unless there is marked resorption or until the resorption has eroded a portion of the *cortical plate*.^{8–11}

The fallibilities and inherent errors in radiographic interpretation were clearly demonstrated by Goldman et al.,¹² who submitted recall radiographs of endodontic treatments, for clinical evaluation, to a group of radiologists and endodontists. They assessed success and failure by observation of radiodensities. There was *more disagreement than agreement* among the examiners.

The techniques outlined in the following sections have proved to be successful and predictable. If followed, they will greatly simplify difficulties in root canal treatment.

Technology Systems

There are basically two radiographic approaches. The traditional is the X-ray exposure of film, that is chemically processed to produce an image. The newer digital systems rely on an electronic detection of an X-ray-generated image that is then electronically processed and reproduced on a computer screen. Overall, the resulting image is similar in interpretative quality to the traditional radiograph.^{13–16} Advantages of digital radiography include reduced radiation, speed of obtaining the image, enhancement of the image, computer storage, transmissibility, and a system that does not require chemical processing.¹⁷ Disadvantages are cost and more difficulty in placing the sensor. Many endodontists are finding that the advantages outweigh

the disadvantages to their practice. As costs decrease and technology improves, use of the digital system will undoubtedly increase. Digital radiography is discussed in full later in the chapter.

TRADITIONAL MACHINES

Two basic types of X-ray machines are commonly used in dental offices. One type has a range of kilovoltage and two milliamperage settings with which the long (16-inch) cone is frequently used. The other type offers only one kilovoltage and milliamperage setting and only the short (8-inch) cone. Either type provides adequate radiographs. However, each has advantages that, under different circumstances, will yield a more satisfactory result. The long-cone system is superior for diagnostic radiographs, whereas the flexible short-cone machine is more appropriate for treatment or “working” films. However, either the “long cone” or the “short cone” is satisfactory if used properly.

LONG CONE

Because of the clarity of detail and minimum distortion inherent in the long-cone parallel technique,^{18–21} the long-cone machine is preferred for exposing diagnostic, final, and follow-up radiographs.

SHORT CONE

Because of the number of working radiographs taken in the course of endodontic therapy, the practitioner treating more than the occasional tooth will find that a short-cone machine, with a small, easily manipulated head, saves time, energy, and frustration.

FILM

Industrial technological advances have allowed film exposure time to be reduced to fractions of a second. Recent improvements in emulsion thickness allow rapid processing of the new films, which are used for diagnostic and “working films” alike. A study of Kodak Ektaspeed film (“E” film), that is coated with

larger silver bromide crystals and has one-half the exposure time of standard Kodak Ultraspeed film, concluded that the “Ektaspeed film had comparable accuracy with the Ultraspeed film in measuring root length,” even though the new Ektaspeed is somewhat grainier.²² A double-blind study found the slower Ultraspeed film superior “in terms of contrast, image, quality, and rater satisfaction.”²³ However, another study found both films “adequate for routine endodontic use.”²⁴

An even faster film (F speed) has been introduced. This film requires 20% less radiation but is grainier. There are no conclusive studies to date on the suitability of this new film for endodontic use.

For endodontists, duplicate film packets are recommended for the diagnostic, final treatment, and recall radiographs—one set for the permanent office record, the other for the referring dentist. The front film in the double pack, the one closest to the X-ray machine, “had significantly superior image quality compared to back films.”²⁵

The standard periradicular size film is used for most situations. In addition, every office should have 3 by 2 1/4-inch *occlusal* film available for use when

1. periradicular lesions are so extensive that they cannot be demonstrated in their entirety on one periradicular film;
2. there is interest in or involvement of the nasal cavity, sinuses, or roof or floor of the mouth;
3. trauma or inflammation prohibits normal jaw opening required to place and hold a periradicular film;
4. a disabled person is unable to hold a periradicular film by the usual means;
5. detection of fractures of the anterior portion of the maxilla or mandible is needed; and
6. very young children are being examined.

INTRAORAL FILM PLACEMENT

Film placed parallel to the long axis of the teeth and exposed by cathode rays at a right angle to the surface of the film yields accurate images, with no

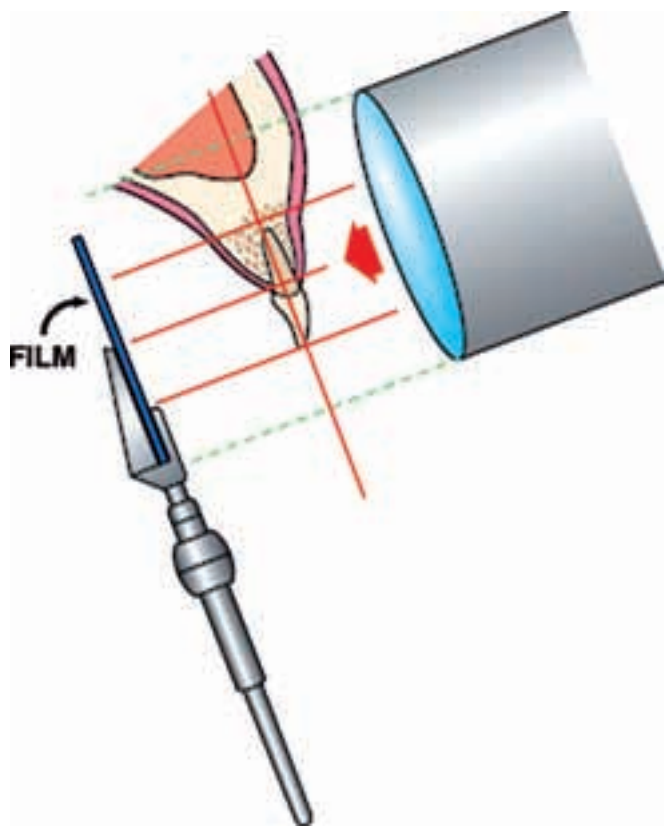

Figure 4 Radiographic parallelism. The long axis of the film, the long axis of the tooth, and the leading edge of the cone are parallel and perpendicular to the X-ray central beam. Reproduced with permission from Goerig AC. In: Besner E, et al., editors. Practical endodontics. St Louis (MO): Mosby; 1993, p. 56.

foreshortening or elongation²⁶ (Figure 4). If this principle is applied, it is unnecessary to memorize fixed cone angulations. Also, a patient need not be returned to an upright position for each exposure.

Because of the complicating presence of the rubber dam, the methods for placement of *working* films differ somewhat from the methods for placement of diagnostic, final, and follow-up films.

DIAGNOSTIC RADIOGRAPHS

These must be the *best radiographs possible*. There are advantages to parallelism, that permits more accurate visualization of structures as well as reproducibility. This facilitates comparison of follow-up radiographs.

There are a number of devices on the market that ensure film placement and parallelism. The *Rinn XCP* (Dentsply/Rinn, Elgin, IL) virtually guarantees distortion-free films but cannot be used with the rubber dam in place. The *Rinn Endoray II endodontic film holder* is designed specifically to ensure parallelism yet

Figure 5 The Universal Rinn Endo Ray plastic film holder is designed for horizontal posterior films or anterior vertical films, maxilla or mandible, right or left. Here it is set for a maxillary posterior view. The “cupped-out” area accommodates the tooth, clamp, and extruding endodontic files. Photo courtesy of Rinn Corp. USA.

Figure 6 A hemostat is used for grasping the film and as a cone positioning and orientation device.

avoid rubber dam clamps while allowing space for files protruding from the tooth (Figure 5). A disadvantage to this system is that the paralleling bar interferes with the cone when varying the horizontal cone angulations. Finger retention of the film should never be used. A *straight hemostat* is a good film holder and additionally serves as a cone-positioning device (Figure 6).

WORKING RADIOGRAPHS

One great difficulty in root canal therapy is the clumsy, aggravating method of making treatment radiographs with the rubber dam in place. The rubber dam frame should not be removed for access in film placement because doing so allows saliva entry to contaminate the operating field. A film-placement technique is used so that the *rubber dam frame need not be removed*. Use of a radiolucent *N-Ø*

(Nygaard–Østby) frame (Coltene/Whaledent/Hygenic, Mahwah, NJ), Lexicon hinge dam frame (Dentsply-Tulsa-Dental) or the *Star VisiFrame* (Dentaleze/Star, USA) will ensure that apices are not obscured.

With the rubber dam in place, a *hemostat-held* film has significant advantages:

1. The film placement is easier when the opening is restricted by the rubber dam and frame.
2. The patient may close somewhat with the film in place, a particular advantage in *mandibular posterior areas* where closing relaxes the mylohyoid muscle, permitting the film to be positioned farther apically.
3. The handle of the hemostat is a guide to align the cone in the proper vertical and horizontal angulation (see Figure 6).

4. There is less risk of distortion of the radiograph caused by too much finger pressure bending the film.
5. Patients can hold a hemostat handle more securely with less possibility of film displacement.
6. Any movement can be detected by the shift of the handles and corrected before exposure.

The *identifying dimple* should be placed at the incisal or occlusal edge to prevent its obscuring an important apical structure.

CONE POSITIONING

It is often a mistake to rely on only one film. Additional exposures taken from varied horizontal or vertical projections give visualization of the third dimension (Figure 7).

Figure 7 “Working” film properly placed and held under rubber dam with hemostat. **A**, Vertical angle. Cone is aligned so that central beam is parallel with the handle. **B**, Cone is aligned at right angle to handle and film. **C**, Varying horizontal angle. Vertical angle is maintained. **D**, Cone is shifted 20–25° to the mesial.

VERTICAL ANGULATION

Ordinarily, it is preferable to align the cone so the beam strikes the film at a right angle. This alignment ensures a fairly accurate vertical image. Elongation of an image, however, *may be corrected by increasing the vertical angle* of the central ray. Conversely, *foreshortening is corrected by decreasing the vertical angle* of the central ray.

Frequently, an impinging palatal vault prevents parallel alignment of the film and the teeth. However, if the film angle is no greater than 20° in relation to the long axis of the teeth, and the beam is directed at a right angle to the film, no distortion occurs, although there is a less effective orientation of structures.²⁶ The resulting radiograph is still adequate.

HORIZONTAL ANGULATION

Walton²⁷ introduced an important refinement in dental radiography that has materially improved the endodontic interpretive film. He demonstrated a simple technique whereby the *third dimension* may be readily visualized. Specifically, the anatomy of superimposed structures, the roots and pulp canals, may be better defined. The basic technique is to vary the *horizontal angulation* of the central ray of the X-ray beam. By this method, overlying canals may be separated, and by applying Clark's rule,²⁸ the separate canals may then be identified. Clark's rule states that "the most distant object from the cone (lingual) moves toward the direction of the cone." Stated in another way, using a helpful mnemonic, Clark's rule has been referred to as the SLOB rule (Same Lingual, Opposite Buccal): the object that moves in the Same direction as the cone

is located toward the *Lingual*. The object that moves in the *Opposite* direction from the cone is located toward the *Buccal*. The SLOB rule, simply stated, is "The lingual object follows the tube head." Goerig and Neaverth²⁹ cleverly applied the SLOB rule to determine, from a single film, from which direction a radiograph was taken: mesial, straight on, or distal. Knowing the direction, one is then able to determine lingual from buccal (Figure 8). Stated more simply, Ingle's rule is *MBD*: Always "shoot" from the *Mesial* and the *Buccal* root will be to the *Distal*.

HORIZONTAL CONE ANGULATIONS

For working and/or interpretive diagnostic radiographs, the following cone angles are preferred:

1. Maxillary anterior teeth (straight facial)
2. Maxillary premolars and molars (mesial angle)
3. Mandibular incisor teeth (distal angle)
4. Mandibular canines (mesial angle)
5. Mandibular premolars (mesial)
6. Mandibular molars (distal).

All teeth require specific film placement and cone positioning for working films (Figure 9).

Mandibular Molars

As previously emphasized, the film must be positioned parallel to the lower arch. The *standard* horizontal X-ray projection then is at a right angle to the film (perpendicular), as shown in Figure 10. The two mesial canals are superimposed one upon the other and appear as a single line.

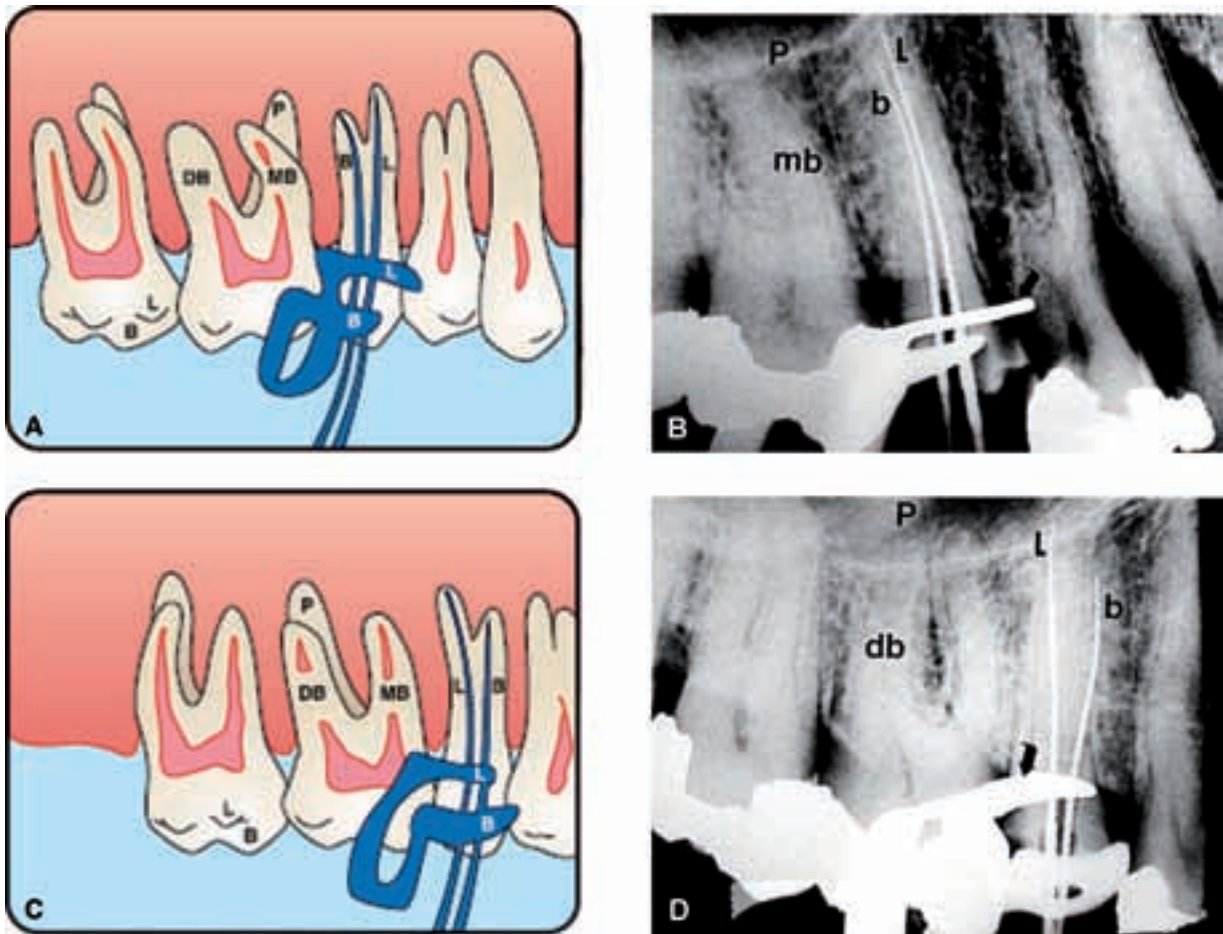

Figure 8 Applying the SLOB (same *lingual*, *opposite buccal*) rule to determine the cone angle. Clues that the cone is oriented from the mesial: **A**, and **B**, The mesial–buccal (MB) root lies over the palatal (P) root, that is, the lingual (palatal) root has moved mesially; the lingual arm of the rubber dam clamp (arrow) has moved mesially. The canine is visible. Once it has been determined that the radiograph was taken from the mesial, the lingual root (toward the mesial) of the premolar is defined. **C**, and **D**, Radiograph of the same teeth taken from the distal. Clues are reversed. The canine is not visible. The lingual premolar canal is now toward the distal. Reproduced with permission from Goerig AC. In: Besner E, et al., editors. *Practical endodontics*. St Louis (MO): Mosby; 1993, p. 54.

Figure 9 **A**, maxillary film/central beam (arrows) position. **B**, mandibular film/central beam (arrows) position. Reproduced from Walton R. Principles and practice of endodontics, 3rd ed. Philadelphia: Saunders and Co.; 2002 p.147.

Figure 10 Mandibular molars. **A**, Central ray directed at right angle to film positioned parallel to arch. **B**, Limited information is gleaned from the radiograph because of superimposition of structures and canals. Reproduced with permission from Walton RE.²⁷

Figure 11 Mandibular molars. **A**, Central ray directed at 20° mesially to film positioned parallel to arch. **B**, Two canals are now visible in both roots of the first molar (black arrows). Open arrow indicates confusing root outlines. Reproduced with permission from Walton RE.²⁷

Through the *Walton projection*, however, the roots can be made to “open up.” This is done by directing the central beam 20 to 30° from the mesial (Figure 11A). In Figure 11B (black arrows), the two canals in each root can now be readily discerned. The contrast gained by varying the horizontal projection is seen in a clinical case with four canals. Figure 12A taken at a right angle, clearly shows the four instruments superimposed on

one another. Figure 12B, on the other hand, taken from a 30° variance in horizontal projection, emphasizes the third dimension: the separation of the instruments in the canals. By applying Ingle’s rule (MBD: project the central beam from the *mesial*), the *buccal* canals are toward the *distal*, the *lingual* canals toward the *mesial*.

Another point concerns a frequent mistake in “reading” periradicular radiographs. It can best be

Figure 12 Mandibular molars. **A**, Right-angle horizontal projection superimposes four files, one on the other. **B**, Horizontal variance of 30° separates four canals. SLOB (same *lingual*, opposite *buccal*) rule proves lingual canals are to the mesial. Reproduced with permission from Walton RE.²⁷

Figure 13 **A**, X-ray beam passing directly through two thicknesses of root structure presents intensified image on film. **B**, Note radiopaque root outline inside lamina dura. B reproduced with permission from Walton RE.²⁷

illustrated by a cross-sectional drawing of molar root structure. Roots containing two canals are often hourglass-shaped (Figure 13A). When an X-ray beam passes directly through this structure, the buccal and lingual portions of the root are in the same path (arrows). Because a double thickness of tooth structure is penetrated by the X-rays, it is seen in the film as a radiopaque root outline in close contact with the

lamina dura. This is readily apparent on the radiograph (Figure 13B).

By aiming the cone 20° from the mesial, however, the central beam passes through the hourglass-shaped root at an angle (Figure 14A). In this case, the two thicknesses of the root are projected separately onto the film. Because less tooth structure is penetrated by the X-ray, the image on the film is less dense. A

Figure 14 **A**, X-ray beam aimed 20° passes through single thicknesses of hourglass root, leaving less dense impression on film. **B**, Radiolucent line is apparent (open arrow) and may be confused with root canal. Note that it emerges at gingival, not into pulp chamber. Black arrows indicate regular canals. B reproduced with permission of Walton RE.²⁷

Figure 15 Mandibular premolars. **A**, Central ray directed at right angle to film positioned parallel to arch. **B**, Radiograph reveals one canal in each premolar, although abrupt change in density (arrow) may indicate bifurcation. Reproduced with permission from Walton RE.²⁷

radiolucent line is clearly seen in Figure 14B (open arrow). This radiolucent line can be erroneously interpreted as a root canal. By following up the length of the line, instead of entering the pulp chamber, the line can be traced to the gingival surface of the root; this is the lamina dura. This simple interpretive error can easily lead to gross mistakes.

Mandibular Premolars

The importance of varying the horizontal angulation when radiographing mandibular premolars is demon-

strated in Figure 15A. The central beam is directed at a right angle to the film. What appears to be a single straight canal is discernible in each premolar (Figure 15B). There is an indication, however, in the image of the first premolar that the canal might bifurcate at the point of the abrupt change (“fast-break”) in density (arrow).

Directing the central ray 20° from the mesial in the *first premolar* (Figure 16A) causes the bifurcation to separate into two canals (Figure 16B). The tapering outline of the tooth, seen in both projections, would

Figure 16 Mandibular premolars. **A**, Central ray directed at 20° mesially to film, parallel to arch. **B**, In first premolar, two canals that are clearly visible (arrow) probably reunite, as indicated by sharply tapered root. Reproduced with permission from Walton RE.²⁷

Figure 17 Maxillary molars. **A**, Central ray is directed through maxillary molar at right angle to inferior border of film. Arrow and dotted line passing through malar process indicate it will superimpose over first molar. **B**, Superimposition of first molar roots, sinus floor, and malar process (white arrow) confuse the diagnosis. Reproduced with permission from Walton RE.²⁷

indicate, on the other hand, that the two canals undoubtedly rejoin to form a common canal at the apex. In both the right-angle and 20° variance projections, the *second premolar* appears as a single canal.

Maxillary Molars

Maxillary molars are consistently the most difficult to radiograph because of their more complicated root and pulp anatomy, the frequent superimposition of portions of the roots on each other, the superimposition of bony structures (sinus floor, zygomatic process) on root structures, and the shape and depth of

the palate. Each of these, singly or in combination can be a major impediment.

As is true of the mandible, the complex root anatomy and superimpositions may be dealt with *by varying the horizontal* angulations. Film placement must again be parallel to the posterior maxillary arch, not to the palate.

The standard right-angle projection for a maxillary first molar, illustrated in Figure 17A, produces the image seen in Figure 17B, wherein the zygomatic process is superimposed on the apex of the palatal root (arrow) and the distobuccal root appears to

Figure 18 Maxillary molars. **A**, Central ray directed at 20° mesially skirts malar process, projecting it distally. **B**, Distobuccal root is cleared of palatal root and malar process is projected far distal (white arrow). Between right-angle and 20° projection, all three roots are clearly seen. Reproduced with permission from Walton RE.²⁷

overlie the palatal root. The sinus floor is also superimposed on the apices of both the first and second molars. When the horizontal angulation is varied by 20° to the mesial (Figure 18A), the zygomatic process is “moved” to the distal of the first molar and the distobuccal root is cleared of the palatal root (Figure 18B, arrows).

The *opposite projection* also can be used to isolate the mesiobuccal root of the first molar, that is, the central ray may be projected from 20° *distal* to the right angle (Figure 19A). Although this projection distorts the shape of the mesiobuccal root, it also isolates it (Figure 19B), so

that the canal is readily discernible (arrow). Also the zygomatic process is moved completely away from any root structure, including the second molar. The same technique illustrated here for the maxillary first molar can be applied to the second or third molars by directing the central beam at a horizontal variance through those teeth.

Maxillary Premolars

Variance in the horizontal projection has great value in maxillary premolar radiography, particularly for the *first* premolar, which generally has two roots and canals, but sometimes three. The clinical efficacy of the Walton

Figure 19 Maxillary molars. **A**, Central beam projected 20° from the distal. **B**, Mesiobuccal root of the first molar is isolated (black arrow) and second and third molars are cleared of malar process, which is projected forward (white arrow). Sinus floor may be “lowered” or “raised” by changing vertical angulation. Reproduced with permission from Walton RE.²⁷

Figure 20 Maxillary premolars. **A**, Horizontal right-angle projection produces illusion that maxillary first premolar has only one canal. **B**, Varying horizontal projection by 20° from the mesial separates two canals. Buccal canal is distal (MBD). Reproduced with permission from Walton RE.²⁷

technique is well illustrated in Figure 20. The right-angle horizontal projection produces the single canal image seen in Figure 20A. By varying the angulation by 20°, however, the two canals are separated (Figure 20B), giving an unobstructed view of the obturation quality in both canals.

Mandibular Anterior Teeth

Aberrations in canal anatomy in the *mandibular* anterior teeth are infamous. Variance of the horizontal X-ray projections in this region will bring out the differences. Figure 21A illustrates the standard X-ray projection bisecting the film held parallel to the arch. The incisor

Figure 21 Mandibular anterior teeth. **A**, Film placement for modified parallel technique. Horizontal central beam projection at right angle to film. **B**, Single canals seen in central incisors with only suggestion of two canals in lateral incisor. In distorted image of canine, note broad labiolingual canal dimension (arrow). Reproduced with permission from Walton RE.²⁷

Figure 22 Mandibular canine. **A**, Film is positioned for canine radiograph. Horizontally, central beam is projected at right angle to film. **B**, Canine image is single straight canal, but incisor image reveals bifurcated canals that reunite in narrow tapered root (arrows). Note “bonus” image of bifurcated canals. First premolar. Reproduced with permission from Walton RE.²⁷

teeth appear to have single canals. But a broad single canal is seen in the distorted canine image (Figure 21B).

By varying the film placement and projecting directly through the canine, as seen in Figure 22A (which is about 30° variance for the incisors), separate canals appear in the incisors (Figure 22B, arrow); the canals join at the apex. This would be expected, however, when viewing the tapered incisor roots seen in both horizontal projections; the roots are far too narrow to support two separate canals

and foramina. Once again, the abrupt change in canal radiodensity in the premolars (arrow) indicates a canal bifurcation.

Maxillary Anterior Teeth

Although canal or root aberrations appear less frequently in the maxillary anterior teeth, root curvature in the maxillary lateral incisors is a particularly vexing problem. Grady and Clausen³⁰ have shown, for example, how difficult it is to determine when foramina exit

Figure 23 **A**, Labiolingual projection through canine shows instrument apparently at apex with slight distal curvature. **B**, Mesiodistal projection reveals instrument actually emerging from labial short of apex. **C**, Instrument perforating foramen to labial well short of radiographic root end. Photos courtesy of Dr. John R. Grady and Dr. Howard Clausen.

to the labial or lingual. Their radiographs of extracted teeth matched with photographs of instrument perforation short of the apex are a warning to all (Figure 23).

EXTRAORAL FILM PLACEMENT

This is useful for patients who cannot accommodate or tolerate intraoral film placement, usually because of gagging or trismus. Acceptable diagnostic and working films are possible.³¹ This requires special positioning of cone and film (Figure 24).

PROCESSING

Another deterrent has been the length of time required to process films. Old, weakened solutions greatly increase the time required for processing. Moreover, adherence to the manufacturer's recommended temperature and time (68°F for 5 to 7 minutes) for developing and clearing has hampered "on-the-spot" processing and viewing.

Ingle et al.³² demonstrated, in a well-controlled blind study, the effects of varied processing tempera-

tures. A processing temperature of 92°F yielded, in less than 1 minute, the most acceptable radiographs. At 92°F, using Kodak developer and fixer mixed to company specifications, *development required only 30 seconds* and fixation required 25 to 35 seconds, with no loss of quality. By comparison, at 70°F temperature, it required 5 minutes' developing time and 10 minutes' fixing time for Ultraspeed film. Ektaspeed is slightly better: 72 to 80°F for 2 1/2 to 4 minutes' developing and 2 to 4 minutes' fixing time. All films need to be *final washed* for at least 30 minutes.

For rapid processing, small quart-size tanks are adequate and economical. Frequent change of solutions is recommended.

RAPID-PROCESSING SOLUTIONS

Concentrated chemicals, such as *Kodak's Rapid Access* solution, have become very popular in endodontic practice. Although more expensive, they save measurable time, requiring only 15 seconds' developing and 15 seconds' clearing time in the fixer at room temperature.

Figure 24 Extraoral film placement. Useful for patients who cannot accommodate or tolerate an intraoral film. The film or sensor is placed on the cheek. Increasing the exposure time is necessary—approximately double. **A**, Maxillary posterior: The cone is positioned a negative 45° to the occlusal plane. **B**, Mandibular posterior: The cone is positioned a negative 35°.

Four rapid-developing solutions were compared, processing both Ultraspeed and Ektaspeed films. Film fog became a problem as the solutions deteriorated with time. Kodak Rapid Access had to be changed every day, whereas the other solutions, Colitts (Buffalo Dental, Syosset, NY), IFP, and Instaneg (Neo-Flo, Inc., Chicago, IL, USA), deteriorated over 60 days. Developing time and 3 to 5 seconds' rinse time between developing and fixing are essential.³³ These rapidly processed films will fade or discolor with time.³⁴ This change can be prevented, after viewing, by returning the wet film for a few minutes of fixation, followed by washing for 30 minutes, and then drying. The films will then retain their quality indefinitely.

TABLE-TOP DEVELOPING

For quick turnaround and ease of processing, combining rapid-speed solutions with a *table-top processing hood* greatly improves radiographic reporting, particularly working films. These hoods are often used right in the operatory. The film is passed through light-proof cuffs; hand movement is seen through the red Plexiglas cover. The rapid solutions and rinse water can be in small cups.

B. DIGITAL IMAGING FOR ENDODONTICS

ALLAN G. FARMAN, RAMYA RAMAMURTHY, LARS G. HOLLENDER

Many acronyms have come about as a result of the development of technology in radiography and the need for terms to describe concepts. The following glossary of the acronyms used in this chapter will assist the reader in understanding these new concepts.

Glossary of Acronyms

AEC: Automatic Exposure Compensation is an enhancement feature that compensates for image variations due to exposure.

ALARA: Acronym for “As Low As Reasonably Achievable,” an important principle in radiation protection.

CBCT: Cone-Beam Computed Tomography is a 3D imaging device that integrates a series of transmission images taken over an arc of 180° or greater.

CBVCT: Cone-Beam Volumetric Computed Tomography (synonym of CBCT).

CCD: A Charge-Coupled Device is an image sensor consisting of an integrated circuit containing an array of linked or coupled, energy-sensitive capacitors.

CDR: Computed Dental Radiography. Digital intraoral sensor manufactured by Schick Technologies (A Division of Sirona AG).

CMOS: Complementary Metal Oxide Semiconductor. This represents a major class of integrated circuits including image sensors.

CMOS-APS: CMOS Active Pixel System.

DICOM: Digital Imaging and Communication in Medicine. The internationally referenced standard for improving the likelihood of interoperability of diagnostic images by setting file format standards and transmission protocols.

dpi: Dots per inch.

H&D: Hurter and Driffield. Descriptor applied to a curve relating optical density to exposure for film photography and radiography.

IP: Imaging Plate. The sensor plate used for photostimulable phosphor (PSP) imaging.

ISO: International Standards Organization.

MB2: For maxillary molar, mesiobuccal root second canal.

PSP: Photostimulable phosphor. An imaging system using IPs that store energy from transmitted X-rays. The PSP IP is processed using laser scanning.

RVG: RadioVisioGraphy. Radiographic system proprietary to Kodak Dental Imaging; Term applied to the first commercial dental digital detector.

SNR: Signal-to-Noise Ratio.

TACT: Tuned Aperture Computed Tomography. A system developed by Richard Webber that integrates a series of transmission images taken from varying beam geometry to tomosynthesize a limited 3D perception.

The success of endodontic treatment is dependent on the identification of teeth requiring such treatment, and then the recognition of the root canal system, so it can be cleaned, shaped, and obturated.¹ Endodontic therapy relies on a series of radiographic images made at different stages of the treatment: preoperatively, periodically during instrumentation, and postoperatively. Radiographs provide important clues about hard and soft tissues of the teeth, including the pulp chamber and root canals. They also facilitate the estimation of root canal length. Furthermore, they aid in detecting tooth fractures and foreign bodies following trauma, provide useful information of the periradicular region, and assist in evaluating post-treatment healing. Hence, radiography is an important adjunct to endodontic diagnosis and image-guided treatment. The use of digital technologies can facilitate the process by speeding image acquisition and display.

The first dental radiograph is attributed to Walkhoff of Braunschweig, Germany, who on January 14, 1896 made images of the crowns of teeth on both sides of his

own jaw using silver halide emulsion on glass plates.² The exposure time was 25 minutes. The thickness and rigidity of the glass plate were akin to those of present-day solid-state digital X-ray detectors; today, however, acquisition can be as fast as one-tenth of a second.

Edison invented the fluoroscope as film imaging was obviously too slow in the 1890s; Eastman, founder of the Eastman Kodak Corporation, was quick to point out, though, that the fluoroscope could not fit inside the mouth. He tasked Stuber, a future President of Eastman Kodak, with the development of a silver halide X-ray film specifically for dentistry.³ Eastman Kodak produces this product to this day.³⁻⁸

Kells, in 1899, was among the first to use a radiograph to determine tooth length during root canal therapy.⁹ One year later, Price drew attention to incomplete root canal therapies resulting in failure as evidenced by radiographs.⁹ The discovery of the X-ray laid a foundation for a new era in the field of endodontics. It took more than eight decades for the next major advance in dental X-ray sensor technology to occur; a patent was issued in Europe to Mouyen in 1983 and in the United States in 1986.¹⁰ Solid-state imaging, using indirect exposure of a charge-coupled device (CCD), became commercially available around 1989 in Europe, with FDA approval for use of the technology in the United States being granted later that same year.

The invention of digital intraoral radiography has “endodontic roots.” In the 1970s Mouyen, then a dental student at the University of Toulouse, France, tells the story that because the distance between the endodontic clinic and the film processors several floors below spurred the idea of finding a way to create instant X-ray images for “operative” purposes. Mouyen realized that the chip in his video camera could detect light and that X-rays could be converted to light by scintillators such as the screens used in extraoral radiography cassettes. In other words, almost 90 years after the discovery of the X-ray, available technology could indeed permit the placement of a “fluoroscope” in the patient’s mouth.

A few years following graduation as a dentist, Mouyen¹⁰ completed the DERSO—a French equivalent to the PhD in engineering—and went on to develop a prototype digital radiographic system that he named RadioVisioGraphy (RVG). The RVG patent was licensed by a French Company, Trophy Radiologie, and digital imaging for operative radiology in dentistry was born (Figure 1). In 1989, in a special issue of the “National Geographic,” celebrating the bicentennial of the French Revolution, the RVG was

included among 10 major French inventions, alongside such inventions as the Train Grand Vitesse (TVG), the Concorde, and the Arienne space rocket. Trophy Radiologie has since been acquired by Kodak Dental Imaging.

Since 1989, there have been seven new generations of RVG, and there are now many alternate solid-state systems (e.g., Figure 2) that can produce almost instant images electronically. Although these images are essentially “instant,” most are not “direct” as the solid-state systems, for the most part, employ a scintillator to convert X-rays to light, and it is the analog light signal that is then converted to a digital image.

Furthermore, it is possible to replace silver halide film by photostimulable phosphor (PSP) plates that interact directly with X-rays but require the added step of subsequent processing by laser scanning to convert the latent image to one that can be viewed on a computer monitor screen.

Digital Intraoral X-Ray Imaging Options

DIGITIZATION USING SECONDARY CAPTURE OF ANALOG FILM IMAGES

Conventional X-ray films consist of a polyester sheet covered on both sides by a thin layer of silver halide emulsion that absorbs X-ray photons resulting in a latent image. When the latent image is developed using developing chemicals, the silver halide crystals are converted into metallic silver (silver is not black but gives such an impression in granular form within the processed radiograph). The unexposed crystals are later removed from the emulsion during the fixing process. This procedure, including the unpacking of the film in a light safe environment, usually takes several minutes and can produce a visible image of high diagnostic quality even when automatic processing is utilized, as long as optimal procedures are employed. Unfortunately, optimal procedures are not always employed in dental practices. To digitize the analog film image adds another time-consuming step, and the extra step also leads to the possibility of impaired image quality.

Once a visible film-based image has been produced, it is possible to use a flat bed scanner with a transparency adaptor to digitize the image by secondary capture. Flat bed scanners are preferred over cameras as the latter is more prone to optical distortion and added noise from light reflected from the surface of the radiograph film. For scanning, the parameters should be

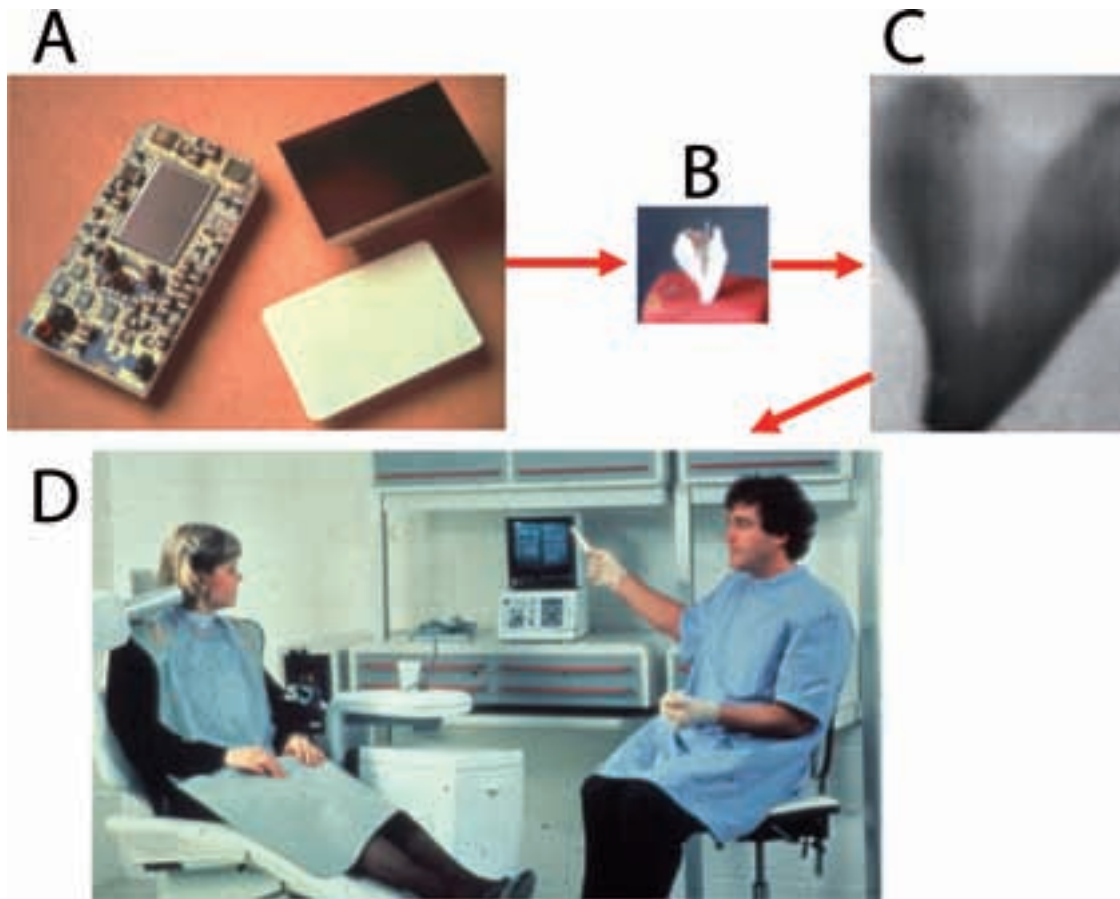

Figure 1 **A**, Components of the RadioVisioGraphy (RVG)-32000 showing the solid-state electronics board with charge-coupled device (CCD) chip, the scintillator, and the fiber optic plate used to reduce the size of the image to the size of the CCD. The fiber optic was made of tungsten glass that protected the CCD from direct exposure to X-rays. **B**, Primary tooth of Mouyen's daughter. **C**, The first "clinical" RVG image achieved in Dr. Mouyen's living room of this tooth. **D**, Commercial version of the RVG with Mouyen himself in the blue gown.

Figure 2 Demonstration of the diversity of available intraoral X-ray sensors.

set at high-definition grayscale images and scanned at a minimum of 300 dots per inch (dpi) using a transparency adaptor and acquisition software parameters set to “transparency.” Secondary capture images are dependent on the person making the input and associate such information as right versus left, patient name, procedure date, and so forth. This can be subject to “human error.”

Conventional X-ray film has survived more than 110 years in dental radiography. It obviously is capable of providing useful diagnostic information. However, disadvantages of analog X-ray film include the following:

1. Inefficiency as photon detectors, therefore requiring a relatively high radiation exposure.
2. Film packet is thin and can be felt by the patient to “cut into the tissues.”
3. Film is not rigid and hence can bend resulting in a distorted radiographic image.
4. Produce static images with no availability of post-image treatments other than varying the brightness of the viewbox illumination.
5. Exposure errors and suboptimal processing conditions can result in poor image quality that is not immediately obvious.
6. Film processing is relatively time-consuming.
7. Costs for maintaining a darkroom.
8. Silver in spent processing chemicals has the potential to cause environmental pollution.
9. Duplicate radiograph in a double film packet is of very slightly lower density compared with the top film. Physicochemical duplication of film radiographs results in copies of higher contrast and less detail.
10. Archiving radiographic film radiographs in physical patient files requires extra storage space in the office. Retrieving radiographs can take time.
11. Intraoral film radiographs not appropriately mounted and labeled cannot in themselves be associated for certainty with a given patient or time of exposure. Although one cannot exclude the possibility that digital radiographs may be attributed to the wrong patient, the use of a Digital Imaging and Communications in Medicine (DICOM) file format that is appropriately populated makes this less likely to occur.

DIGITAL RADIOGRAPHY

Figure 2 represents some recent choices in intraoral digital X-ray systems for dentistry. Several of these systems may share an identical detector; however, they generally differ in electronics and the application

software supplied. There is increasing acceptance of filmless X-ray alternatives in dentistry. As of 2006, approximately 28% to 40% of US dentists using software from the three top vendors of practice management packages were using digital X-ray detectors. This represented a fivefold increased penetration of the technology over the past 2 to 3 years. The adoption of digital imaging technologies by endodontists is undoubtedly much greater than is the case for general dental practice. With the continuous addition of improvements and sophistications in the already existing digital systems and introduction of new systems, the diagnostic quality of digital intraoral systems is now generally considered equal to conventional X-ray film even for tasks where film is known to do well such as in endodontic assessment and detection of proximal dental caries.¹¹

Digital systems utilize computer technology in the capture, display, enhancement, and storage of radiographic images. Computers work on the binary number system consisting of two digits (0 and 1) to represent data. These two characters are called bits (binary digits), and they form “words” of eight or more bits in length called bytes. The total number of possible bytes for 8-bit language is $2^8 = 256$. The analog-to-digital converter (ADC) transforms analog data to digital data based on binary number system. The strength of the output signal is measured and assigned a number from 0 (black or white depending on designation) to 255 (white or black—opposite of “0”) according to the intensity of the electric signal. These numeric assignments translate into 256 shades of gray in an 8-bit system. A digital image consists of a number of pixels (picture elements), and each pixel is represented by a number corresponding to its gray level. The pixel is the smallest picture element of the image, and the resolution of an image is directly related to the pixel size among other factors. Images of 12, 14, or 16 bits will have a greater range of pixel values and also consume greater memory space of the computer. For instance, a 12-bit image can have a range up to 4,096 gray values, and window and level adjustments can permit selection of the gray levels to be displayed on the monitor as the latter is usually restricted to 256 gray levels at one time.

The two major technologies presently used in intraoral digital X-ray systems are as follows:

1. Solid-state detectors (Figures 3 and 4)
 - a. Charge-coupled device (CCD)
 - b. Complimentary metal oxide semiconductor (CMOS)

Solid-state detectors (CCD and CMOS) can be indirect detectors using a scintillating screen such as

Figure 3 Indirect solid-state X-ray sensor using a scintillator to convert X-rays to light photons. The image represents a small section of such a sensor.

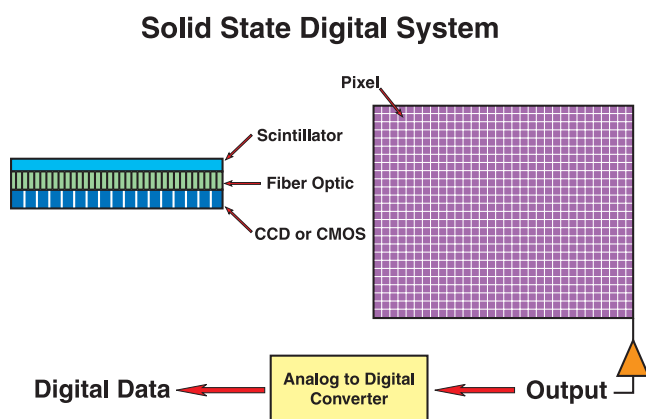

Figure 4 Solid-state sensor process. With the charge-coupled device (CCD), the pixel wells are read out in sequence, whereas with the complimentary metal oxide semiconductor (CMOS), each pixel can be read independently.

cesium iodide or gadolinium oxysulfide, or (less commonly) can use direct conversion of X-ray photons to electrons (e.g., Cadmium-Telluride technology).

2. Storage phosphor detectors (Figures 5 and 6)
 - a. Photostimulable phosphor (PSP)

Working Principles of Digital Systems¹²

SOLID-STATE SYSTEMS

Charge-Coupled Device

The CCD is composed of an electronic circuit embedded in several thin layers of silicon. The silicon

Figure 5 The intraoral photostimulable phosphor (PSP) is composed of a phosphor layer, a thin protective layer, support, and backing. X-ray energy is stored during exposure and subsequently released as photoluminescence on application of energy from a scanning laser. The emitted light is photomultiplied and then converted to an electronic signal that is digitized. (Note that this figure is of the PSP during exposure only and represents only a small section of a PSP.)

chip usually is composed of an array of light sensitive pixels (picture elements), and each pixel consists of a small electron well into which the X-ray or light energy is deposited upon exposure. Each silicon atom in the detector chip is covalent with another silicon atom. When light photons strike the silicon and the energy exceeds the strength of the covalent bond, an electron hole pair is formed. Alternatively, electrons can be produced by a coating layer when direct technology is used instead of a scintillator layer. Either way, an electric charge is established by release of electrons. The electric charge in each “pixel” well is proportional to the incident X-ray or photon energy. Charge-coupling is a process by which the electrons from one well are transferred to another in a sequential manner, and this transfer concept has been compared to a “bucket brigade.” The charge of each pixel is converted from an analog electric signal representing the energy absorbed by the solid-state chip to a digital signal representing the discrete numeric pixel values for image display on a computer monitor.

Complimentary Metal Oxide Semiconductor Active Pixel Technology (CMOS-APS)

CMOS chips are commonly used in digital cameras, video cameras, and computers. Externally, CMOS detectors appear similar to CCDs, but the former use an active pixel technology, that is, each CMOS-APS has an active transistor built into each pixel and provides a reduction by a factor of up to 100 in the system power (translating into electric voltage) required when compared with CCDs. This has permitted the introduction of wireless radio frequency (RF) transmission of the acquired image. Other advantages of

Figure 6 Example of a photostimulable phosphor (PSP) laser scanner (Scan-X; Air Techniques, NY). Detail shows loading area for the individual PSPs. Scanners come in a variety of sizes and configurations from the various vendors of this technology.

the CMOS-APS include design integration and a potential for relatively low cost manufacture that, however, has not so far translated into cost savings for the consumer. In addition, the APS system eliminates the need for charge transfer between adjacent pixel wells extending the exposure latitude by suppressing “pixel blooming.”

STORAGE PHOSPHOR DETECTORS

Photostimulable Phosphor

The PSP imaging plate (Figure 7) works on the principle of radiation-induced emission of photostimulated luminance. PSPs generally contain barium fluorohalide crystals with small amounts of bivalent europium atoms as an activator. When a storage phosphor imaging plate is exposed to X-radiation, the europium atoms in the phosphor crystalline lattice are ionized liberating a valence electron. This results in the formation of electron vacancy. The valence electrons are excited to the level of conduction band where they travel freely until trapped by so-called Farbzentren centers present in halide crystals to form metastable electrons with an energy level slightly lower than the conduction band but greater than that of the valence bond. These trapped metastable electrons constitute the latent image and their number is proportional to the number of incident X-rays. When the latent image is exposed to the red light of solid

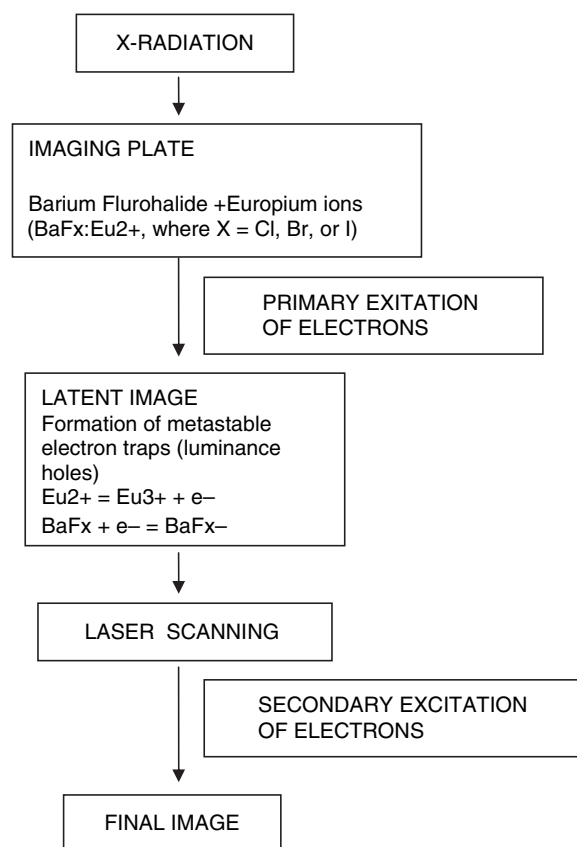

Figure 7 Flow diagram to demonstrate the sequence involved in the formation of a photostimulable phosphor (PSP) image.

state laser, the metastable electrons are again excited to reach high-energy conduction band where they recombine with Eu^{3+} atoms and return to low-energy valence band ($\text{Eu}^{3+} + e^- = \text{Eu}^{2+}$). This results in the liberation of energy, emitted as blue light. The light is registered by a photo multiplier tube and converted into an analog electric output signal that is digitized, resulting in a digital image. Each pixel has a numeric value that is proportional to the amount of light emitted from the corresponding area of the PSP imaging plate.

Advantages of Digital X-Ray Imaging

Potential advantages of digital X-ray over analog film imaging include the following:

1. Reduced time between exposure and image formation when using solid-state detectors.
2. Reduced radiation dose per image sometimes possible.
3. Multiple exposures, from various angles, both vertical and horizontal, may be made without moving the sensor once positioned.
4. Elimination of chemical processing and disposal of spent chemicals.
5. Images can be duplicated any number of times without any loss of image quality (each is a perfect clone of the original).
6. Images can be stored and retrieved electronically.
7. Images can be transmitted electronically for referrals and other purposes.
8. Dynamic nature of the image with the ready option of post-imaging enhancements.
9. Digital systems also have measurement tools that given a suitably positioned fiducial reference (e.g., an endodontic instrument of known length placed in a root canal) can accurately measure, for example, the root canal working length.
10. Reusable detector reduces expenditure on consumables.
11. With DICOM image file usage, digital images can provide greater security regarding radiographic image integrity and tags include such information as patient name, date of exposure, and laterality.
12. Wired detectors have an advantage when working on special needs patients as the wire makes swallowing or ingesting the detector unlikely.

Potential Disadvantages of Digital Imaging over Films

There are also some potentially negative issues that should be considered:

1. Relatively high initial investment cost if the practice has previously sunk costs in film-processing facilities.
2. Issues related to infection control as the detectors cannot be autoclaved.
3. Solid-state detectors are somewhat thicker and more rigid (however, this can also be an advantage in preventing disproportionate distortion from film bending).
4. Packaged PSP imaging plates (IPs) are thinner than prepackaged analog intraoral X-ray films and may not be held firmly in position in film holders.
5. As most current versions of CCD and CMOS detectors are wired, this could create patient psychological discomfort. It might also be a drawback for the inexperienced operator, requiring adjustments in technique and patience through the learning curve of a new methodology.
6. Competency using software may take time to master. The learning curve may be longer or shorter depending on the computer literacy of the operator.
7. With PSPs, the intraoral imaging plates have been prone to mechanical degradation necessitating replacement of plates to sustain image quality.
8. Although unlikely to occur given reasonable diligence, mishandling can cause mechanical damage with high replacement costs for CCD and CMOS detectors.

Examples of Digital Images Used in Endodontics

It is now appropriate to illustrate some examples of digital radiographic images used in the practice of endodontics so one might get a better appreciation of attainable image quality (Figures 8–10). It should, however, be remembered that the printed page is static and does not permit the modifications to image density and contrast that are available when the digital images are viewed on the computer monitor.

Figure 8 **A**, Endodontic instruments in a mandibular second premolar tooth with a radiolucent periapical pathosis. **B**, Mandibular molar with slight widening of the apical periodontal ligament space of the distal root. These images were made using the DentX Eva (CMOS) system from AFP/DentX (New York).

Figure 9 Endodontic evaluations using the Kodak RVG-6000 (Kodak Dental Imaging, Marne-la-Vallée, France) CMOS system. These details clearly demonstrate the ability of solid-state sensors to demonstrate periapical lesions and tooth length (even with long root length in rhizodontia).

CONVENTIONAL VERSUS DIGITAL: WHICH IS BETTER?

With the introduction of digital imaging systems in dentistry, a question arises: “How effective are these systems when compared with film for specific diagnostic tasks in endodontic practice?” The reported studies are rather consistent and have shown that the diagnostic ability of the digital image is equivalent to film-based radiographs as referenced in the subsequent sections of this chapter. The following discussion concentrates on investigations concerning diagnostic tasks in endodontology.

DETECTION OF PERIAPICAL LESIONS

Accurate assessment of the periradicular status is crucial in diagnosis, treatment, and evaluation of healing in endodontic therapy. However, from some reported studies, it is believed that periapical lesion cannot be detected until a comparatively advanced bone destruction, that is, not until the lesion erodes the junction between cortical and cancellous bone.^{13,14} Alternatively, it has been postulated that changes in the lamina dura are key to the detection of periapical lesions.^{15,16} Several studies have evaluated the efficacy of digital images in detecting periradicular bone changes. Most of the studies, concluded that digital imaging did not increase the rate of detection of lesions.^{15,17–20} Paurazas et al.,¹⁹ for instance, found no difference in diagnostic accuracy between film radiographs, CCD, and CMOS-APS systems in detecting periradicular lesions. However, the use of CMOS-APS system has been supported because of perceived

functional advantages over CCD systems such as “low cost,” reduced electric power requirement, and suggested increased life time of the product. Digital imaging was preferred over film-based imaging as the former, according to one report, requires 50% less radiation than the latter.

In 1994, Yokota et al.¹⁷ studied mechanically created lesions in human cadaver specimens using film radiographs and an early vintage RVG CCD X-ray detector. It was concluded that (1) when no lesion exists, conventional radiograph were more accurate than the vintage RVG; (2) when the lesion is enlarged to involve lamina dura and medullary bone, the vintage RVG was superior; and (3) when the lesion involved the cortical bone, there was no difference between a conventional radiograph and vintage RVG. This study was in agreement with a similar study conducted by Tirrell et al.²¹

It has been reported that digital images have been found to be more accurate than conventional radiographs when image enhancements are performed.²² In another study, image processing was found to be of limited value on diagnostic quality, but altering the basic functions such as contrast and brightness were preferred for the detection of periapical lesions.²³ However, Wallace et al.²⁴ concluded that enhanced digital images perform inferior to film-based images in periapical lesion detection. This was attributed to the observers’ lack of familiarity with digital images and lack of experience with the image enhancement procedures.

Other image-processing functions such as color enhancement and reverse imaging have been found to be of limited diagnostic value in the detection of

periapical lesions.²⁵ In this context, it should be noted that many times the enhancement leads to worse performance, although the subjective impression is that of improvement. It should be remembered that when enhancements are applied, they generally hide information, thereby making certain features stand out. Also many studies have used rather underexposed films or digital detectors, before the enhancement of the digital images leading to improved performance of the digital system. One has to caution the readers about these inherent fallacies and also point out the great variation sometimes reported among observers in periapical radiographic diagnosis. When high variability between observers is present, one can predict that the studies concerned will result in no proven differences between the modalities compared. Woolhiser et al.²⁶ even reported great variation in the seemingly straightforward task of estimation of root length, with variations for the same observation being as great as 1.5 to 8 mm. Nevertheless, they did conclude that observers using enhanced digital images outperformed the same observers using conventional radiographs.

EVALUATION OF ASSESSMENT OF ROOT CANAL LENGTH

A too short working length can result in infected tissue being left in the root canal, and this can then continue to damage the periapical tissue. Hence, a correct estimation of working length is crucial for endodontic success. The radiographic apex does not always coincide with true apex. Even though, the ISO recommended smallest file size for a working length radiograph is #15, files smaller than #15 are required for initial instrumentation in fine, curved, and calcified canals to prevent root perforation or ledge formation within the canal. The problem encountered with small-sized files is that the instrument tip will not always be clearly visible on a radiograph. Comparative studies have been conducted between film radiographs and digital detectors to evaluate their accuracy in estimating endodontic length and perceived clarity in visualizing fine endodontic files. It has been reported that digital systems closely approximate film radiographs in the accuracy they provide for practitioners in estimating root length.^{27,28} However, digital images were found to be inferior to film images when #10 rather than #15 files are used.^{29,30}

Cederberg et al.³¹ compared the difference in interpretation of the position of endodontic file tips between PSP imaging (Digora; Soredex, Helsinki, Finland) and intraoral radiographic film (Ektaspeed Plus; Kodak, Rochester, NY) for a limited number of patients ($n =$

13). Film radiographs were viewed using a 7× measuring magnifier. PSP was reported to outperform film radiographs in that a smaller difference was found between the file tip and root apex with digital imaging.

Eikenberg and Vandre²⁸ sectioned human skulls into 15 sextants. Teeth were then removed and 45 canals were instrumented to their apical foramina. Endodontic files were glued in place at random distances from the apical foramina. Image geometry was maintained by a custom mounting jig. Images were captured with two types of analog film and a solid-state digital radiographic system (Dexis). Digital images were read on a conventional color monitor (cathode ray tube) and a laptop screen (active-matrix liquid crystal display). Fifteen dentists measured the distance from the file tip to the apical foramen of the tooth. Results showed that the measurement error was significantly less for the digital images than for the film radiographs.

Martinez-Lozano et al.³² evaluated the diagnostic efficacy of an electronic system for the determination of working length, in comparison with two radiologic methods (conventional film and digital radiography). The study sample consisted of 28 root canals in 20 human mandibular teeth. A comparison was made between the working length measurements obtained by the radiologic methods and an apex locator, using as “gold standard” the observation of the actual file position within the root following selective grinding of the root tissue. It was concluded that none of the techniques was totally satisfactory in establishing the true working length. No statistical differences were proven comparing the techniques investigated.

DETECTION OF ROOT CANAL ANATOMY

Success of endodontic treatment depends mainly on the identification of all the canals in the tooth that can then be cleaned, shaped, and obturated. The ability to locate all the canals is crucial in determining the eventual success of the therapy, and radiographs are considered one of the important tools apart from clinical examination. Reported studies are contradictory to one another. Naoum et al.³³ compared conventional with PSP images to visualize the root canal system contrasted with radiographic contrast medium. The image clarity on conventional radiographs was found to be better than with Digora PSP images.

Nance et al.³⁴ studied maxillary and mandibular molars using conventional D-speed film radiographs versus tuned aperture computed tomography

(TACT) in the identification of root canals. TACT, using arrays of several digital images to tomosynthesize the third dimension, was reported to be superior to conventional film radiographs in the detection of root canal in molars. There was a reported 36% detection rate of the (elusive) second mesiobuccal canal (MB2) in maxillary molars and 80% detection rate of the mesiolingual canal in the mandibular molar using the TACT system. By contrast, with the film-based images, there was a somewhat unbelievable 0% detection of MB2 canals. This highly skewed result might be caused by using a standard paralleling technique for making conventional images, leading to overlap of canals.

In a similar study by Barton et al.,³⁵ parallax analog and parallax digital images were compared with TACT in the ability to detect MB2 canals in maxillary first molars. With TACT, there was 37.9% chance of locating the MB2 canal, which is consistent with the results of Nance's study. However, in this study, the success rate of detecting MB2 canals using film-based images was approximately equal to that using TACT, and TACT did not significantly affect the rate of detection of MB2 canals. It was also observed that the distance between first mesiobuccal and the MB2 canal is quite small and perhaps too minute for current TACT applications.

Stereoscopic radiographs might be helpful and would probably be superior to parallax radiographs viewed one by one. High-resolution cone-beam volumetric computed tomography (CBVCT) might provide a solution to this problem in the near future. The CBVCT characterization in three-dimensions of an apical dental cyst affecting the palatal root of a right maxillary first permanent molar tooth is demonstrated in Figure 11.

Recent studies using high-resolution CBVCT have shown that this technology might well have a role in defining the number of canals present in a tooth and the positions of the apical foramen.³⁶

Digital Subtraction Radiography

Given radiographs taken in precisely the same position and with the same beam geometry and exposure parameters, images can be subtracted to show changes over time. This technique has been largely conducted for research purposes in view of the difficulties experienced in practice in achieving images with reproducible projection geometry over time.

Digital subtraction has been performed for endodontic tasks, and digital detectors have been used for this

purpose (Figure 12).^{37–39} Yoshioka et al.³⁷ evaluated the efficacy of digital subtraction radiography using an old version of the RVG system (RVG-S) in a follow-up study of endodontically treated teeth. The intra-image variation of the original RVG-S image caused by dark current and sensitivity variations among pixels in this vintage digital system was corrected pixel-to-pixel. The inter-image variation was further corrected using a copper step-wedge attached to the detector. Standardized images were obtained using the same beam geometry at patient follow-up. Pixel values at the regions of interest, positioned on the periapical lesion, increased after endodontic treatment, and this change continued during an observation period of up to 545 days. It was concluded that subtraction radiology is possible for the purpose of endodontic follow-up.

Nicopoulou-Karayianni et al.³⁸ also evaluated the effect of root canal treatment on periapical lesions by conventional and subtracted digital radiographic images of patients. Better observer agreement was achieved by digital subtraction radiography during the evaluation than without digital subtraction at follow-ups 3 to 12 months after treatment.

Mikrogeorgis et al.³⁹ evaluated the suitability of digital radiograph registration and subtraction in the assessment of the progress of chronic apical periodontitis. Ninety cases of teeth with chronic apical periodontitis were studied. In each case, a preoperative radiograph was made, root canals were prepared, and a calcium hydroxide paste was placed in the root canals. Radiographic control and replacement of calcium hydroxide paste took place at 15-day intervals before final obturation. The root canals were obturated 1.5 months after the first appointment, and recall radiographs were made 2 weeks, 6 weeks, 3, 6, and 12 months after the obturation. Digital radiography using a solid-state detector was employed. Changes to the periapical tissue structure were detectable using digital subtraction, even during short time intervals.

Radiation Dose

The ALARA (*As Low As Reasonably Achievable*) principle advocates the use of the smallest possible radiation dose that can still produce an image without compromising diagnostic quality. Conventional direct exposure emulsion X-ray films are relatively poor detectors of radiation and can require relatively high radiation dosages to produce images of optimal diagnostic value.

By contrast, digital detectors can be more quantum efficient and, therefore, require lower radiation

Figure 11 i-CAT cone-beam volumetric computed tomography (CBVCT) demonstrating an apical dental cyst (green arrows). **A**, Axial section through the lesion. **B**, Constructed panoramic detail (magnified) of the same lesion. **C**, Buccolingual cross-sections of the lesion at 1 mm intervals. The lesion is clearly demonstrated for clinical diagnosis despite the relatively low-resolution 0.4 mm scan that was used in this case where the cyst was an incidental finding. High-resolution images with isotropic voxel dimensions of less than 0.1 mm can be performed with some CBVCT systems if needed to help in diagnosis.

exposure. On the other hand, intraoral X-ray films are now available in higher speed than heretofore and this has greatly increased film's quantum efficiency to radiation. Hence, with the use of high-speed films, it is possible to obtain high-contrast images at relatively low exposure. Underexposing X-ray film still tends to increase radiographic "mottle" and graininess of the images, giving an impression of a lack of sharpness in the image.⁴⁰ This finding was supported by Sheaffer et al.,⁴¹ who found that underexposed

radiographs, in an attempt to minimize radiation dosage, result in inferior images irrespective of film speed.

With the invention of increasingly more efficient digital X-ray detector technologies, with an added advantage of contrast enhancement as well as reported reduction in radiation dose, it might be possible to achieve diagnostically efficient images at lower exposures than with conventional film. Velders et al.⁴² found that it was possible to achieve a dose reduction

Figure 12 Digital subtraction comparing baseline (column 1) to follow-up images made at 3, 6, and 12 months following endodontic therapy (column 2). Column 3 indicates subtraction of respective follow-up images from the baseline radiograph. Progressive remineralization of the radiolucency at the apex of the distal root of the first molar is evident.

of approximately 95% compared with Ektaspeed film when digital systems were used for dental radiographic imaging. One should remember, however, that the use of such low dosages can impair image quality because of a reduced signal-to-noise ratio (SNR).

Although the possible dose reduction for thinner objects has, however, been questioned for a PSP detector, in a study by Huda et al.,⁴³ the low-contrast discrimination of PSPs was found to be superior to that of X-ray films when using the same exposure time. By way of contrast, in a study by Berkhout et al.,⁴⁴ it was found that the PSPs required 10 times more radiation than the minimally acceptable dose to produce images of preferred quality. Further these authors state that PSPs require more radiation than E-speed films and that dose reduction with digital technology can be achieved only when using solid-state systems. PSP systems have a wide dynamic range, much larger than CCD systems and films. PSPs are said theoretically to have an exposure latitude ratio of approximately 10,000:1.⁴³ Hence, they should be

capable of producing usable images over a wide range of exposures.^{43–48} The actual exposure latitude for PSP systems is dependent on the acquisition software and scanning electronics. It does not exceed 25:1 for PSP intraoral radiography when the relative exposure latitude is determined using clear discrimination of the enamel–dentin junction as the lower limit and pixel blooming or unacceptable levels of cervical burnout as the upper limit.⁴⁹

The effective latitude range for solid-state detectors can exceed 20:1 for some CMOS systems. However, intraoral X-ray systems using a CCD generally have narrower recording latitudes (<10:1), because high exposure results in pixel blooming.⁴⁹

Dynamic range, also known as latitude, corresponds to the range of exposures that will produce images within the useful density range. Radiographic modalities, that produce diagnostic images over a wide range of exposures, are said to have a wide dynamic range and vice versa. The Hurter and Driffield (H&D) curve was invented to characterize photographic emulsion some 5 years before the

Figure 13 Hurter and Driffield curve relating radiograph density to exposure.

discovery of the X-ray but was extended to include X-ray film radiographs (Figure 13). Using pixel values rather than film density, the H&D curve concept can also be applied to digital imaging. The straight-line portion of the curve for film corresponds to the dynamic range. This curve demonstrates for conventional film the relationship between exposure (log number of X-rays) and the optical density (darkness) of an image detector. The scale of useful densities for film radiographs ranges approximately from 0.5, which produces low density or light images, to 3.0, which results in darker images of high density. However, outside this range, images tend to lose diagnostic detail. For films, this curve takes a form of stretched letter S appearance, with the top horizontal portion of the curve called “shoulder” that corresponds to higher exposure and the lower portion called “toe” that corresponds to lower exposure. Exposure changes in these portions of the curve have little effect on density. Even little changes in the straight-line and vertical portion of the curve significantly affect image density. Thus, the more vertical the straight-line portion of the curve, the smaller is the latitude. This explains the relatively wider dynamic range of digital receptors, especially storage phosphors. The curve can be linear and wider with no shoulder or toe when compared with film images (Figure 14).

Many digital systems have an option of using an “image equalize” function, and this is commonly the

automated default setting. Equalization is a method of enhancing the contrast in a nonlinear fashion by stretching the pixel values disproportionately to obtain images of optimum image quality. In a study by Hayakawa et al.,⁵⁰ equalization exposure compensation for computed dental radiography (CDR) was found to be useful only for underexposed images but not for overexposed images. They also found that this compensation for underexposure did not significantly change the SNR. Furthermore, other studies have found that lower exposures, when severe, can in fact result in increased background noise and thus negatively affect the detection of small and low-contrast details within an object or tissue.⁵¹

Similar to equalize function in PSP images, the fourth generation RVG (RVG-4) had an option of automatic exposure compensation (AEC), which compensated for exposure errors by stretching the pixel value range to increase the contrast of structures within the images. It was found that both under- and overexposed images can be compensated using this algorithm. Because it can compensate for overexposure, it might lead to the risk of practitioners overexposing their patients. Moreover, it was also found that AEC reduces the SNR and produces disproportionate pixel values relative to exposure.⁵⁰ Newer versions, such as the RVG-6000, have dose indicator that warns the dentist in cases of exposure errors.

There is evidence that dentists, particularly endodontists, routinely prefer and view high-contrast and relatively dense images when performing endodontic tasks.⁴¹ Likewise, detection of occlusal caries was found to be more accurate when using darker radiographs.⁵² This is probably because higher exposure allows easier discrimination between small and low-contrast objects. Moving the exposure difference up on the H&D curve increased contrast results. The smaller the change in structure, the greater the contrast required to differentiate between adjacent structures. One of the methods employed to achieve required contrast is increasing the exposure. Furthermore, if there is superimposition of structure by the images of other objects, the signal of the latter has to be handled as additional noise. Thus, the dose has to be increased in order to notice the structure in the image. This is proposed by Thoms,⁵³ who believes that attempting a dose reduction will result in images having a low SNR and thereby reducing the visibility of small structures. However, higher exposures also negatively affect the diagnostic accuracy. Whereas images with lower exposures resulted in more false negatives, overexposed images resulted in higher false-positive responses.⁵⁴ With these rather contrasting studies in the literature and unanswered questions, there is

confusion regarding the exposure time that is actually required to produce images of diagnostic quality and more so in the detection of low-contrast objects. Questions that still need to be addressed are as follows: (1) What is the optimal exposure time or range of exposures required by each of the intraoral radiographic systems that are presently used? (2) Is high radiation exposure really necessary for endodontic tasks? (3) What are the effects of radiation dose on the detection of low-contrast objects such as fine root canals? Many of these questions have not yet been fully answered even for analog film radiography.

Summary

Digital imaging systems, using solid-state detectors, have definite advantages over analog film in terms of immediacy of image display and seem to be equal to film imaging for most tested diagnostic purposes. There is still a need, however, for further scientific validation of the best exposure strategies for imaging optimizing specific diagnostic tasks including those used for endodontics.

C. ULTRASONIC IMAGING

ELISABETTA COTTI

Given the importance of imaging systems in the diagnosis, description, follow-up, and study of endodontic lesions in the mandible and maxilla, as well as the development of advanced diagnostic systems in traditional radiology, alternative imaging techniques are constantly being investigated.^{1,2}

Osteolytic endodontic lesions in the jaws are a consequence of pulpal and periapical inflammation.³⁻⁵ The clinical diagnosis of a tooth with a root-end radiolucency of endodontic origin is apical periodontitis. However, following biopsy and depending on the microscopic features of an apical lesion, it may receive a histopathologic diagnosis of either granuloma or cyst. The possibility of making a clinical differential diagnosis between a granuloma and a cyst may be important in the management of such lesions, especially in predicting the outcome of endodontic treatment or explaining lack of healing.^{4,6-9} Unfortunately, radiographs allow visualization of hard tissues only and not soft tissues. Therefore, radiographs are not good guides for differentiating these types of lesions.¹

Basic Principles of Ultrasound Real-Time Imaging

Ultrasound real-time imaging, also called real-time echotomography or echography, has been a widely used diagnostic technique in many fields of medicine since 1942.^{10,11} The production of ultrasonic images is based on the generation and reflection of ultrasound waves. Ultrasound waves are generated as a result of the so-called *piezoelectric effect* by quartz or a synthetic ceramic crystal, when it is exposed to an alternating electric current of 3 to 10 MHz. Ultrasound waves, oscillating at the same frequency, are bundled by means of an acoustic lens and directed toward the area of interest in the body via an ultrasonic probe (transducer) (Figure 1A).

Various biologic tissues of the body possess different mechanical and acoustic properties. When the

ultrasound waves encounter the interface between two biologic tissues with different acoustic impedance, they undergo the phenomena of reflection and refraction. The echo is the part of the ultrasound wave that is reflected back from the tissue interface toward the crystal (Figure 1B). The crystal is capable of transforming an incoming ultrasound wave (echo) of the same frequency back to an electromagnetic wave. The echo is then transformed into electric energy, which in turn is transformed into a light spot, using a gray scale, into a computer monitor built into the ultrasound apparatus (Figure 2A and B).¹¹

The intensity of the echoes depends on the difference in acoustic properties between two adjacent tissue compartments: the greater the difference, the greater the amount of reflected ultrasound energy, the higher the echo intensity. Low echo signals appear

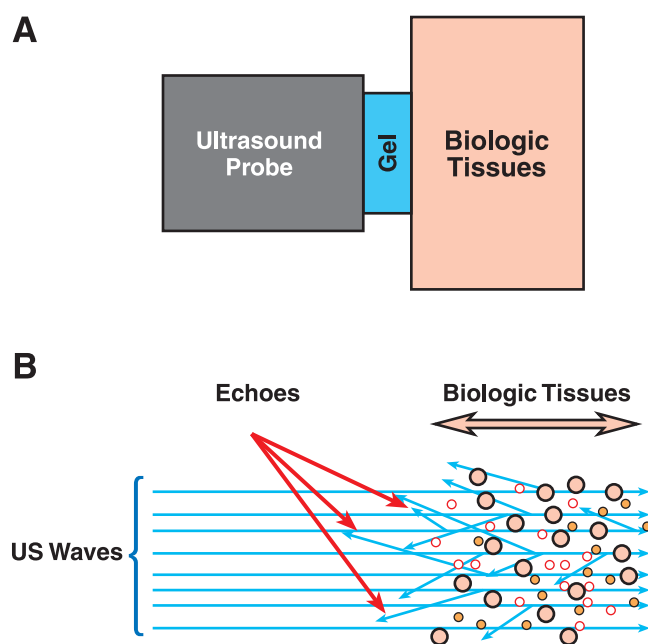

Figure 1 A, Schematic representation of sending ultrasounds into biologic tissue with a probe. **B**, Production of echoes from ultrasound waves sent into biologic tissues and reflected back.

Figure 2 Ultrasound technical equipment. **A**, Ultrasound imaging apparatus. **B**, Echographic probes and gel.

as dark spots whereas high echo signals appear as bright/white spots. The point in the tissue where the echo originates is calculated by the computer from the time delay between the beginning of the wave signal and the return of the echo. The ultrasound images seen on the monitor are produced by the automatic movement of the crystal over the tissue of interest. Because each movement of the crystal gives one image of the tissue (depending on its plane), and

an average of 30 images per second are produced, the tissue being examined will appear on the monitor as a sequence of moving images. The movement by the operator of the probe, on the area of examination, creates a change on the sector plane, thus allowing the creation of a “real-time three-dimensional image of that space.”^{10,11}

The interpretation of the gray values on the images is based on a comparison with those of normal tissues.

When an area in a given tissue has *high echo intensity*, it is called “hyperechoic.” When it displays *low echo intensity*, it is termed “hypoechoic”; if characterized by *absence of echo intensity*, it is called “anechoic.” Any fluid-filled area where no reflection occurs is anechoic, whereas bone, from which total reflection occurs, is hyperechoic. Areas that contain different types of tissues show a “dishomogeneous echo.”¹¹

The ultrasound examination can be supplemented by the use of color power Doppler (CPD) ultrasound to determine the perfusion of the tissue of interest. When applied to the ultrasound, examination with the CPD offers the opportunity to observe the presence and direction of the blood flow and the intensity of the Doppler signal with its changes in real time (*Doppler*), in the format of color spots superimposed on the images of blood vessels (*color*), and with very high sensitivity (*power*).¹¹

The Doppler ultrasound test uses sound waves transmitted to a vessel from a transducer in a probe. The part of the waves reflected back to the probe is processed by a computer that creates graphs or pictures representing the blood flow within the vessel. The movement of blood cells causes a change in pitch in the reflected sound waves (*Doppler effect*). The Doppler shift of the moving blood is monitored continuously to form the Doppler signal. Because the transmit frequency is about 2 to 4 MHz, the Doppler

shift of moving blood is in the audible range. The CPD technique combines ultrasound real-time imaging with the color encoding of the Doppler frequency shift and is used to visualize the presence and velocity of blood flow within an image plane. The frequency shift is color-encoded depending on the velocity and the direction of the blood flow relative to the transducer and is superimposed on the grayscale image. The way in which the frequency shifts are encoded is defined by the color bar located to the left of the image (Figure 3). Blood flow is assigned different hues that reflect the flow velocity and the insonation angle. Fast flow is assigned lighter hues whereas slow flows appear with deeper hues (Figure 3).^{12–14}

Positive Doppler shifts are caused by the blood moving toward the transducer and are encoded as red; negative Doppler shifts are caused by blood moving opposite to the transducer and are encoded as blue. Because CD (Color Doppler) presents some shortcomings such as dependency on the insonation angle and the “aliasing,” PD (Power Doppler) is best associated with it to improve its sensitivity to low flow rates. CPD is based on the integrated power spectrum, is angle independent, and is up to five times more sensitive in detecting blood flow than color Doppler.^{12–14}

Intravenous injections of contrast media increase the echogenicity of the blood by enhancing the

Figure 3 Picture representing the echo color power Doppler applied to the echographic examination of a periapical lesion. On the upper right the ultrasound image of the lesion is shown (framed), the colored spots represent the presence and direction of the blood flow (color Doppler). The intensity of the Doppler signal with its modification in time is represented in the lower part of the figure.

difference in acoustic impedance in the area of interest, thus rendering the CPD examination more sensitive.^{11,13}

Ultrasound imaging is considered to be a relatively safe technique. Ultrasound waves targeted into biologic tissues are absorbed in the form of heat energy. This could be hazardous because it causes cavitation and vibration.¹¹ On the other hand, it is important to note that the crystal emits energy only during 0.1% of its activity, whereas the remainder of the time it receives echoes: it is “listening.” Any potential adverse effects of the system depend on the length of application time of the sound energy; safety, therefore, is achieved by limiting the number and the repetitions of the examinations. No adverse effects of ultrasound waves have been reported in experimental and clinical studies.^{15–17} In any case, the risk entailed is much lower than that associated with radiographic investigations.¹⁷

Ultrasound Imaging in the Study of Periapical Lesions

In 2001, a pilot project was conducted at the University of Cagliari, Italy, to try ultrasound real-time examination in the study of periapical lesions of endodontic origin. Several patients diagnosed with apical periodontitis, based on clinical signs and symptoms and intraoral and panoramic radiographs, were asked to participate. They signed an informed consent and had echographic examinations of the areas affected by the apical lesions. An endodontist, an oral surgeon, and a radiologist expert in echography were involved in the project.

After a few trials, it was possible to consistently trace the lesions within the mandible and maxilla and describe them by means of echography. A protocol was subsequently developed and used in the first published investigation.¹⁸ Twelve patients diagnosed with endodontic periapical lesions were chosen to participate. In each patient, the area of interest was selected for the echographic examination. Intraoral and/or panoramic radiographs were used as a guide. Patients were placed in the echographic “bed” and an Elegra Siemens apparatus (Siemens, Erlangen, Germany) with a standard, high-definition multi-frequency ultrasound probe of 7 to 9 MHz was used for the examinations (Figure 4).

The echographic probe, covered with a latex protection and topped with echographic gel, was then

moved into the buccal area of the mandible or maxilla, corresponding to the radicular area of the tooth of interest. When the bony defect was identified, the probe was moved slightly around the area to obtain an adequate number of transversal scans to define the lesion.

The images were evaluated, based on the echographic principles used to describe the appearance of bone pathosis, and compared with the radiographic appearances of the lesions. The data were accurately reported in a descriptive chart. It was noted that the examinations were relatively easy to perform and that the patients reported no discomfort. In all the cases examined, it was possible to obtain an echographic three-dimensional image of a given lesion, to measure its dimensions, and to evaluate its content (fluids, solid, or a combination of both).

Following the application of CPD to echography, it was possible to see the presence of blood vessels within a lesion. One drawback was that it was not easy to distinguish specific anatomic reference points within the echographic image (i.e., roots of teeth).

Based on these first data, it was possible to confirm the following information:

1. Alveolar bone, if healthy, is hyperechoic because it exhibits a total reflecting surface that appears white in the image.
2. The roots of the teeth are also hyperechoic and appear as an even whiter shade than bone and can be seen in three dimensions.
3. Solid lesions in the bone are echogenic or hypoechoic presenting various intensities of echoes and appear as different shades of gray (Figure 4A).
4. A bone cavity filled with clear fluids (i.e., serous) is anechoic (or transonic) because it has no reflection and it appears dark (Figure 4B).
5. A bone cavity filled with fluids containing inclusions is hypoechoic and exhibits various degrees of darkness, depending on the contents of the fluid.
6. The irregular bone (resorbed) around a lesion shows a dishomogeneous echo (Figure 4A).
7. The reinforced bony contour of a lesion is usually very bright (hyperechoic) (Figure 4B).
8. By applying the CPD to the examination procedure, the presence and direction of blood vessels around and within the lesion can be detected (Figure 4A).
9. The mandibular canal, the mental foramen, and the maxillary sinus can often be distinguished and appear mostly transonic.

Figure 4 Ultrasound real-time imaging of two different lesions in the jaws. **A1**, Periapical lesion (granuloma) as seen in the ultrasound image (framed); it is an “echogenic” area where echoes are reflected at different intensities. **A2**, The same lesion after the application of color power Doppler. The colored spots represent the vascularization within the lesion. **B**, Ultrasound image of a cystic lesion (framed): it shows an “anechoic”/“transonic” cavity; the reinforced lower bone contour of this lesion is hyperechoic” (arrow).

Figure 5 Ultrasound real-time imaging of a lesion of endodontic origin in the mandible. **A**, Periapical lesion as seen in the intraoral radiograph; the lesion involves the periapical area of the lower right lateral incisor, canine, and first premolar. **B**, The same lesion as seen in the ultrasound image (framed): it is a “transonic” cavity with reinforced, hyperechoic bony contour (arrow). The vascular supply appearing at the CPD (red spots) is external to the lesion. **C**, Histopathologic features of the previous lesion that has confirmed the echographic diagnosis of “cystic lesion.”

Given all this information, a second study was done to differentiate between cystic lesions and granulomas based on the ultrasound examination complemented with the CPD procedure.¹⁹ Eleven patients, with clinical diagnoses of apical periodontitis and whose treatment plan included endodontic surgery with apicoectomy, retrograde filling, and biopsy, were chosen for this study. The ultrasound examination with CPD was performed in each area of diagnostic interest in the maxilla. A representative echographic image was

selected for each lesion, analyzed, and recorded. An attempt was made to make a differential diagnosis between cystic lesions and granulomas based on the following principles:

Cystic lesion: a transonic, well-contoured cavity filled with fluid, surrounded by reinforced bony walls with no evidence of internal vascularization based on CPD (Figure 5A–C).

Granulomas: a distinct lesion that could be echogenic or mixed in content, with non-precisely

Figure 6 Ultrasound real-time imaging of a lesion of endodontic origin in the maxilla. **A**, Intraoral radiograph showing a periapical lesion involving the upper left central and lateral incisors. **B1**, Periapical lesion as seen in the ultrasound images. It is possible to distinguish an “echogenic” area with irregular contours; the dotted areas correspond to the diameters of the lesion. **B2**, The same lesion with the CPD which shows the presence of blood vessels within the lesion. The lesion was diagnosed as periapical granuloma. **C**, Histopathologic features of the previous lesion confirming the echographic diagnosis.

defined contours and exhibiting the presence of blood vessels based on CPD (Figure 6A–C).

The results from the histopathologic examination confirmed the tentative echographic diagnosis. Six of eleven lesions that were described as transonic cavities, well contoured, and without blood vessels corresponded to the histopathologic feature of a cyst: a cavity lined with stratified squamous epithelium with necrotic debris and impressions from cholesterol crystals within its lumen. One lesion, whose transonic content showed

also scattered echogenic particles, revealed a cystic lumen with areas of secretory epithelium. This case supports the specific sensitivity of this technique with respect to the content of the studied bone pathosis.

Four of the remaining lesions were echographically diagnosed as granulomas because of their echogenic appearance and the presence of internal blood vessels. Their histopathologic reports described the typical appearance of granulomas: connective tissue with peripheral mononuclear (PMN) cells, lymphocytes, monocytes, and newly formed blood vessels. The only case

that presented with both an echogenic appearance in the lower portion and a hypoechoic aspect toward the upper end showed the histopathologic feature of a large granuloma containing a cyst. Based on these findings, ultrasound imaging showed enough potential sensitivity to allow the distinction between a cyst and a granuloma, to define a mixed type of lesion, and to evaluate the various degrees of turbidity of the fluid content in the bony lesion.^{19,20}

Furthermore, these findings were recently confirmed by researchers²¹ who replicated our study and evaluated the efficacy of ultrasound as opposed to digital radiographs and conventional radiographs, in the differential diagnosis of 15 periapical lesions. Their results were consistent with our findings even if they used the ultrasonic probe to conduct the examination only from outside the mouth; the echographic apparatus and the probe were different from the ones we used, and the clinical situation of the selected patients might not have been the same.

The possibility of monitoring inflammatory changes in diseased bone using the ultrasound real-time examination associated with CPD has been the subject of a recently concluded pilot project. The rationale was that the various degrees of inflammation of a given lesion can be assumed by evaluating the diffusion of blood vessels within or/and around the lesion, and that the application of CPD has the sensitivity to detect the presence of newly formed vessels. Six clinical cases diagnosed with clinical diagnoses of apical periodontitis, whose treatment plan included endodontic orthograde treatment, were included in this experiment. A clinical protocol was established and it was decided to complete the treatment in two appointments using calcium hydroxide as an intermediate medication. Besides routine radiographs, echographic examinations of each case were carried out as follows: (1) before treatment; (2) 1 week after root canal cleaning, disinfection, and application of intermediate medication; and (3) 1 month after completion of root canal treatment.

The results from this investigation have shown an active response to endodontic treatment in all phases of all examined cases. A reduction in the vascularization within the lesions, both after application of the inter-

mediate medication and after filling the root canals with gutta-percha and cement, was observed in all cases (Figure 7A–E). The degree of reduction of vascular supply was not the same in each case, but it was not possible to quantify it in this experiment.

These data are very preliminary and cannot yet lead to general conclusions, but they open new horizons on the follow-up of endodontic treatment with special regard to tissue reactions at different stages and protocols for endodontic treatment.

Recently, real-time ultrasound examination with CPD was used to monitor five apical lesions in the mandible and maxilla 6 months after orthograde treatment was completed. The rationale was that when the healing process starts within a lesion in bone, the Doppler signal will show the formation of new vessels. As the bone is remodeled, the flow signal will progressively decrease to the point of disappearing when the lesion is completely healed.²² In conclusion, ultrasound imaging appears to be clinically useful in the dimensional assessment of lesions, the evaluation of their content (fluid versus mixed or solid), and obtaining information on the patterns of expansion, vascularization, evolution in time, and response to treatment. In terms of its potential in differential diagnosis, cysts may be distinguished from granulomas, and cystic content may be defined as “clear” or “turbid.”^{19,20}

Trope et al.⁸ reported that a granuloma could be differentiated from a cyst by density using CT scan. Ultrasound imaging is more convenient than CT because it is less expensive and entails lower biologic adverse effects.^{23,24} Other investigators have used digital radiographs to measure grayscale values to differentiate cysts from granulomas.²⁵ Recently, cone-beam CT has been applied to the differential diagnosis of large apical radiolucencies, based on the negative and positive gray values with promising results.⁹

Ultrasonic imaging may find a place in research of apical radiolucencies and may also become a part of clinical procedures for dental diagnosis. But as with many other technological improvements, it will take some time for equipment and training to catch up with the possibilities of using these new modalities.

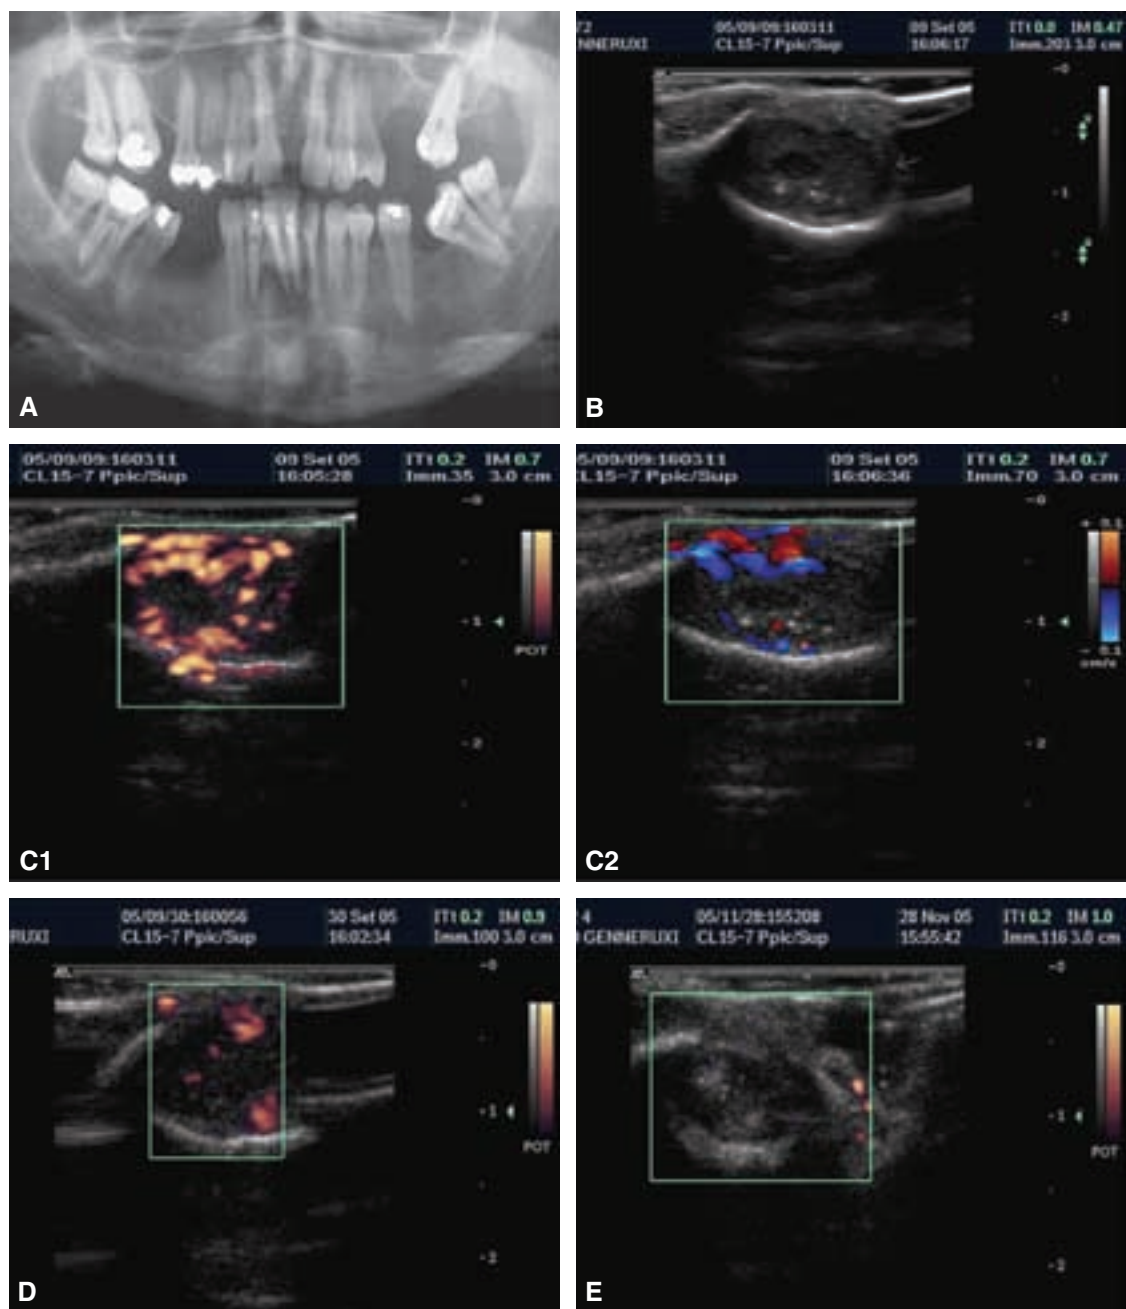

Figure 7 Ultrasound real-time imaging follow-up of an endodontic treatment with application of CPD. **A**, Panoramic radiograph showing periapical lesion involving all four mandibular incisors, before endodontic re-treatment. **B**, The same lesion seen in the ultrasound image (framed and arrowed): it is an “echogenic” image with solid content and well-defined contours. **C**, The two echographic images of the same lesion after the application of the power Doppler (1) and Color Doppler (2) show the presence of vascular supply. The diagnosis was periapical granuloma. **D**, Echography of the lesion (framed) 1 week after endodontic re-treatment was initiated and an intracanal medication was placed. The CPD shows reduced vascularization. **E**, Ultrasound image of the same lesion (framed) 1 month after completion of re-treatment on all four teeth. The CPD indicated that the vascular supply was greatly reduced.

CHAPTER 16

RADIOGRAPHIC INTERPRETATION

DAG ØRSTAVIK, TORE ARNE LARHEIM

Radiographs are indispensable in most aspects of endodontic practice. They are important for diagnosis, treatment planning, monitoring details during treatment, control of details at conclusion of treatment, and for follow-up control of treatment outcome. The main focus in this chapter will be on interpretation of periapical radiographic images as intraoral films or digital counterparts, sensors, and image plates are the most frequently used means of radiographic examinations for endodontic diagnosis.

More sophisticated methods for radiographic diagnosis have become available, providing better details of normal and pathological structures with multiplanar imaging. Examples of such advanced imaging interpretation are also given, mainly in the section dealing with differential diagnosis.

Biological Processes Related to Radiographic Diagnosis

It is basic knowledge that radiographic details portray variations in mineral density in tissues and that conventional film- or sensor-detected exposures are two-dimensional reflections of a three-dimensional reality. Normal anatomical structures are recognized by density variations in tooth and bone tissues. The interpretation is done by relating the radiographic signs to our mental image of what the three-dimensional image normally should look like, and how we perceive this to be projected to the film. With time and experience, we rely increasingly on how a given radiograph relates to other radiographs we have seen and learned to accept as normal or pathological structures.

Obviously, interpretation of even simple radiographic exposures is subject to a great deal of bias: the knowledge base of basic, three-dimensional anatomy

will vary among observers, there is bias and variation in the learning process from peers et al., and we develop individual preferences in attaching importance to specific elements of the radiograph. As clinical and radiographic signs of endodontic disease often are small and rather unspecific, there is always pressure on the diagnostician to read as much as possible into small variations in radiographic appearance of tooth and periapical structures. This bias and individual variation in diagnosis of periapical disease by radiography was elegantly demonstrated by Goldman et al.¹ and more scientifically by Reit and Gröndahl.²

CARIES

In caries diagnosis, the endodontic dilemma is to determine the spatial relationship of the carious lesion to the pulp. On the one hand, we are conditioned to think that proximal caries goes deeper than what can be seen in the radiograph; on the other, caries located on the buccal or lingual aspect may project over the pulp and give the false impression of pulpal involvement. Interpretation of radiographic findings in crowned teeth represents special challenges.³

PULPAL CHANGES: CALCIFICATION, OBLITERATION, AND RESORPTION

Abnormal pulp calcification may be reactionary (tertiary) dentin to caries or trauma (operative procedures); degenerative localized or diffuse calcifications in the coronal and, characteristically, the radicular pulp; and pulp obliteration following traumas such as tooth concussion or luxation or intentional or necessary replantation.⁴⁻⁷

Internal resorptions are usually associated with the replacement of dentin by a soft tissue with resorbing cells causing a balloon-shaped lesion starting from the radicular pulp.⁸⁻¹² The radiographic end result is a round or ovoid radiolucent area observed on the

Figure 1 *A, B*, Internal resorption of left upper canine before and after endodontic treatment (Courtesy, Dr. Harald Prestegaard); *C*, Rare case of multiple resorptions (Courtesy, Dr. Elisabeth Samuelsen).

radiograph (Figure 1). It is a characteristic radiographic sign that the internal pulpal wall is destroyed, whereas cementum and periodontium are not affected, at least not initially.

PATHOLOGICAL REACTIONS OF TOOTH STRUCTURE: FRACTURE, RESORPTIVE PROCESSES

Fracture of a root can be difficult to diagnose but may result in reparative processes that become recognizable in later radiographs.^{13–16} Diagnosis of root fractures may be made easier by using multiple projections (Figure 2) or advanced radiographic techniques, particularly computed tomography (CT).^{14,16} There may be a hard tissue union of the two fragments if they are in close apposition to each other, the pulp is vital, and the fracture line is in its entirety within the periodontal ligament (PDL). Remodeling may then lead to a near normalization of the radiographic appearance of the root (Figure 3). In the case of fibrous repair, the fragments remain separated by a structure resembling periodontal membrane, and remodeling processes in the form of blunting of the fragment edges may become visible in the radiograph.

Resorptive processes of the tooth structure induce changes in radiographic structures that may be challenging both from a diagnostic and therapeutic point of view.^{17–20} Surface resorption and repair may be seen as the body's way of coping with damage to the cementum, and these processes are sometimes extensive enough to be detectable radiographically. In cases of trauma with pulp damage, it then becomes a diagnostic challenge to differentiate resorption and repair from progressive inflammatory resorption, which, when uncontrolled, will lead to rapid loss of tooth substance.

Cervical root resorption²¹ attacks dentin from pinpoint openings in cementum at the bottom of the gingival pocket and progresses either in irregular pathways in all directions into dentin or as semilunar, distinct caries- or erosion-like lesions (Figure 4), sometimes in multiple locations. As the process tends to halt when the inner dentin and predentin

Figure 2 Root fracture examined two days after trauma. *A*, Uncertain diagnosis on the periapical radiograph. *B, C, D*, Fracture is evident when multiple projections are obtained.

Figure 3 **A**, Tooth remodeling of fragments after healing of horizontal root fracture. **B**, Blunting of edges shown in insert with artificially increased contrast.

are reached, radiographically the lesions are often characterized by an outline of the pulp space appearing through the radiolucent area caused by the resorption (Figure 5).

PERIAPICAL CHANGES: WIDTH OF PERIODONTAL LIGAMENT, BONE TEXTURE CHANGES, DEMINERALIZATION, BONE FORMATION, APICAL SURGERY

Apical root resorption, bone resorption, cementum formation, and bone deposition are the biological processes primarily associated with radiographic changes in the periapical area. Furthermore, there are often structural changes in the periapical bone reflecting either increased density of bone (condensing apical osteitis)^{22,23} or altered organization of trabeculae (incipient apical osteitis) (Figure 6).

Resorption/remodeling of the apical lamina dura and a widening of the periodontal ligament may occur as an early or limited response to infection in the root canal system, but is also common as a consequence of increased tooth mobility, as in marginal periodontal inflammation or during orthodontic

Figure 4 Cervical root resorption; erosive type.

tooth movement. In the latter case, apical root resorption and remodeling of the root apex may be very extensive (Figure 7).

Apical periodontitis leads to demineralization of periapical bone with subsequent lesion development. Preceded by structural changes in the bone, this lesion may be evident in radiographs before overt demineralization has begun in the area.

Apical periodontitis (granuloma, radicular cyst) develops with variable speed, and the effects on the surrounding bone will also vary. Bone deposition with the formation of a distinct bony rim may occur, which has been associated with stable lesions more likely to have cyst formation; however, there is little evidence to support this concept.^{24,25} On the other hand, cyst formation is more likely to be found in large lesions compared to small.²⁶ Histological studies have indicated that in lesions with acute characteristics there are changes in bone structure peripherally to the outer margin of the lesion proper.²⁷

Surgical endodontic or other periapical procedures leave a blood clot that organizes and eventually heals by formation of cortical and medullary bone. This healing process is faster than healing of apical lesions after conservative endodontic therapy,²⁸ and leads to

Figure 5 Cervical root resorption progressing apically with characteristic outline of pulp chamber clearly visible (Courtesy, Dr. Nabeel Mekhlif).

radiographic signs that may differ from normal periapical structures, particularly if scar tissue with reduced mineral content is formed.^{29,30}

OTHER ENDODONTIC APPLICATIONS OF PERIAPICAL RADIOLOGY

There are several situations and cases where other aspects of endodontic treatment are detected and monitored by radiographs. Examples are iatrogenic mishaps such as root perforations and overfillings, root fractures and special procedures such as root resection and hemisection.

Periapical Diagnosis

Apical periodontitis is typically a droplet-shaped radiolucent area associated with the root apex surrounded by bone in continuity with the lamina dura at some distance from the pulpal exit.³¹ Being dependent on the egress of infectious material through the apical pulp

Figure 6 Condensing apical periodontitis at distal root, incipient apical periodontitis at mesial root of mandibular first right molar. Note foreign material in pulp chamber, a likely cause of chronic pulpitis or pulp necrosis.

orifice, lesions of apical periodontitis may be situated in lateral or furcal locations in association with lateral or furcal accessory canals, respectively.

Apical periodontitis is a defense mechanism against infection. When apical cementum and dentin are invaded by microbes, the structures are attacked by resorbing cells, and root resorption, albeit limited, is integral to lesion development.^{32,33} The development of a granuloma and/or a cyst may be seen as the mobilization of an area where host defense mechanisms are concentrated, and the resorption of bone is a process necessary to provide space for the defending tissues.³⁴ The granuloma/cyst is also protecting from direct infection of the bone marrow (osteomyelitis). While the granuloma/cyst is defined to a degree by the relative resistance of the bone, it occupies a place that is effective for the mobilization of a host defense, and cortical bone may be eroded for this purpose even if the path of least resistance would have pointed in another direction.

As the cortex makes up a very large percentage of the bone mass in the radiograph of a normal periapical area,³⁵ the proposition has been made that involvement of cortical bone loss is necessary for detection of a lesion in a radiograph. While it is a matter of course that any lesion involving the cortex is more easily detectable,^{36,37} research has documented that the changes induced by resorptions and changes in the medullary and subcortical, trabecular bone can also be seen.^{37,38}

Figure 7 **A**, Periapical radiographs of maxillary premolar made before orthodontic treatment, **B**, at 5.2 months and **C**, 11.9 months after bracket placement, and **D**, at end of 22.1 months of orthodontic treatment. Projections **A**, **C** and **D** are reconstructed according to projection **B**. Note apical root resorption of 2.6mm at 5.2 months **B**, of 5.1mm at 11.9 months **C**, and of 7.0mm at end of treatment **D**. (Modified with permission from Årtun J, Van 't Hullenaar R., Doppel D., Kuijpers-Jagtman A.M. Identification of orthodontic patients at risk of severe apical root resorption. *Am J Orthod Dentofacial Orthop* 2007; 132:in press.)

Radiographic signs must be correlated with macroscopic or microscopic anatomical and pathological features. Several studies have compared the radiographic and histological appearance of apical periodontitis, of which Brynolf's²⁷ is by far the most extensive and detailed. Table 1 lists some of her findings that relate radiographic signs to histological characteristics of periapical inflammation.

There are few things easier than the radiographic diagnosis of a well-established, chronic apical periodontitis. Two particular radiographic aspects of apical periodontitis, however, may be difficult and frustrating: the detection of incipient changes and the monitoring of healing or post-treatment development of disease.

Advanced Multiplanar Imaging

Advanced imaging of the periapical area usually means section imaging. With computer technology it is possible to obtain an image of virtually any plane through a structure, greatly improving the diagnostic information of its three-dimensional morphology. However, the interpretation of multiple sections versus one projectional radiographic image is challenging and may require collaboration between specialists in endodontics and oral and maxillofacial radiology as given in the following paragraphs.

Advanced imaging, in particular CT, may be used supplementary to conventional periapical radiography for demonstration of complex anatomy of the root and surrounding structures, including associated lesions (Figure 8). With the development of cone beam CT, the root and periapical bone can be examined in axial, coronal, and sagittal sections with less patient exposure than with conventional CT to evaluate, for instance, the integrity of the cortical bone (Figure 9).

Table 1 Histological and Radiographic Correlates

Histological Appearance	Radiographic Features
Incipient apical periodontitis	Bone structural changes
Initial inflammation with acute features	Bone structural changes
Chronic inflammation	Bone demineralization; lesion area defined
Granuloma or cyst formation	Radiolucent area; peripheral bony rim
Lesion with features of exacerbation	Bone structural changes peripheral to lesion

Adapted from Brynolf²⁷

Problems and Potentials of Periapical Radiographic Diagnosis and Follow-up of Apical Periodontitis

INCIPIENT CHANGES

Based on a concept of apical periodontitis (granuloma, cyst) formation as an expanding balloon starting at the apical orifice of the pulp, it has been held that the first sign of disease can be recognized as a widened periodontal ligament. Brynolf's²⁷ and later studies^{39,40} have documented that this is a poor indicator of disease development. Rather, it may reflect increased tooth mobility or a limited tissue reaction to root filling surplus, or traumatic occlusion. Initial or limited inflammatory processes in relation to root canal infection can be detected by changes in the bone structure periapically rather than by overt demineralization.²⁷ While it may be possible through extensive training to obtain proficiency in observing these changes,⁴¹ it should probably be accepted that such initial changes cannot reliably be diagnosed by conventional radiographic methods. In keeping with standard procedures for diagnosing disease in clinical practice and epidemiological studies, a high threshold should be set to exclude weak radiographic signs.

HEALING OF APICAL PERIODONTITIS

The biological dynamics of healing apical periodontitis are rarely studied and therefore not well known. It is a slow process,²⁸ probably because of the resistance to resorption/replacement of the tissue components of cysts and, particularly, granulomas. By quantitative analyses of radiographs, healing may be seen as early as 3 months after therapy,^{42,43} and by 1 year, almost all cases that will eventually heal completely, show unequivocal, radiographic signs of healing⁴⁴ (Figure 10). But healing processes that were not in evidence for as long as 10 to 17 years after treatment can be activated later to re-establish normal radiographic structures.⁴⁵

ANATOMICAL LIMITATIONS

Normal anatomical structures and their variable location, size, and characteristics in different individuals, interfere with the interpretation of the periapical tissue responses in endodontic diagnosis. It is not simple in individual cases to account for variations of this kind; for example, while the alveolar bone surrounding roots of mandibular second and third molars is often free of confounding anatomical structures and thus should lead to an unquestionable diagnosis of periapical changes, the variations in trabecular pattern in this area is a frequent source of misdiagnosis of apical lesions that do not actually exist.

Figure 10 A, B, C, Complete healing of apical periodontitis within 17 months of treatment.

Figure 11 Idiopathic osteosclerosis. **A**, Closely located to the apex of a vital tooth. **B**, Separated from the apex of a tooth with vital pulp.

DIFFERENTIAL DIAGNOSIS

Although conventional periapical radiography will be sufficient for differential diagnostic radiographic evaluation in most cases, the usefulness of advanced imaging is evident in the examination of a number of conditions, particularly when more serious disease is suspected.⁴⁶

Hypercementosis may occur in response to pulpal inflammation without infection in the apical part of the canal. While the pulpitis usually requires endodontic treatment, the cementum deposited is not remodeled and will persist after endodontic treatment. Condensing apical osteitis is also associated with chronic pulpitis and will resolve following adequate therapy. It is the bone structure that is altered, and remodeling is possible and likely, although areas of persistent condensed bone may be seen in apposition to apparently adequately treated teeth. Idiopathic osteosclerosis may be a differential diagnostic problem if located close to the apices (Figure 11). Marginal periodontitis may show radiographic features similar to apical periodontitis, and when presenting with a necrotic and

Figure 12 **A**, Typical endodontic-periodontal lesion. **B**, Healing 10 months after endodontic treatment. (Courtesy, Dr. Birte N. Myrvang)

Figure 13 Oblique-vertical root fracture with laterally widened periodontal ligament due to infection.

infected pulp may need combined treatment (Figure 12). Root fractures may indeed be seen as a variant of apical periodontitis; if the pulp canal space and the fracture slit are infected, this will result in a periodontitis where the fracture communicates with the periodontal space (Figure 13). The radiographic signs are somewhat characteristic in the case of vertical fractures, in that the whole length of the root may be affected, producing a diffuse halo of radiolucent bone around the root (Figure 14). Similarly,

Figure 14 Vertical root fracture with bone resorption along the entire length of the mesial root.

Figure 15 Osteomyelitis with fistula formation and sequestration. **A, B**, Destructive foci, apparently with normal bone structures in between. **C, D**, Apical periodontitis with sequester and gutta-percha point in sinus tract.

osteomyelitis may follow an initial root canal infection that for some reason has escaped the protective functions of the cyst or granuloma and invaded the bone marrow spaces (Figures 15, 16). Osteomyelitis characteristically may show sequestration and apparently nor-

mal bone structures between areas of bone destruction (see Figure 15). Another characteristic feature is periosteal bone formation that in young patients may become extensive (Figures 16, 17). In patients with irradiated mandibles, osteoradionecrosis may develop

Figure 16 Osteomyelitis in 12-year old patient with extensive periosteal reaction. **A**, Apical periodontitis associated with both molars with necrotic pulps in left mandible and onion-peel bone formation of the lower mandibular border. **B, C**, One year later extensive bone formation is evident (arrow). **D**, Two years after baseline new bone destruction because of increased disease activity is clearly seen (arrow). that is indistinguishable from osteomyelitis, although usually with less prominent periosteal reaction (Figure 18). This may occur even many years after the radiation therapy of the malignancy. Bisphosphonate-related osteonecrosis of the jaws with a similar radiographic picture has been reported to occur with increasing frequency.⁴⁷

The inflammatory paradental cyst is a rare entity, occurring exclusively in the mandibular molar area,

and should not cause major difficulties in differentiation from apical periodontitis.⁴⁸ However, the cyst may be projected over the apex on a conventional radiograph, making advanced imaging a valuable supplement for diagnosis (Figure 19). The lateral paradental cyst is a developmental cyst occurring primarily in the premolar area of the mandible and may be difficult to distinguish radiographically from apical periodontitis.⁴⁹ It can also occur in the maxilla, and when

Figure 18 Osteoradionecrosis two years after radiation therapy and surgery of malignancy in maxilla. **A, B,** Extensive bilateral bone destruction with sequestration (arrows). (Reproduced with permission from Larheim, T.A., Westesson, P.-L. Maxillofacial Imaging, Springer 2006.)

projected over the apex on a conventional radiograph, supplementary advanced imaging may add decisive diagnostic information (Figure 20). The non-odontogenic incisive canal developmental cyst is located centrally between the maxillary incisors and may be easily mistaken for apical periodontitis if projected over the apex. An axial view may be helpful to identify the cyst in a palatal position in the jaw (Figure 21). A normal apical periodontium and pulp sensitivity will rule out apical periodontitis in such cases. The simple bone cyst (traumatic bone cyst) is not a true cyst but an empty hole in the jaw bone without epithelial coverage and of unknown origin,

Figure 21 Incisive canal cyst. **A, B, C**, Occlusal view and conventional periapical radiographs show the cyst palatally located to the incisors.

Figure 22 Simple bone cyst. Periapical radiograph showing radiolucency between first and second molars. There was no expansion of the mandible.

usually found in young individuals (Figure 22). Oss- eous (cemental) dysplasia may completely mimic almost any phase, productive or resorptive, of chronic apical periodontitis. The condition may be

Figure 23 Osseous (cemental) dysplasia. Apical radiolucencies (early stage dysplasia) around apices of three incisors.

Figure 24 Giant cell granuloma mimicking apical periodontitis.

multiple and is predominantly found in the incisal region of the lower jaw (Figure 23). It is characteristic of most of the conditions mentioned in this paragraph that the pulps are vital and there are no clinical symptoms. The giant cell granuloma is another lesion that usually presents as a large, some-

times multilocular, radiolucent area. It may also be more unilocular (Figures 24, 25), like eosinophilic granuloma, and sometimes give radiographic signs not unlike apical periodontitis. The value of advanced imaging is clearly demonstrated with the case of giant cell granuloma; it could be determined

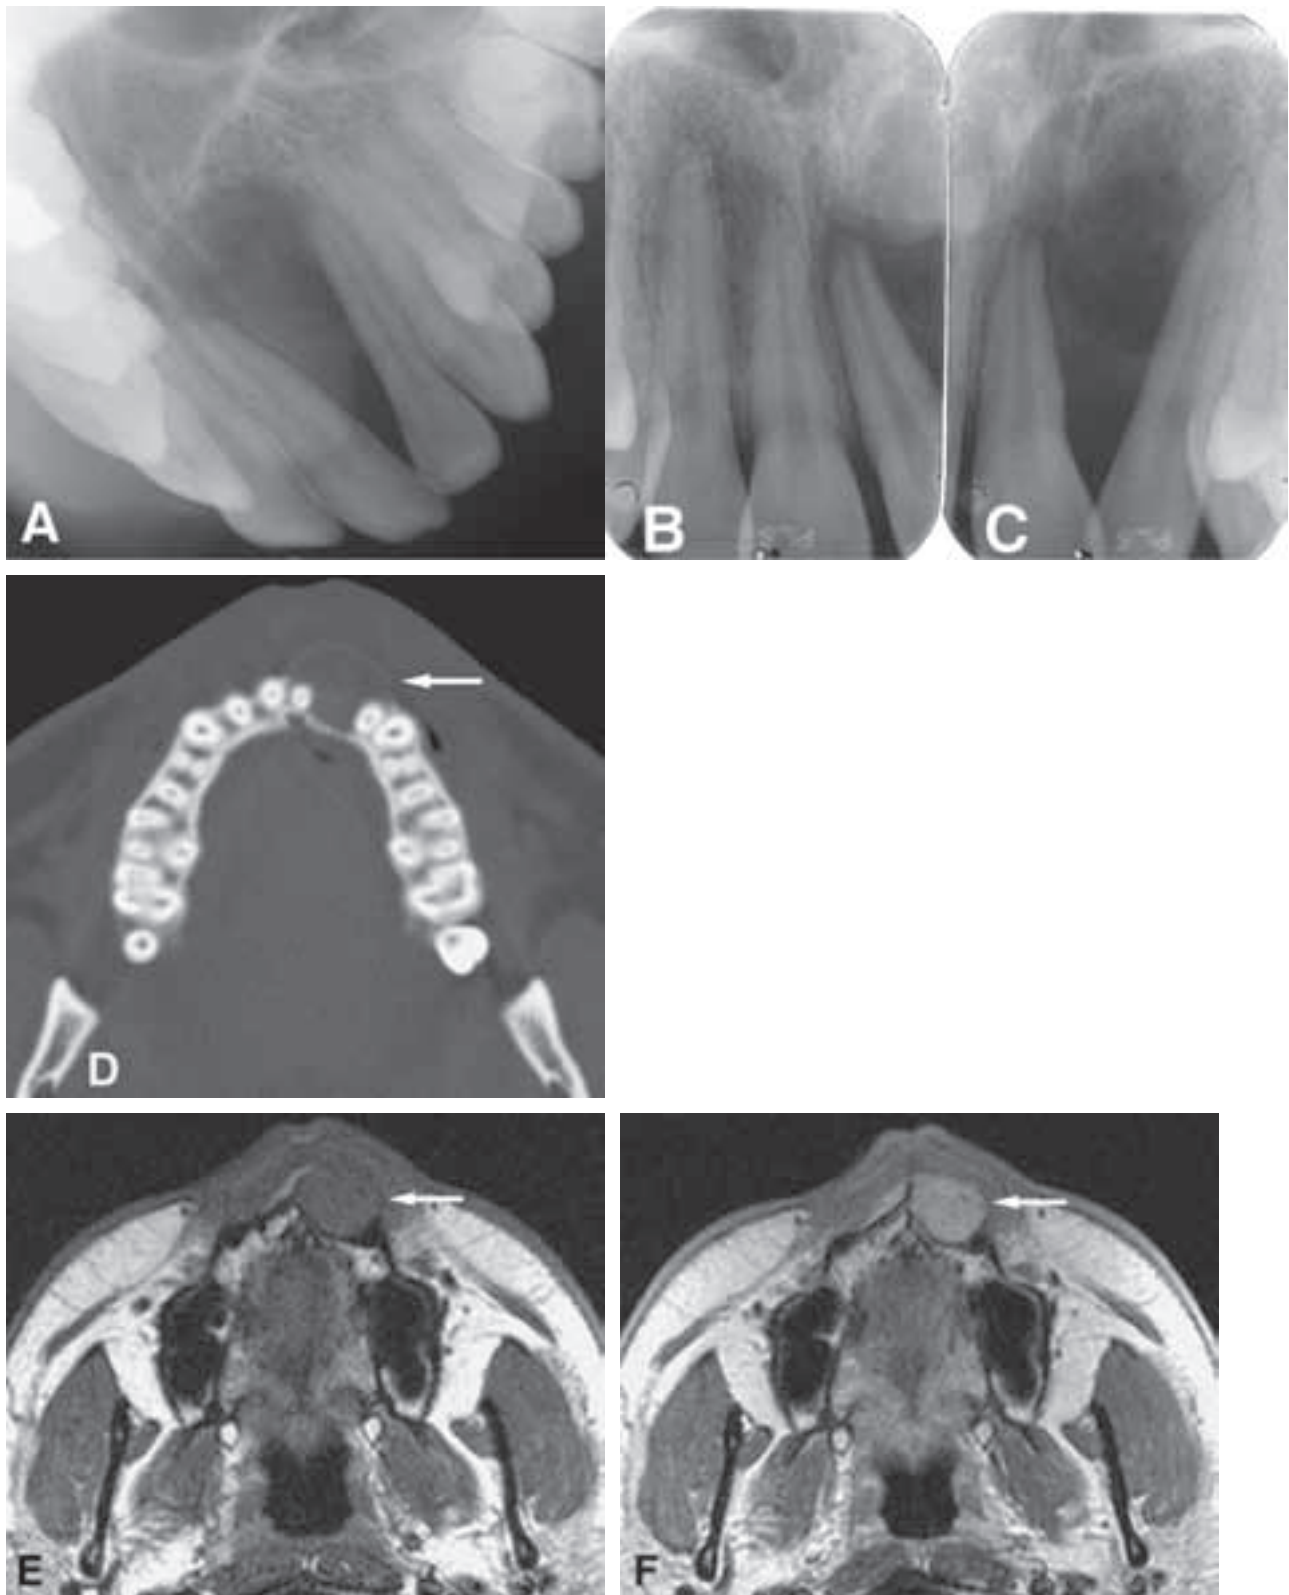

Figure 25 Giant cell granuloma. **A, B, C**, Unilocular radiolucency with displacement of two incisors; **D**, CT scan shows severe expansion buccally without corticated outline (arrow); **E, F**, MR imaging scans before **E** and after **F** intravenous contrast injection show contrast enhancement of entire lesion, consistent with solid tumor (arrow). Figure 26 Primary hyperparathyroidism. Defects in dentin structure and wide pulp chambers and root canals make the pulp tissue highly susceptible to damage and infection.

before surgery and histology that the lesion was solid and not cystic when supplementary magnetic resonance imaging was performed (see Figure 25).

Hyperparathyroidism (Figure 26) is a systemic condition predisposing for pulpal and periapical infections.

Tumors of the jaw present radiolucencies that sometimes may mimic apical periodontitis. Pulp sensitivity will normally rule out apical periodontitis. The odontogenic keratocyst (keratocystic odontogenic tumor) and the ameloblastoma may appear close to root apices in singlelobular or multilobular forms, the latter tumor frequently demonstrates evident root resorption (Figure 27). A case of ameloblastoma, seen as a unilocular radiolucency on a conventional radiograph, proved to be multicystic with advanced imaging (Figure 28). Ossifying fibroma may also simulate apical periodontitis

Figure 27 Ameloblastoma, multicystic/solid type. **A, B**, Multilocular radiolucencies with evident root resorptions (arrow). **C**, CT scan shows severe bone destruction and evident buccal expansion with destroyed lingual cortical bone (arrow). (Figure 29), but unlike the other conditions mentioned (except cemental dysplasia), it also produces bone giving a mixed radiographic appearance.⁵⁰

Malignant tumors in the jaws are rare but may cause severe bone destruction, and displace, but rarely resorb, adjoining teeth; floating teeth are more typical.⁴⁶ A case of metastatic breast carcinoma in the mandible is shown in Figure 30, detected when the patient had a postoperative follow-up after apicoectomy.

Periapical Radiographs in Clinical and Epidemiological Endodontic Research

Clinical radiographic research in endodontics is primarily concerned with apical periodontitis: its emergence following pulp extirpation or its healing after root canal treatment of infected teeth.

SPECIFICITY AND SENSITIVITY, REPRODUCIBILITY

Any system for registering disease must address the issue of specificity and sensitivity: how specific is a given criterion for the disease in question (i.e., how often will the diagnosis be wrong) and how quickly/early the criterion can be detected (i.e., how sensitive is the sign). From the discussions above, it is apparent that initial signs of apical periodontitis in radiographs may be of low specificity (widened periodontal ligament (PDL) reflecting increased mobility rather than disease), and increasing the sensitivity may come at the expense of specificity in registering initial disease. Also with reference to the discussion above, the personal bias in interpreting radiographs makes it imperative that for research purposes, harmonization and calibration of observers, while difficult, is carried out.

SUCCESS AND FAILURE

Endodontic treatment is performed under conditions with a theoretical potential for complete asepsis or effective antisepsis. This leads to a concept of a potential also for absolute “success” (complete elimination of infection) or “failure” (residual, recurrent or de novo infection). Complete radiographic maintenance or reestablishment of normal periapical structures have thus been defined as “success,” whereas persistence or emergence of radiographic signs of disease is termed “failure.”⁵¹ The concept is simple

Figure 29 Ossifying fibroma. **A**, Apical radiolucency (and pulp sensitivity). **B**, 2.5 years later a mixed lesion was found including second molar. (Reproduced with permission from Mork Knutsen B., Larheim T.A., Johannessen S., Hillestad J., Solheim T., Strømme Koppang H. Recurrent conventional cemento-ossifying fibroma of the mandible. *Dentomaxillofac Radiol* 2002; 31:65-8.)

and easily understandable to patient, clinician, and researcher and has been widely used for assessments of treatment outcome (for review see refs 52, 53). However, the bias and variation in observers' perceptions of what constitutes success or failure has made comparisons among studies with different observers problematic.

PROBABILITY ASSESSMENTS

Acknowledging the bias and difficulties in calibration, Reit and Grøndahl⁵⁴ and Zakariassen et al.⁵⁵ applied a probability scoring system for monitoring apical disease: the observers were assigned to assess the probability that disease be present on a 5- or 6-point scale. The system provides numerical data amenable to more sophisticated analyses than the dichotomous

scoring, but it does in no way address the problem of harmonization of observers.

THE PERIAPICAL INDEX SCORING SYSTEM

This was developed⁵⁶ for two reasons: to integrate radiographic score with histological characteristics of the disease and to make possible harmonization of observers across studies and geographical distance. The histological reference was to the studies by Brynolf,²⁷ by adoption of her findings with a degree of simplification deemed necessary for calibration of scorers (Figure 31). Bias was reduced by making scoring a visual exercise rather than relying on verbal descriptors in characterization of radiographic findings and controlled by providing a

Figure 30 Metastasis to the mandible from breast cancer. **A**, Periapical radiolucency after apicectomy of premolar in left mandible. **B, C, D**, CT scans show the postoperative defect and otherwise normal bone. **E**, Healed surgical defect, but new radiolucency had developed one year and 4 months later. **F, G, H**, CT scans confirm healed area and bone destruction including buccal cortex.

Figure 32 Periapical index scores used to monitor and compare healing of teeth with apical periodontitis with and without cultivable bacteria at the filling session. Average change in PAI score from baseline at 4, 12, 26 and 52 weeks used as indicator of healing (Data from Waltimo T., Trope M., Haapasalo M., Ørstavik D. Clinical efficacy of treatment procedures in endodontic infection control and one year follow-up of periapical healing. *J Endod* 2005;31:863-6.)

calibration kit with precise measurement of a given observer's performance in relation to a set of "true" scores. The system has been applied to more than 30 peer-reviewed publications since 2001, from Canada to China, with applications typically in endodontic epidemiology⁵⁷ and clinical, follow-up studies⁵⁸ (Figures 32, 33).

DIGITAL QUANTIFICATION OF RADIOGRAPHIC DATA

Using direct digital or digitized, conventional radiographs, the numerical information in the acquired image may be used for quantitative assessment of grey level/mineral content changes. Digital subtraction is one attractive option for this purpose, but despite several attempts to apply this procedure to endodontic, periapical radiographs,^{42,59} this has not been successful. A method whereby lesion grey levels are

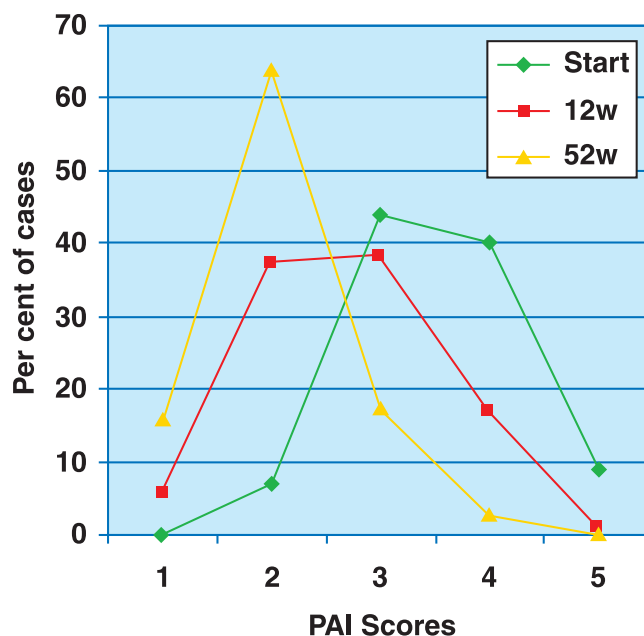

Figure 33 Periapical index scores used to monitor healing in a group of teeth treated for apical periodontitis (Data from Sathorn C., Parashos P., Messer H.H. Effectiveness of single- versus multiple-visit endodontic treatment of teeth with apical periodontitis: a systematic review and meta-analysis. *Int Endod J* 2005;38:347-55.)

Table 2 Application of the Ratio Method in Evaluation of Healing After Treatment of Apical Periodontitis with Three Modalities

Treatment	n	Ratio Gray Value at 52 Weeks

related to a peripheral area in the same jaw, unaffected by pathological or healing processes in the bone, has proven more robust and found application in quantitative studies^{42,60-63} (Table 2) (Figure 34).

Figure 34 Delineation of areas to be monitored during healing. AP, lesion as outlined at start, N, peripheral, stable normal bone (Modified from Ørstavik D., Farrants G., Wahl T., Kerekes K. Image analysis of endodontic radiographs: digital subtraction and quantitative densitometry. *Endod Dent Traumatol* 1990;6:6-11.)

APPLICATIONS TO CLINICAL RESEARCH

New procedures, materials, and medicaments keep emerging for use in endodontics with claims of superior performance. While many such products and methods may be evaluated for their feasibility by *in vitro* technological and biological tests, true progress in treatment outcome can only be measured in controlled, follow-up studies with randomized design and in comparison with conventional methods of reference. Very few such studies have been performed and that is reflected in the scarcity of solid data at the higher levels of evidence found when endodontic treatment is studied in systematic reviews and meta-analyses.^{52,64-67} Extensive, at times costly, randomized clinical trials are necessary for documentation of performance, and it is unfortunate that many new techniques and products do not have such data available.

The Periapical Index (PAI) scoring system has been used in several studies with randomization of techniques and has proven useful for strict comparisons of, particularly, root filling materials^{68,69} (see Figure 34), but also for comparison of treatment

methods.⁷⁰ Similarly, digital analyses have been used successfully in both situations.^{42,61} With intra-study calibration of observers, simple success–failure analyses may of course also be applied for such comparisons. However, comparisons across studies cannot be done reliably.

EPIDEMIOLOGY

Eriksen et al.⁷¹⁻⁷⁷ have conducted a series of epidemiological surveys using the PAI scoring system. This has made possible direct comparison of the distribution of apical periodontitis and endodontic treatment results in several different regions and countries. Other investigators^{78,79} have also produced epidemiological data with the index, adding to our knowledge base with the same methodology. Based on these surveys, with a standardized interpretation of radiographic information, the realization is growing that chronic apical periodontitis is quite prevalent in most societies all over the world and that periapical disease is an important dental health issue and a major cause of tooth extraction in many populations⁸⁰ (Figure 35).

Figure 35 Periapical index scores used to record the prevalence of apical periodontitis in 35–45 year-olds in selected countries (Data from Skudutyte-Rysstad R., Eriksen H.M. Endodontic status amongst 35-year-old Oslo citizens and changes over a 30-year period. *Int Endod J* 2006;39:637-42.)

Radiography in the Future of Endodontics

The periapical radiograph has successfully maintained a position of ubiquity and remains indispensable in endodontic practice. The ease and precision with which relatively detailed knowledge can be obtained with this diagnostic tool makes it superior for routine applications today and in the foreseeable future. Critical and evidence-based knowledge of how endodontically relevant changes in teeth and bone are reflected in radiographs remains crucial, and it is an ever challenging task to reduce personal and institutional bias in radiographic interpretation. The dose and cost of scans and the difficulty to use other, sophisticated methods in real time at chairside make it unlikely that these techniques will affect the basic procedures in endodontic diagnosis and treatment. The continued reinforcement of clinicians' proficiency in reading and interpreting the information in periapical radiographs is therefore a key for maintaining and improving the quality in endodontic practice.

On the other hand, tremendous advances are being made with the development of, particularly, the computer-assisted scanning techniques. The technology producing localized scans of areas in the jaw with much reduced dosage holds a promise for future improvements in diagnostic and treatment procedures. New insights and concepts may have to be developed of how the three-dimensional appearance and localizations of apical periodontitis lesions appear in areas of the jaw, where conventional radiography offers limited if any help.

CHAPTER 17

RHINOSINUSITIS AND ENDODONTIC DISEASE

RODERICK W. TATARYN

Maxillary Rhinosinusitis as a Source of Dental Pain

The most common nonodontogenic cause of dental pain arises from the maxillary sinus and associated pain-sensitive ostial mucosa.¹ Maxillary rhinosinusitis therefore deserves important consideration when developing a differential diagnosis for maxillary discomfort. Despite its prevalence, differentiating pain caused by rhinosinusitis from that of pulpal etiology can be one of the more difficult diagnostic challenges faced by the clinician? The result of a misdiagnosis in this area has led to unnecessary endodontic therapy, periapical surgery, and even multiple tooth extractions, with no effective pain relief for the patient.

In order to effectively distinguish rhinosinusitis from odontalgia, it is imperative that clinicians understand the anatomy and functions of the paranasal sinuses both in healthy and diseased states, and recognize the signs and symptoms associated with sinus inflammation. It should be made clear that it is not expected of the endodontist, and is in fact outside the scope of dentistry, to definitively diagnose or provide treatment for a sinus condition. This diagnosis and treatment is best left to an otorhinolaryngologist, or ear, nose, and throat physician (ENT). Nevertheless, it is essential that the endodontist have a thorough understanding of this system and its potential disease processes to effectively diagnose and treat or rule out pain of odontogenic origin and to make an appropriate ENT referral if rhinosinusitis is suspected. A knowledge of these structures is also crucial to understanding the effects of periapical infection on the adjacent sinus tissues and the role of endodontic disease in acute and chronic rhinosinusitis.

Paranasal Sinuses: Anatomy and Function

Sinuses are hollow air spaces or cavities located within the skull surrounding the nasal cavity. There are four pairs of paranasal sinuses: the maxillary, the frontal, the ethmoid, and the sphenoid (Figure 1). The sinuses are lined with a membrane of ciliated and nonciliated pseudostratified columnar epithelium that is continuous with the nasal cavities. The columnar cells are interspersed with mucous-producing goblet cells that constantly produce a thin layer of mucinous fluid. The mucous is rich with immune cells, antibodies, and antibacterial proteins that serve in immune defense and air filtration by trapping and filtering particles such as dust, spores, and bacteria. The cilia beat in a coordinated, rhythmic wavelike pattern moving the mucous toward a small opening or ostium into the nasal cavity and then on to the throat where it is swallowed and finally dissolved by digestive acids. In addition to air filtration, the paranasal sinuses serve to humidify and warm inspired air and are also important in giving the voice resonance, defining tonal quality and voice amplification as well as reducing the weight of the skull.²

The largest of the paranasal sinuses and most prone to infection are the maxillary sinuses. The maxillary sinus, also known as the antrum, is somewhat pyramidal in shape with the lateral wall of the nasal cavity forming the base and the apex extending into the zygoma. The floor of the maxillary sinus is the maxillary alveolar and palatine process, the roof is the floor of the orbit, and the posterior wall is adjacent to the infratemporal fossa. The ostium of the maxillary sinus is located approximately two-thirds up the medial sinus wall and is a small (1 to 3 mm diameter) passageway into the nasal cavity.

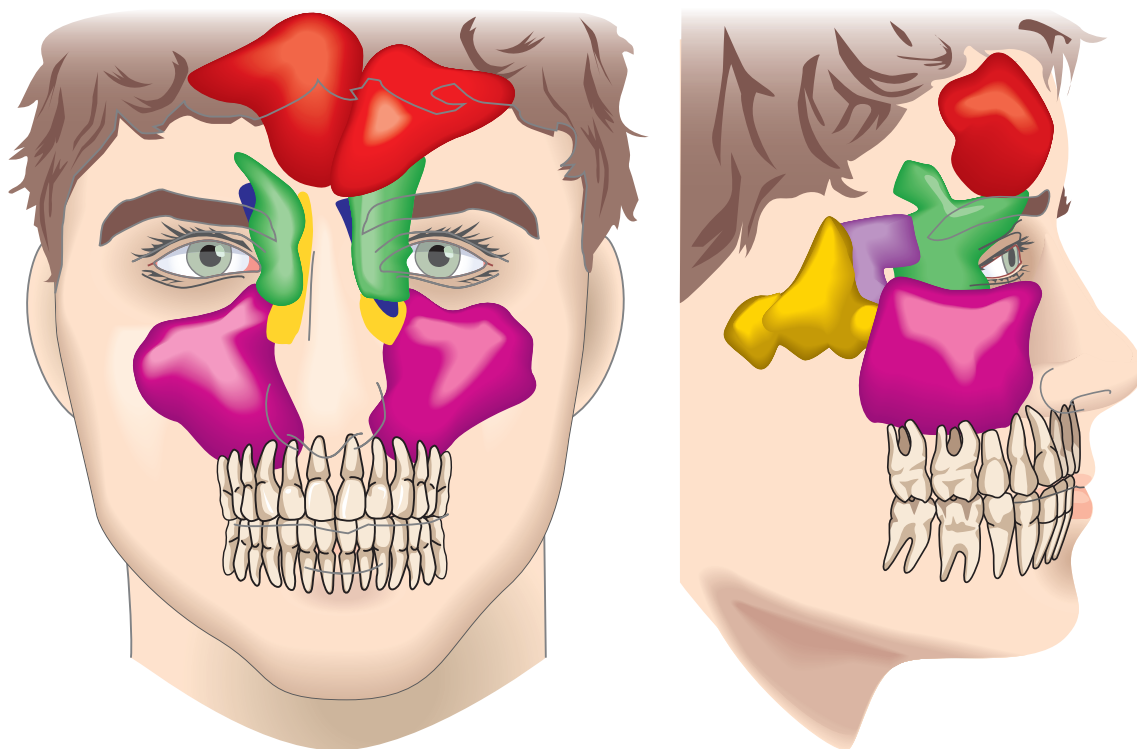

Figure 1 The paranasal sinuses. Maxillary sinuses (red), frontal sinuses (orange), anterior ethmoid sinuses (green), posterior ethmoid sinuses (purple), and sphenoid sinus (yellow).

This ostium opens into the semilunar hiatus of the middle meatus of the nasal cavity and is a highly innervated structure and is extremely sensitive when inflamed or stimulated during sinus-related pain episodes.³ Although the mucosa of the sinuses is rather insensitive to pain, the region of the ostia of the sinuses is the most sensitive of any of the nasal structures.⁴

Rhinosinusitis: Etiology, Epidemiology, Symptoms, and Treatment

The sinus openings or ostia are the focal point for sinus disease with blockage of the sinus ostia initiating the cycle of events leading to rhinosinusitis. Obstruction is commonly caused by inflammatory edema of the nasal lining mucosa usually in response to a virus, an allergen, or bacteria. This blockage can also occur from an anatomic obstruction such as a septal deviation or polyp, or a foreign body obstruction such as dried mucus. When a blockage occurs, mucous secretions, normally expelled through the ostium, accumulate within the sinus cavity where they begin to stagnate and thicken. The lack of sinus ventilation and stagnation of the secretions results in a lowered oxygen tension and a

decrease in pH, providing an excellent environment for bacterial pathogens to colonize.⁵ As the condition progresses, the cilia and the epithelium become damaged, preventing fluid movement, and there is further mucosal thickening creating a more severe obstruction. The condition of sinusitis has recently been redefined as *rhinosinusitis* due to the contiguous lining membrane of the paranasal and nasal cavities and its similar responses to therapy; however, both terms are presently used in the current literature.^{6,7}

Rhinosinusitis is the single most common chronic medical condition in the United States affecting approximately 16% of the population and accounting for up to 5% of all visits to primary care physicians.⁸ Rhinosinusitis is more prevalent in patients with congenital or acquired immunodeficiency, asthma, or allergic rhinitis. Symptoms may include nasal congestion, facial pain and pressure, purulent rhinorrhea, cough, headache, fever and fatigue, and pain in the maxillary posterior teeth.⁹ In a prospective study of 247 men, Williams et al.¹⁰ found that the symptom with the highest specificity for maxillary rhinosinusitis was a maxillary toothache at 93%.

A diagnosis of rhinosinusitis is generally made through clinical examination and is based on the

Figure 2 Maxillary rhinosinusitis. **A**, Coronal CT image of mucosal thickening and fluid accumulation in the maxillary sinuses (arrows). **B**, Coronal CT image of a completely obstructed right maxillary sinus (arrow).

patient's history and physical signs and symptoms, with no single clinical finding being conclusively predictive of the condition.¹⁰ In recurrent acute or chronic cases, endoscopy and CT scanning may be helpful in the diagnosis.⁶ Coronally viewed sections of a CT scan can reveal ostial patency or blockage, soft tissue changes, or any retained fluids that may be indicative of sinus disease (Figure 2). Although CT scanning has a high sensitivity, it has a low specificity for demonstrating rhinosinusitis. More than 40% of asymptomatic patients and 87% of patients with common colds show sinus abnormalities on sinus CT.^{11,12} It is also important to note that sinus inflammation and symptoms can occur in the absence of CT findings, thus the physician's overall clinical impression is superior to any single physical or radiological finding.¹³ Treatment of sinus disease is centered on re-establishing and then maintaining adequate drainage.

Rhinosinusitis is classified as acute, subacute, and recurrent acute or chronic according to the temporal course of the disease.^{6,9} Acute rhinosinusitis by definition lasts less than 4 weeks. Four or more episodes of acute rhinosinusitis within a 1-year period are defined as a recurrent acute rhinosinusitis. Subacute rhinosinusitis is a continuation of an acute form lasting between 4 and 12 weeks. Persistent signs and symptoms that continue unresolved for more than 12 weeks are classified as a chronic rhinosinusitis.

Acute rhinosinusitis usually has a sudden onset, usually with severe symptoms, but 40 to 50% of

patients will recover spontaneously and the remainder will respond fairly well to antibiotic and/or adjunctive treatments. The predominant bacterial flora isolated in acute rhinosinusitis includes *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Amoxicillin or trimethoprim-sulfamethoxazole is the preferred antibiotic as a first-line treatment although the role of antibiotics in uncomplicated rhinosinusitis has been questioned because of concern regarding its overuse.^{5,14,15} The bacterial species isolated from acute rhinosinusitis has not changed in the last 50 years; however, antibiotic resistance in these organisms is a growing problem due to a significant increase in the production of β -lactamase. It has been estimated that up to 40% of *H. influenzae* strains and more than 90% of *M. catarrhalis* isolates are now resistant to amoxicillin.¹⁶

Chronic rhinosinusitis usually has less severe symptoms, yet is more difficult to resolve. Because symptoms are poorly localized and mild, this condition may be extremely difficult to recognize. The bacterial flora of chronic rhinosinusitis tends to be a more mixed infection with *Staphylococcus aureus* and anaerobes being the more frequent isolates.¹⁷ Narrow spectrum antibiotic regimens are typically ineffective against chronic rhinosinusitis. Current treatment includes the use of broader spectrum antibiotics such as amoxicillin-clavulanate, clindamycin, or the combination of metronidazole and penicillin.¹⁸ Other adjunctive

treatments include the use of steroid nasal sprays, decongestants, or saline irrigation. If antibiotic therapy and adjunctive treatments prove ineffective, then endoscopic sinus surgery is currently the recommended procedure to surgically remove any diseased tissue or blockage and open the natural ostium in an attempt to re-establish drainage.¹⁸

Referral of Maxillary Sinus Pain to the Teeth

The referral of pain from the maxillary sinus to the maxillary dentition is primarily due to the close anatomic relationship between the floor of the maxillary sinus and the roots of the posterior maxillary teeth. In a highly pneumatized antrum, the sinus floor will extend between adjacent teeth and between individual roots of the maxillary molars (Figure 3). In a study of adults, Eberhardt¹⁹ found the average thickness of the bony partition between the apices of the maxillary second molar teeth and the antral mucosa to be only 0.83 mm. Occasionally, no bony partition exists at all with the roots apices and the sinus separated only by the mucosal lining.³ With such an intimate relationship, increased sinus pressure during sinusitis can produce the sensation of pain and pressure in the maxillary alveolar process and the corresponding teeth. Percussion of these proximate teeth produces acute tenderness due to the direct transfer of shock pressure to the inflamed sinus and the sensitive ostium. Often, for some patients, the most sensitive trigger for their sinus pain is by manipulation of the

Figure 3 Radiograph of a highly pneumatized left maxillary sinus in close approximation to the roots of the maxillary posterior teeth. The dense cortical bone defines the inferior border of the antrum (arrows).

maxillary posterior teeth, leading them to believe with near certainty that teeth are the source of their pain.

Heterotropic or neurologically referred pain can also be responsible for a patient mistaking rhinosinusitis for odontalgia.²⁰ It has been demonstrated that stimulation of the maxillary sinus ostium can induce dental pain in the maxillary posterior teeth.^{21–23} It has also been demonstrated that the local topical anesthetic applied to the maxillary sinus ostium can relieve perceived dental pain in the case of referred sinus pain.²⁴ Anesthetic nerve blocks, however, may not be reliable in differentiating maxillary rhinosinusitis from odontalgia due to mutual dental and antral innervations. Sensory innervation of the maxillary sinus is via the maxillary division of the trigeminal nerve with branches coming from the anterior, middle, and posterior superior alveolar nerves, the infra-orbital nerve, and the anterior palatine nerve.⁴ These nerves travel along the floor of the maxillary sinus innervating the related teeth.²⁵

Distinguishing Differences between Symptoms of Odontalgia and Sinus Pain

Proper diagnosis always starts with a complete medical and dental history. An important question to ask the patient during the endodontic exam as well as on the medical history form is, “Do you have chronic allergies, a current cold, congestion, or nasal drainage, or a history of sinus infections or problems?” Although many patients suffering with maxillary rhinosinusitis may perceive dental pain, they usually complain of a dull aching pain that is difficult to pinpoint or localize to a single tooth. In addition, the patients often feel pressure in their cheeks and below their eyes, which usually can be reproduced by external palpation of the cheeks. Positional changes can cause increased pain due to the movement of mucosal fluid over the sensitive sinus ostium as well as from increased intracranial pressure from blood flow.²⁶ The pain usually increases when patients are lying down, usually on one side more than the other, or if they bend over and place their heads below their knees. In addition, patients with acute rhinosinusitis can have potentially severe symptoms, but then experience sudden and total relief if the sinus pressure is temporarily alleviated.

In contrast, pain of pulpal origin is more easily localized, unchanged with variations in position and rarely intermittent in intensity. In cases of maxillary rhinosinusitis, often all teeth that are proximate to the sinus floor test positive to percussion, whereas with

odontalgia usually only the offending teeth are percussion-sensitive. The key diagnostic test in differentiating maxillary sinus etiology from pain of pulpal origin is the pulp vitality test. If the tooth in question responds within normal limits to a pulpal stimulus such as Electric pulp test (EPT) or ice, when compared with other healthy teeth, then pulpal etiology is effectively ruled out. Regardless of percussion sensitivity or the patient's complaint of spontaneous dental pain, endodontic therapy is not indicated, as removal of a healthy pulp will surely not provide pain relief.

Although periapical radiographs are crucial to a thorough endodontic examination, the clinician must be careful not to establish the entire diagnosis on radiographic interpretation alone, particularly when evaluating the posterior maxillary area. A variation in bone density, the presence of the maxillary sinus and its bony septa as well as the zygomatic and palatal

processes can impede important periradicular details necessary for accurate interpretation. Ambiguous radiographic conclusions are often the result, and multiple radiographic angles are highly recommended in combination with a thorough clinical examination.

Periapical Mucositis

A maxillary posterior tooth with apical periodontitis can produce a localized mucosal thickening in the adjacent sinus mucosa. This localized mucosal response to periapical odontogenic inflammation has been termed *periapical mucositis*.²⁷ Periapical mucositis is the inflammation or the swelling of the sinus membrane secondary to periapical inflammation, and will present as a radiopaque soft-tissue dome directly above the offending tooth²⁸ (Figures 4 and 5).

Figure 4 Periapical mucositis. **A**, Radiograph of a mucositis lesion (white arrows) in the right maxillary sinus apical to tooth #4 with necrotic pulp. **B**, Corresponding coronal CT image of the mucositis lesion (arrow). **C**, Follow-up radiograph taken 4 weeks after Root Canal Therapy (RCT) demonstrating full resolution of the mucositis.

Figure 5 Periapical mucositis. **A**, Radiograph of a mucositis lesion in the left maxillary sinus apical to tooth #13 (arrow). **B**, Follow-up radiograph taken 6 weeks after RCT showing full resolution of the mucositis.

Mucositis is usually asymptomatic and can be expected to resolve following endodontic treatment. It is important not to confuse a periapical mucositis with a mucous retention cyst or a mucocele on the floor of the maxillary sinus. Mucous retention cysts are seen in approximately 10% of the routine sinus CTs and are considered incidental findings. They can develop in all areas of the sinus and normally do not require surgical intervention by the physician unless they are blocking the ostium.⁹ Careful pulp testing is imperative in distinguishing a routine mucosal abnormality on the floor of the sinus from a mucositis secondary to periapical inflammation. Occasionally, apical periodontitis will not penetrate the antral floor, but rather will displace the periosteum, which in turn will deposit a thin layer of new bone on the periphery of the disease process. This has been termed periapical osteoperiostitis or “halo” shadow and will resolve following endodontic treatment of the offending tooth²⁷ (Figure 6).

Maxillary Sinusitis of Dental Origin

The link between dental and sinus pathosis is widely recognized in both the dental and the medical litera-

ture.^{28–39} This condition was first referred to by Bauer in 1943 as maxillary sinusitis of dental origin (MSDO) and occurs when a dental infection extends directly through the mucosal floor of the antrum causing a secondary maxillary sinus infection.²⁹ Bauer’s classic study on cadavers showed histological evidence of the extension of endodontic disease into the maxillary sinus, destruction of the cortical bone normally separating the teeth from the sinus floor, and causing pathological damage to the sinus tissues.

The pathological extension of dental disease into the maxillary sinus has since been well documented. Abrahams et al.³⁶ have reported that infections of the maxillary posterior teeth show maxillary sinus pathology in 60% of the cases, while Matilla³⁷ found sinus mucosal hyperplasia present in approximately 80% of teeth with periapical osteitis. Sinus inflammation in response to dental infection is usually localized to the floor of the sinus; however, if ostial obstruction occurs, this can lead to bacterial colonization and a sinus infection. The reported frequency of MSDO varies considerably, between 4.6 and 47% of all sinus infections.⁴⁰ This wide variation may be due to the difference in criteria and definitions as well as the inherent difficulty in establishing an exact causal relationship in maxillary sinusitis.⁴¹

Figure 6 Periapical osteoperiositis (“halo” lesion). **A**, Radiograph showing expansive bone formation resulting from a displaced periostium by the periapical infection from pulp necrosis in tooth #4. **B**, Post-operative radiograph of RCT in tooth #4. **C**, Follow-up radiograph taken 1 year after RCT demonstrating full resolution of the halo lesion.

It is generally accepted that dental infections account for approximately 10 to 15% of the cases of acute maxillary sinusitis.^{9,40} This phenomenon however, may be much higher in chronic cases. Melen et al.³⁸ in a study of 198 patients with 244 cases of chronic bacterial maxillary sinusitis, found dental etiology in 40.6% of the cases. It is also well documented that the predominant anaerobic bacterial isolates frequently found in chronic sinusitis are *Prevotella* sp., *Porphyromonas* sp., *Fusobacterium nucleatum*, and *Peptostreptococcus* sp., the same bacterial species that are found in endodontic infections.^{17,42–44} It is unclear if the presence of these species is an indication of dental etiology or simply develops due to environmental changes within the sinus as the condition becomes more chronic.

If a sinus infection is secondary to a dental infection, sinus healing cannot occur unless the offending tooth is endodontically treated or removed. The dental literature provides numerous case reports of the resolution of maxillary sinusitis following endodontic treatment or extraction.^{45–47} The challenge for patients with MSDO is that they often have primary symptoms of maxillary sinusitis yet are rarely able to localize pain to a specific tooth or sense any dental pain. These patients typically first seek care from their physicians or ENTs who may diagnose and treat the condition as a primary sinus infection, as dental infections are easily overlooked during routine ENT examinations.⁴⁸ Regrettably, some patients have undergone multiple antibiotic regimens and even sinus surgery before a dental condition is finally diagnosed as the primary etiology⁴⁹ (Figure 7).

Figure 7 Maxillary sinusitis of dental origin (MSDO). **A**, Coronal CT image of chronic unresolved rhinosinusitis despite extensive sinus surgery and more than 2 years of multiple antibiotic regimens (arrow). **B**, Periapical radiograph shows evidence of a failing RCT in tooth #14 adjacent to the antral floor. **C**, Post-operative radiograph following retreatment of RCT in tooth #14. **D**, Follow-up coronal CT image taken 6 weeks after endodontic retreatment showing full resolution of sinus infection.

This unfortunately occurs despite strong suggestions in the medical literature for careful oral examination including dental radiographs in all patients with recurrent acute or chronic maxillary sinusitis.^{38,44,48,50}

The importance of properly diagnosing and treating MSDO is heightened with reports in the literature

of dental infections spreading rapidly through the maxillary sinus causing orbital cellulitis, blindness, meningitis, subdural empyema, brain abscess, and life-threatening cavernous sinus thrombosis.⁵⁰⁻⁵² More recent medical literatures on sinus management have emphasized the need to rule out and treat any possible

dental etiology for both acute and chronic rhinosinusitis.^{16,41} However, to date none of the current medical guidelines for management of acute or chronic rhinosinusitis include the recommendation for referral to a dentist or an endodontist to rule out a possible dental etiology.^{18,53–55} An improved communication between the endodontic and ENT communities is essential in providing improved patient care and resolving a greater number of cases of MSDO.

When diagnosing a possible dental etiology for a patient with maxillary rhinosinusitis, the endodontist must seek out any pulpal necrosis and periapical disease and must carefully evaluate all previous endodontic treatments for failure in the suspected quadrant. In order for a periapical infection to occur, bacteria must be present within the root canal system.⁵⁶ A vital pulp,

whether healthy or inflamed, will not contribute significantly to any periapical or secondary sinus infection. Thus, in order for MSDO to occur, the causative tooth must either have necrotic pulp tissue or have a failing endodontic treatment.

Properly angled periapical radiographs can offer helpful information regarding sinus pathosis. A generalized inflammatory reaction of the sinus mucosa will result in mucosal hyperplasia, which may be seen as a radiopaque band of tissue following the contours of the sinus floor.⁵⁷ Periapical and panoramic radiographs may also reveal the presence of significant mucosal fluid buildup in the sinus floor or complete opacification, which can be confirmed with a corresponding CT scan and through communication with the ENT physician (Figure 8). If the sinus infection is

Figure 8 Maxillary sinusitis of dental origin (MSDO). **A**, Coronal CT image of a patient diagnosed with right maxillary sinusitis (arrow). **B**, Periapical radiograph shows no evidence of periapical radiolucency; however, the right maxillary sinus appears cloudy. Clinical tests reveal the pulp in tooth #2 to be necrotic. **C**, Follow-up radiograph taken 4 weeks after RCT in tooth #2 with patient reporting resolution of sinusitis symptoms. The sinus appears less cloudy than preoperatively on the periapical radiograph.

Figure 9 Maxillary sinusitis of dental origin (MSDO). **A**, Patient presented with radiating spontaneous pain in the upper left quadrant. Tooth #15 tested necrotic; however, radiographic evidence was inconclusive for periradicular or sinus pathosis. **B**, Digital CT imaging reveals significant left maxillary sinus pathosis apical to tooth #15 (arrow) and evidence of periapical radiolucency associated with the palatal root of tooth #15. **C**, Postoperative radiograph following RCT of tooth #15. **D**, One-year follow-up digital CT images show complete resolution of left maxillary sinus pathosis and endodontic disease.

determined to be secondary to periapical infection, endodontic therapy or extraction should resolve the problem. However, concomitant management of the associated rhinosinusitis may be necessary to ensure complete resolution of the infection and to prevent any complications.⁴³ The resolution should be confirmed with a follow-up radiograph or a CT scan and a positive patient report. The increased availability and resolution of digital CT imaging should be of great future benefit in the diagnosis of MSDO as well as for the post-treatment follow-up confirming the resolution of the mucosal inflammation (Figure 9).

CHAPTER 18

ENDODONTIC—PERIODONTAL INTERRELATIONSHIPS

ILAN ROTSTEIN, JAMES H.S. SIMON

Endodontic—Periodontal Communication

Understanding the interrelationship between endodontic and periodontal diseases is crucial for correct diagnosis, prognosis, and treatment decision making. The dental pulp and the periodontium are closely related, and pathways of communications between these structures often determine the progress of disease in these tissues. The main pathways for communication between the dental pulp and the periodontium are (1) dentinal tubules, (2) lateral and accessory canals, and (3) the apical foramen.

DENTINAL TUBULES

Direct communication between the pulp and the periodontium may occur via patent dentinal tubules if the cementum layer is interrupted. This is usually attributed to developmental defects, disease processes, or surgical procedures involving root surfaces. Exposed dentinal tubules, in areas devoid of cementum, may serve as communication pathways between the pulp and the periodontal ligament (Figure 1).

Radicular dentin tubules extending from the pulp to the cemento-dentinal junction run a relatively straight course.¹ Their diameter ranges from 1 μm at the periphery to 3 μm near the pulp.² The tubular lumen decreases with age or as a response to chronic low grade stimuli causing apposition of highly mineralized peritubular dentin. The density of dentin tubules varies from approximately 15,000/mm² in the cervical portion of the root down to 8,000/mm² near the apex. At the pulpal end, however, tubular numbers increase to 57,000/mm².² When the cementum and enamel do not meet at the cemento-enamel junction (CEJ), these

tubules remain exposed, thus creating pathways of communication between the pulp and the periodontal ligament. Cervical dentin hypersensitivity is a classic example of such tubular exposure.

Scanning electron microscopic studies have demonstrated that dentin exposure at the CEJ occurs in about 18% of teeth.³ This incidence is even higher in anterior teeth reaching up to 25%.³ The same tooth may also have several different CEJ characteristics, presenting dentin covered with cementum on one side while the other sides have dentin exposure.⁴ Dentin exposure plays an important role in the progression of endodontic or periodontal pathogens, as well as cementum root scaling and planing, trauma, and chemically induced pathosis.^{5–8}

LATERAL AND ACCESSORY CANALS

Lateral and accessory canals may be found anywhere along the root^{9–15} (Figure 2). It is estimated that 30 to 40% of all teeth have lateral or accessory canals, mostly found in the apical third of the root.¹ De Deus¹² found that 17% of the teeth examined presented lateral canals in the apical third of the root, about 9% in the middle third, and less than 2% in the coronal third. Kirkham,¹³ however, reported that only 2% of lateral canals were associated with periodontal pockets.

Accessory canals in the furcation of molars may also be pathways of communication between the pulp and periodontium.^{10,14} The reported incidence of furcal accessory canals varies from 23 to 76%.^{11,12,16} In vital pulps, these accessory canals contain connective tissue and blood vessels that connect the circulatory system of the pulp with the periodontium. However, not all these canals extend the full length from the

Figure 1 **A**, Scanning electron micrograph of open dentinal tubules. **B**, Higher magnification demonstrates absence of odontoblastic processes.

Figure 2 Non-surgical endodontic treatment of a maxillary central incisor with a lateral radiolucency. **A**, Pre-operative radiograph showing previously treated canal with mesial lateral lesion. **B**, Tooth was re-treated and the root canal filled with thermoplasticized gutta-percha. Note, lateral canal extending toward the lesion. **C**, One-year recall shows evidence of active healing.

Figure 3 Micrograph stained with Masson's trichrome of a maxillary lateral incisor with a necrotic pulp associated with a lateral inflammatory process in the periodontal ligament. **A**, Main canal, accessory canal, and the resultant inflammatory response in the periodontal ligament are evident. **B**, Higher magnification of the area shows chronic inflammation with proliferating epithelium.

pulp chamber to the floor of the furcation.¹⁶ Seltzer et al.¹⁷ suggested that pulpal inflammation or necrosis may cause inflammatory reaction in the inter-radicular periodontal tissues. Patent accessory canals are a potential pathway for the spread of microorganisms and their toxic byproducts, as well as other irritants, from the pulp to the periodontal ligament and vice versa, resulting in an inflammatory process in the involved tissues (Figure 3).

Clinically, lateral canals are very difficult to detect. Pineda and Kuttel¹⁸ reported that about 30% of lateral canals could be identified through use of two-view radiographs, whereas standard radiographs identified only about 8%. Moreover, using this method, the identification of any accessory canals in the furcation area of molar teeth was also possible. Clinically, predictable identification of lateral and accessory canals, on the basis of radiographic interpretation alone, may be achieved in a very small number of cases. Several clinical aids, however, may be helpful for their identification: (1) a radiographic image of a discrete lateral lesion associated with a necrotic pulp; (2) radiographic identification of a "notch" on the lateral root surface suggesting the presence of an orifice; and (3) demonstration of root canal filling material, or sealer, extruding through the patent orifices.

APICAL FORAMEN

The apical foramen is the main pathway of communication between the pulp and periodontium. Irritants from a diseased pulp may permeate readily through the apical foramen resulting in periapical pathosis. The apical foramen may also be a portal of entry of irritants from deep periodontal pockets into the pulp. Often, such irritants cause a local inflammatory response associated with bone and root resorption. Elimination of the etiologic irritants from the root canal, as well as from the periodontal tissues, is therefore essential to promote healing.

Pulpal–Periodontal Interrelationship

When the pulp becomes infected, it elicits an inflammatory response of the periodontal ligament at the apical foramen and/or openings of lateral and accessory canals. Inflammatory by-products of pulpal origin may permeate through the apex, lateral and accessory canals, and dentinal tubules to trigger an inflammatory vascular response in the periodontium. Among those products are living pathogens such as certain bacterial strains, fungi, and viruses^{19–27} as well as several non-living pathogens.^{28–31} In certain cases,

pulpal disease may stimulate epithelial growth that will affect the integrity of the periradicular tissues.^{32,33}

The result of pulp inflammation can range in extent from minimal inflammation, confined to the periodontal ligament to extensive destruction of the periodontal ligament, tooth socket, and surrounding bone. Such a lesion may result in a localized or diffuse swelling that occasionally involves the gingival attachment. A lesion related to pulpal necrosis may result in a sinus tract that drains through the alveolar mucosa or attached gingival. Occasionally, it may also drain through the gingival sulcus of the involved tooth or the gingival sulcus of an adjacent tooth. In most instances, after adequate root canal treatment, lesions resulting from pulpal necrosis resolve uneventfully, and the integrity of the periodontal tissues are re-established.³⁴

Certain procedures involved in root canal treatment as well as irrigants, intra-canal medicaments, sealers, and filling materials have the potential to cause an inflammatory response in the periodontium. These inflammatory responses, however, are usually transient in nature and quickly resolved if the materials are confined within the canal space. Periodontal defects, resulting from attachment breakdown, may occur after procedural mishaps, such as perforations of the floor of a pulp chamber or the root surface apical to the gingival attachment, strip perforations, or root perforations from cleaning and shaping procedures. Periodontal defects may also be caused by vertical root fractures associated with excessive force used during canal obturation or restorative procedures.

Periodontal–Pulpal Interrelationship

The effect of periodontal inflammation on the pulp is more controversial.^{17,35–49} It appears that, clinically, the pulp is usually not affected by periodontal disease until the defect has exposed an accessory canal to the oral environment.⁹ At this stage, pathogens that pass from the oral cavity through the accessory canal into the pulp may cause a localized inflammatory reaction that could be followed by pulp necrosis. On the other hand, if the microvasculature of the apical foramen remains intact, the pulp may test positive to pulp vitality tests. The effect on the pulp of periodontal treatment is similar during scaling, curettage, or periodontal surgery if accessory canals are severed and/or opened to the oral environment. In such cases, pathogenic invasion and secondary inflammation and necrosis of the pulp may result.⁴⁴ It has been suggested that endodontic infection in molars, involved

with periodontal disease, might enhance progression of periodontitis by spreading pathogens through accessory canals and dentinal tubules.^{47,48}

Etiological Factors

Among the pathogens from a diseased pulp, that can cause lesions in the apical tissues and periodontium, are bacteria (Figure 4), fungi (Figure 5), and viruses (Figure 6). These pathogens and their by-products must be eliminated during endodontic treatment. Pathogens and other irritants associated with apical periodontitis other than microbes are discussed in Chapter 8, “Non-microbial Endodontic Disease.”

BACTERIA

Bacteria play a critical role in both endodontic and periodontal diseases.^{25,50–57} Periapical tissues become involved following bacterial invasion of the pulp, leading to partial or total pulp necrosis. Kakehashi et al.⁵⁰ demonstrated the relationship between the presence of bacteria in the pulp and periapical disease. Pulp of normal rats were exposed and left open to the oral environment. Pulp necrosis ensued followed by periapical inflammation, lesion formation, and furcal inflammation. On the other hand, when the same procedure was performed in germ-free rats, the pulps remained vital and relatively non-inflamed and the exposure sites were repaired by dentin. The study demonstrated that without bacteria and their products, periapical lesions would not occur from exposed pulps. Möller et al.⁵² confirmed these findings in monkeys.

Proteolytic bacteria predominate in the root canal flora, which changes over time to a more anaerobic microbiota.^{58,59} Specific profiles of periodontal pathogens in pulpal and periodontal diseases associated with the same tooth were also studied.⁶⁰ It appears that periodontal pathogens and endodontic pathogens are similar and that endodontic–periodontal interrelationships are a critical pathway for both diseases.

Spirochetes are associated with both endodontic and periodontal diseases. Spirochetes are found more frequently in subgingival plaque than in root canals. As several studies have shown a large diversity of oral treponemes present in subgingival biofilms of periodontal pockets,^{61–63} it has been assumed that the presence or absence of oral spirochetes can be used to differentiate between endodontic and periodontal abscesses.²⁰ However, today, the presence of spirochetes in the root canal system is well documented and has been demonstrated by different identification

Figure 4 Periapical *Actinomyces* infection. This case demonstrates the growth of bacteria past the apical foramen and their invasion of apical cementum and periapical tissues. **A**, Radiograph of a maxillary central incisor with a necrotic pulp showing a large periapical lesion. **B**, Non-surgical endodontic therapy was done but symptoms persisted. **C**, Apical surgery was then performed. Photomicrograph shows part of the root with the attached lesion. **D**, Colonies of *Actinomyces* in the lumen of the lesion are evident. **E**, Higher magnification shows large colony of *Actinomyces*. **F**, Foamy macrophages attacking the bacteria. **G**, Edge of the bacterial mega-colony showing the absence of inflammatory cells unable to penetrate the colony. **H**, Higher magnification of the bacterial colony. **I**, Center of the colony devoid of inflammatory cells. **J**, Viable bacteria within the apical cementum.

techniques.^{22,23,64,65} The spirochete species most frequently found in root canals are *Treponema denticola*^{66,67} and *Treponema maltophilium*.⁶⁸

L-form bacteria may also have a role in endodontic disease.⁶⁹ Some bacteria strains can undergo morphological transition to their L-form after exposure to certain agents, particularly penicillin. L-form bacteria may transform with several intermediate L-form transitional stages. This may occur either spontaneously or by induction in a cyclic manner. Under certain conditions, depending on host resistance factors and bacterial virulence, the L-forms revert to their original pathogenic bacterial form and may then be responsible for acute exacerbation of chronic apical lesions.⁶⁹

FUNGI

The presence and prevalence of fungi associated with endodontic infections is well documented.^{26,70–78} The majority of these fungi are *Candida albicans*.^{79,80} Fungi may also colonize canal walls and invade dentinal tubules.⁸¹ Other species such as *Candida glabrata*, *Candida guilliermondii*, *Candida inconspicua*,⁷⁹ and *Rodotorula mucilaginosa*²⁴ have also been detected.

Factors affecting the colonization of the root canal by fungi are not fully understood. It has been suggested that the reduction of specific strains of bacteria in the root canal during endodontic treatment may allow fungal overgrowth in the remaining low nutrient environment.^{75,82} Another possibility is that fungi

Figure 6 Transmission electron micrograph of the nucleus of a macrophage in a periapical lesion suggesting a possible viral infection.

may gain access to the root canal from the oral cavity as a result of poor asepsis during endodontic treatment or post-preparation procedures. It has been found that approximately 20% of adult periodontitis patients also harbor subgingival yeasts.^{83,84} As in endodontic infections, *C. albicans* was the most common species isolated.⁸⁵

It has also been demonstrated that the presence of fungi in root canals is directly associated with their presence in saliva.²⁴ These findings further stress the importance of using aseptic endodontic and periodontal techniques, maintaining the integrity of dental hard tissues, and covering the tooth crown as soon as practical with a well-sealed permanent restoration in order to prevent re-infection.

VIRUSES

Viruses may also play a role in the pathogenesis of both endodontic and periodontal diseases. In patients with periodontal disease, herpes simplex virus was frequently detected in gingival crevicular fluid and in

gingival biopsies of periodontal lesions.⁸⁶ Human cytomegalovirus was observed in about 65% of periodontal pocket samples and in about 85% of gingival tissue samples. Epstein–Barr virus type I was observed in more than 40% of pocket samples and in about 80% of the gingival tissue samples.⁸⁶ Gingival herpesviruses were found to be associated with increased occurrence of subgingival *Porphyromonas gingivalis*, *Bacteroides forsythus*, *Prevotella intermedia*, *Prevotella nigrescens*, *T. denticola*, and *Actinobacillus actinomyces-comitans*, thus suggesting a role in overgrowth of periodontal pathogenic bacteria.⁸⁷

Recent data suggest that certain viruses may also be involved in pulpal disease and associated periapical pathoses such as human cytomegalovirus and Epstein–Barr virus.⁸⁸ Thus far, however, herpes simplex virus has not been detected in periapical lesions. It appears that active virus infection may give rise to production of an array of cytokines and chemokines with the potential to induce immunosuppression and tissue destruction.⁸⁹ Herpesvirus activation in periapical inflammatory cells may impair the host defense mechanisms and give rise to overgrowth of bacteria, as seen in periodontal lesions. Herpesvirus-mediated immune suppression may also be detrimental in periapical infections due to already compromised host resistant factors and affected connective tissues in situ.⁹⁰ Alterations between prolonged periods of herpesvirus latency interrupted by periods of activation may explain some burst-like symptomatic episodes of periapical disease. Absence of herpesvirus infection or viral reactivation may be the reason that some periapical lesions remain clinically stable and asymptomatic for extended periods of time.⁸⁸ However, more research is needed to further clarify the relationship between viral infections and pulpal and/or periodontal diseases.

Contributing Factors

Periapical disease of non-endodontic origin is reviewed in Chapter 8, “Non-microbial Endodontic Disease”.^{91–98}

INADEQUATE ENDODONTIC TREATMENT

It is essential to clean, shape, and obturate the canal system well in order to enhance successful outcomes.^{99–101} Poor endodontic treatment often results in treatment failure. Endodontic failures can be treated either by orthograde retreatment or by endodontic surgery with good success rates. In recent years, retreatment techniques have improved dramatically due to use of the operating microscope and development of new armamentarium.

CORONAL LEAKAGE

The term coronal leakage refers to leakage of microbes and other irritants to the root canal filling. Coronal leakage is a major cause of endodontic treatment failure.^{102–104} Root canals may also become contaminated by microorganisms due to delay in placement of a coronal restoration and fracture of the coronal restoration and/or the tooth.¹⁰² Defective restorations and adequate root canal fillings will have a higher incidence of failures than teeth with inadequate root canal fillings and adequate restorations.¹⁰³ In an *in vitro* study, it was found that packing excess gutta-percha and sealer over the floor of the pulp chamber, after completion of root canal filling, did not provide a better seal of the root canals.¹⁰⁴ It is therefore recommended that excess of gutta-percha filling should be removed to the level of the canal orifices and the floor of the pulp chamber be protected with a

well-sealed restorative material. An adequate coronal restoration is the primary barrier against coronal leakage and bacterial contamination of the root canal treatment.¹⁰⁰ It is essential that the root canal system be protected by good endodontic obturation and a well-sealed coronal restoration.

TRAUMATIC INJURIES

Traumatic injuries to teeth may involve the pulp and the surrounding periodontal attachment apparatus. Dental injuries may vary but generally can be classified as enamel fractures, crown fractures without pulp involvement, crown fractures with pulp involvement, crown-root fracture, root fracture, luxation, and avulsion.¹⁰⁵ Treatment and prognosis will depend on the type of injury.^{105–113} Surgical exposure of the remaining tooth structure is one option (Figure 7). Treatment of traumatic injuries is

Figure 7 **A**, Canine fractured below the gingival level, compromising root canal treatment. **B**, Gingivoplasty and osteoplasty to remove gingival tissue and bone uncovering the root while maintaining normal gingival architecture. Strip of attached gingiva must be retained. Root canal filling is completed. **C**, Temporary crown has been placed and attached gingiva has regrown at new level. (Courtesy, Dr. Edward E. Beveridge)

covered in Chapter 35 “Endodontic Considerations in Dental Trauma.”

ROOT PERFORATIONS

Root perforations may often cause clinical complications that lead to periodontal lesions. Root perforations may result from extensive carious lesions, resorption, or from operator error during root canal instrumentation or post preparation.¹¹⁴ Treatment prognosis of root perforations depends on the size, location, time of diagnosis and treatment, degree of periodontal damage as well as the sealing ability and biocompatibility of the repair material. It has been recognized that treatment success depends mainly on immediate sealing of the perforation and appropriate infection control. When the root perforation is situated close to the alveolar crest, it may be possible to raise a flap and repair the defect with an appropriate filling material. In deeper perforations, or in a furcation, immediate repair of the perforation has a better prognosis than management of an infected one. Many materials have been used to seal root perforations. Mineral Trioxide Aggregate is widely used to seal root perforations. Techniques for perforation repair are covered in Chapter 30 “Retreatment of Non-Healing Endodontic Therapy and Management of Mishaps.”

Another treatment modality for perforations, root resorptions, and certain root fractures in the cervical third region is orthodontic root extrusion.^{115–118} The procedure has very good prognosis and a low risk of relapse. It can be performed either immediately or over a few weeks period depending on each individual case. The goal of controlled root extrusion is to modify the soft tissues and bone and is therefore used to

correct gingival discrepancies and osseous defects of periodontally involved teeth.¹¹⁶ It is also used in the management of non-restorable teeth and as a non-surgical alternative to crown lengthening.¹¹⁷

DEVELOPMENTAL MALFORMATIONS

Radicular invaginations or radicular grooves can lead to an untreatable periodontal condition (Figure 8). These grooves usually begin in the central fossa of maxillary central and lateral incisors crossing over the cingulum and continuing apically down the root for varying distances. Such a groove is probably the result of an attempt of the tooth germ to form another root. As long as the epithelial attachment remains intact, the periodontium remains healthy. However, once this attachment is breached and the groove becomes contaminated, a self-sustaining infrabony pocket can be formed along its entire length. This fissure-like defect provides a nidus for accumulation of microorganisms and an avenue for the progression of periodontal disease that can also affect the pulp. Radiographically, the area of bone destruction follows the course of the groove.

Clinically, the patient may present symptoms of a periodontal abscess or a variety of asymptomatic endodontic conditions. If the condition is purely periodontal, it can be diagnosed by visually following the groove to the gingival margin and by probing the depth of the pocket, which is usually tubular in form and localized to this one area, as opposed to a more generalized periodontal problem. The tooth will also respond to pulp testing procedures. If this condition is also associated with an endodontic disease, the patient may present clinically with any of the

spectrum of endodontic symptoms. While performing clinical examination, the clinician must look for the groove as it may have been altered by a previous access opening or restoration placed in the access cavity. The appearance of a teardrop-shaped area on the radiograph should immediately arouse suspicion. The developmental groove may be visible on the radiograph as a dark vertical line. This condition must be differentiated from a vertical fracture, which may give a similar radiographic appearance.

The prognosis of root canal treatment in such cases is guarded, depending on the apical extent of the groove. Radicular grooves are self-sustaining infra-bony pockets and therefore scaling and root planing will not suffice. Although the acute nature of the problem may be alleviated initially, the source of the chronic or acute inflammation must be eradicated by a surgical approach. Treatment consists of burring out the groove, placing bone substitutes, and surgical management of the soft tissues and underlying bone. A clinical case using Emdogain as a treatment adjunct was recently described.¹¹⁹ If unsuccessful, the tooth needs to be extracted due to poor prognosis.

Differential Diagnosis

Differential diagnosis for treatment and prognosis of endodontic–periodontal diseases can be achieved by using the following classification: (1) primary endodontic diseases, (2) primary periodontal diseases, and (3) combined diseases.¹²⁰ The combined diseases include (1) primary endodontic disease with secondary periodontal involvement, (2) primary periodontal disease with secondary endodontic involvement, and (3) true combined diseases. This classification is based on how these lesions are formed. By understanding the pathogenesis, the clinician can then offer an appropriate course of treatment and better assess the prognosis.

PRIMARY ENDODONTIC DISEASE

A chronic apical abscess may drain coronally through the periodontal ligament into the gingival sulcus. This condition may clinically mimic the presence of a periodontal abscess draining through a pseudo-pocket. In reality, the pocket is a sinus tract from pulpal origin that opens through the periodontal liga-

ment area. A deep solitary pocket in the absence of periodontal disease may indicate the presence of a lesion of endodontic origin. For diagnosis purposes, a gutta-percha cone, or another tracking instrument, should be inserted into the sinus tract and radiographs taken. This will determine the origin of the lesion. A sulcular pocket of endodontic origin is typically very narrow compared to a pocket of periodontal origin. A similar condition occurs where drainage from the apex of a molar extends coronally into the furcation area. This may also occur in the presence of lateral canals extending from a necrotic pulp into the furcation area. A vertical root fracture or a radicular crack should always be ruled out as they may give initially similar periodontal clinical findings. Primary endodontic lesions usually heal following root canal treatment. The sinus tract extending into the gingival sulcus or furcation area quickly heals once the affected pulp has been removed and the root canals cleaned, shaped, and obturated (Figures 9, 10).

PRIMARY PERIODONTAL DISEASE

These types of conditions are caused primarily by periodontal pathogens. In this process, chronic marginal periodontitis progresses apically along the root surface. In most cases, pulp tests indicate a clinically normal pulpal reaction (Figure 11). There is frequently an accumulation of plaque and calculus and the pockets are wider. The prognosis depends upon the stage of periodontal disease and the efficacy of periodontal treatment. The clinician must also be aware of the radiographic appearance of periodontal disease associated with developmental radicular anomalies (Figures 12, 13).

PRIMARY ENDODONTIC DISEASE WITH SECONDARY PERIODONTAL INVOLVEMENT

Untreated suppurating primary endodontic disease may sometimes become secondarily involved with marginal periodontal breakdown. In such cases, marginal periodontitis is developed as a result of plaque formation at the gingival margin of the sinus tract. When plaque or calculus is present, the treatment and prognosis of the tooth are different than those of teeth involved with only primary endodontic

Figure 9 Primary endodontic disease in a mandibular first molar with necrotic pulp. **A**, Preoperative radiograph showing periradicular radiolucency associated with the distal root. **B**, Clinically, a deep narrow buccal periodontal defect can be probed. **C**, One-year after root canal therapy, resolution of the periradicular bony radiolucency is evident. **D**, Clinically, the buccal defect healed and probing is normal.

Figure 10 Osseous repair of primary endodontic lesion following trauma. **A**, Following root canal treatment, surgical approach removed inflammatory tissue to initiate repair. There was no periodontal disease. **B**, "Reentry" 2 years later reveals excellent repair with regrowth of alveolar bone, cementum, and periodontal ligament. (With permission, Hiatt W. J Am Soc Periodont; 1963;1:152.)

Figure 11 Primary periodontal disease in a mandibular second molar. Patient was referred for endodontic therapy. **A**, Preoperative radiograph showing periradicular radiolucency; however, the tooth responded to pulp sensitivity tests. The referring dentist insisted that endodontic therapy should be done. **B**, Photomicrograph of the pulp tissue removed during treatment. Note normal appearance of the pulp. **C**, Higher magnification shows normal cellular components as well as blood microvasculature. **D**, Post-operative radiograph. The tooth was subsequently lost due to the periodontal disease.

disease. The tooth now requires both endodontic and periodontal treatments. If the endodontic treatment is adequate, the prognosis depends on the severity of the marginal periodontal damage and the efficacy of periodontal treatment. With endodontic treatment alone, only part of the lesion will heal to the level of the secondary periodontal lesion (Figure 14).

A similar clinical picture may also occur as a result of root perforation during root canal treatment, or where pins or posts have been misplaced during coronal restoration. Sometimes, symptoms may be acute, with periodontal abscess formation associated with pain, swelling, purulent exudate, and pocket formation and tooth mobility. A more chronic response may also occur without pain and involves the sudden

Figure 12 Primary periodontal lesion simulating endodontic lesion. **A**, Radiograph of mandibular first molar showing periradicular radiolucency and periapical resorption. **B**, and **C**, Buccal and lingual views of the affected tooth. Note, gingival swelling and evidence of periodontal disease. In addition, an occlusal filling is present close to the pulp chamber. In spite of the clinical and radiographic picture, the pulp responded normal to vitality testing procedures indicating the radiolucency, resorption and gingival swelling are of periodontal origin. **D**, Microphotograph stained with H&E showing floor of the pulp chamber and entrance to the mesial canal containing normal pulp tissue.

appearance of a pocket with bleeding on probing or exudation of pus.

Root fractures may also mimic the appearance of primary endodontic lesions with secondary periodontal involvement. These typically occur on endodontically treated teeth often with a large post. In such cases, a local deepening of a periodontal pocket and more acute periodontal abscess symptoms can be found.

PRIMARY PERIODONTAL DISEASE WITH SECONDARY ENDODONTIC INVOLVEMENT

A periodontal pocket may continue and progress until the apical tissues are involved. In this case, the pulp may become infected due to irritants entering via lateral canals or the apical foramen and subse-

quently become necrotic. In single-rooted teeth, the prognosis is usually poor. In molar teeth, the prognosis may be better because not all the roots may suffer the same loss of supporting tissues. In some of these cases, root resection can be considered as a treatment alternative.

Bacteria originating from the periodontal pocket can be a source of root canal infection. A strong correlation between the presence of microorganisms in root canals and their presence in periodontal pockets of advanced periodontitis has been demonstrated indicating that similar pathogens may be involved in both diseases.^{121,122} As long as the neurovascular supply of the pulp remains intact, prospects for survival are good. If the neurovascular supply is lost to periodontal disease, pulpal necrosis will ensue.⁴²

Figure 13 Primary periodontal disease in a maxillary first premolar. **A**, Radiograph showing alveolar bone loss and a periapical lesion. Clinically, a deep narrow pocket was found on the mesial aspect of the root. There was no evidence of caries, and the tooth responded normally to pulp sensitivity tests. **B**, Radiograph showing pocket tracking with gutta-percha cone to the apical area. It was decided to extract the tooth. **C**, Clinical view of the extracted tooth with the attached lesion. Note a deep mesial radicular development groove. **D**, Photomicrograph of the apex of the tooth with the attached lesion. **E**, and **F**, Higher magnification shows the inflammatory lesion, cementum and dentin resorption, and osteoclasts. **G**, and **H**, Histologic sections of the pulp chamber shows uninfamed pulp, odontoblastic layer, and intact predentin.

Figure 14 Primary endodontic disease with secondary periodontal involvement in a mandibular first molar. **A**, Preoperative radiograph demonstrating interradicular defect extending to the apical region of the mesial root. **B**, Radiograph taken at completion of root canal therapy. **C**, One-year follow-up radiograph showing resolution of most of the periradicular lesion; however, a bony defect at the furcal area remained. Note that endodontic treatment alone did not yield complete healing of the defect. Periodontal treatment is necessary for further healing of the furcal area and inflamed gingival tissues.

Figure 15 Primary periodontal disease with secondary endodontic involvement in a maxillary premolar. **A**, Radiograph showing bone loss in one-third of the root and separate periapical radiolucency. The crown was intact, but pulp sensitivity tests were negative. **B**, Radiograph taken immediately after root canal therapy showing sealer in lateral canal that was exposed due to bone loss.

Figure 16 True combined endodontic–periodontal disease in a mandibular first molar. Radiograph showing separate progression of endodontic disease and periodontal disease. The tooth remained untreated and consequently the two lesions joined together.

Treatment complications of periodontal disease can also lead to secondary endodontic involvement. Lateral canals and dentinal tubules may be opened to the oral environment by curettage, scaling, or surgical flap procedures. In such cases, blood vessels within a lateral canal can be severed by a curette and microorganisms introduced into the area during treatment. This may often result in pulp inflammation and necrosis (Figure 15).

TRUE COMBINED DISEASES

True combined diseases occur less often. They are usually formed when an endodontic disease progressing coronally joins with an infected periodontal pocket progressing apically.^{17,123} The degree of attachment loss in this type of lesions is large and the prognosis guarded in single-rooted teeth (Figures 16, 17, 18). In most cases, periapical healing may be anticipated

Figure 17 True combined endodontic-periodontal disease. **A**, Radiograph showing bone loss in two-thirds of the root with calculus present and separate periapical radiolucency. **B**, Clinical examination revealed coronal color change of the tooth involved and pus exuding from the gingival crevis. Pulp sensitivity tests were negative.

following successful endodontic treatment. However, the periodontal tissues may not respond well to treatment, and healing will depend on the severity of the condition.

The radiographic appearance of combined endodontic-periodontal disease may be similar to that of a vertically fractured tooth. A fracture that has invaded the pulp space causing pulp necrosis may also be considered a true combined lesion and yet not be amenable to successful treatment. Often, it is necessary to perform surgical exploration of the affected site to confirm the diagnosis.

Prognosis

Correct diagnosis of the etiology of the disease process, whether endodontic, periodontal, or combined, will determine the treatment and long-term prognosis. The main factors to consider are pulp vitality and type and extent of the periodontal condition. For example, the prognosis for a tooth with a necrotic pulp, with or without a sinus track, is excellent following adequate root canal therapy. However, the prognosis of root canal treatment in a tooth with severe periodontal disease is dependent on the success of the periodontal therapy.

Primary endodontic disease need only be treated by endodontic therapy. Good prognosis is to be expected if appropriate endodontic treatment is carried out. Primary periodontal disease should only be treated by periodontal therapy. In this case, the prognosis depends on severity of the periodontal disease and the patient's tissues response.

Primary endodontic disease with secondary periodontal involvement should first be treated with endodontic therapy. Treatment results should be evaluated in 2 to 3 months and only then periodontal treatment should be considered. This sequence of treatment allows sufficient time for initial tissue healing and better assessment of the periodontal condition.^{15,124} It also reduces the potential risk of introducing bacteria and their byproducts during the initial phase of healing. Aggressive removal of the periodontal ligament and underlying cementum during interim endodontic therapy might adversely affect periodontal healing.¹²⁵ What is of endodontic etiology will heal, in most cases, following adequate endodontic therapy, leaving periodontal disease to be treated.

Primary periodontal disease with secondary endodontic involvement and true combined endodontic-periodontal diseases require both endodontic and periodontal considerations. The prognosis of primary periodontal disease with secondary endodontic

Figure 18 True combined endodontic–periodontal diseases in a mandibular first molar. **A**, Preoperative radiograph showing periradicular radiolucencies. Pulp sensitivity tests were negative. **B**, Immediate post-operative radiograph of non-surgical endodontic treatment. **C**, Six-month follow-up radiograph showing no evidence of healing. Gutta-percha cone is inserted in the buccal gingival sulcus. **D**, Clinical photograph showing treatment of the root surfaces and removal of the periradicular lesion. **E**, One-year follow-up radiograph demonstrates evidence of active healing.

involvement and true combined diseases depends primarily upon severity of the periodontal disease and periodontal tissues response to treatment. True combined diseases usually have a more guarded prognosis. The prognosis of combined diseases depends mainly on the success of periodontal therapy.

CHAPTER 19

TOOTH INFRACTIONS

LEIF K. BAKLAND

Tooth fractures include trauma-related crown, crown-root, and root fractures (see Chapter 36) and a broad group of cracked teeth. The latter is divided into five categories by the American Association of Endodontists (AAE)¹: *Craze lines*—confined to enamel (Figure 1A,B); *cuspal fracture*—usually diagonal fractures that do not involve the pulp directly (Figure 2A,B); *cracked teeth*—incomplete vertical fractures, often involving the pulp (Figure 3A,B); *split tooth*—complete vertical fractures (Figure 4); and vertical root fractures (VRFs)—longitudinal complete fractures, usually of endodontically treated teeth (Figure 5). This is a fairly representative classification of cracked teeth and will be used in the descriptions to follow.

The term “cracked tooth” is one of many used for this condition. Others include *cuspal fracture odontalgia*,² *incomplete tooth fracture*,³ *cracked tooth syndrome*,⁴ *green stick fracture*,⁵ *split root syndrome*,⁶ *hairline fracture*,⁷ and *tooth infraction*.⁸

The number of terms used to show the confusion about this complex situation of tooth fractures is estimated to be responsible for about one-third of the loss of molars and premolars.⁹ A review of the rather extensive available literature points to the presence of two main categories: (1) *tooth infraction* and (2) *vertical root fracture* (VRF).

Tooth infraction can be defined as an incomplete tooth fracture extending partially through a tooth. It

Figure 1 **A**, Multiple craze lines are common in teeth (arrows). **B**, When an enamel fracture line becomes larger, organic debris will fill the crack and discolor (arrow).

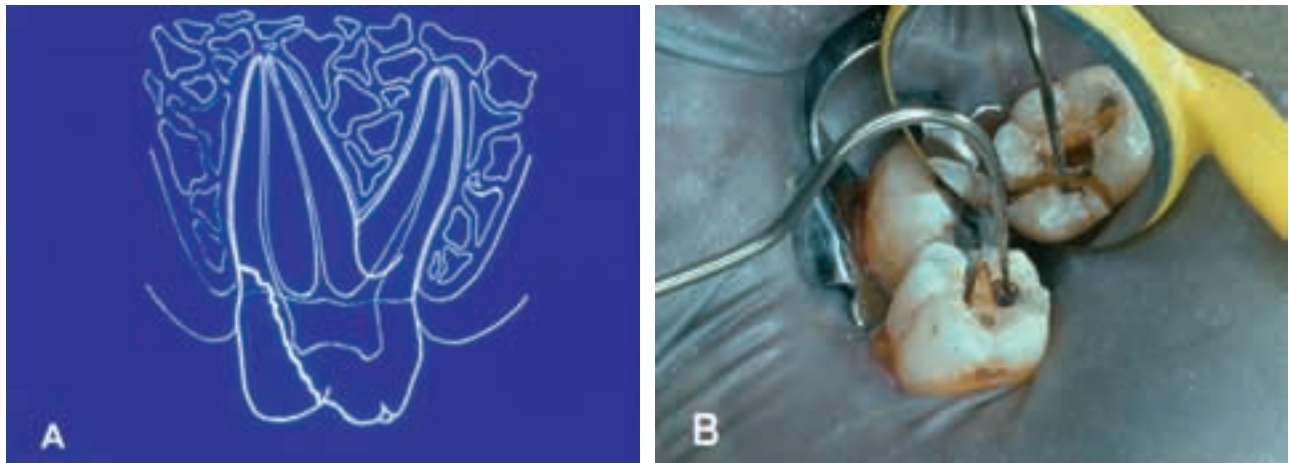

Figure 2 *A*, Graphical illustration of cuspal fracture. *B*, Clinical example of cuspal fracture; these often do not communicate directly with the pulp.

Figure 3 *A*, Graphical illustration of an infraction located centrally and which is likely to communicate with the pulp; it also typically runs in a mesiodistal direction and involves one or both marginal ridges. *B*, Clinical example of fracture line that extends to the floor of the chamber (arrow). Note mesiodistal direction of the fracture.

Figure 4 Example of a split tooth, a vertical fracture not involving an endodontically treated tooth.

Figure 5 Vertical root fracture (VRF) of an endodontically treated tooth.

Figure 6 Extracted tooth shows tooth infraction (arrow), having started in the crown and propagating apically.

is an accurate description that matches the use of the term ‘infraction’ in other medical situations.¹⁰ Tooth infraction can be further described as originating in the tooth crown, originating from the pulp toward the dentinoenamel junction, and propagating apically in the root^{11–13} (Figure 6).

Tooth infractions can be identified as three fairly distinct types: (1) those confined to enamel (“craze lines”) and usually do not require treatment, (2) those related to cuspal fracture that typically do not involve the pulp, and (3) those more centrally located that do involve the pulp. Diagnosis, treatment, and prognosis are different for the latter two types and will be described.

Vertical root fractures are longitudinal fractures that originate in the roots of teeth, in contrast to tooth infractions that originate in the crowns.^{14,15} With few exceptions,^{14,15} these fractures occur almost exclusively in endodontically treated teeth.

In summary, there are two main groups of cracked teeth: (1) tooth infractions, including craze lines, cuspal fractures, and cracked teeth; and (2) VRFs that occur in endodontically treated teeth. The latter will be discussed in Chapter 20 “Vertical Root Fractures of Endodontically Treated Teeth”.

Characteristics of Tooth Infractions

PROBLEMS IN DIAGNOSIS

Gibbs² was one of the first to describe the problem of pain during mastication that was unrelated to caries or infected teeth. He noted cracks associated with cusps in posterior teeth and termed the condition “cuspal fracture odontalgia.” He pointed out the problem in identifying the involved tooth, a situation also described by Ritchey et al.³ as a vague discomfort during mastication and often associated with elevated sensitivity to cold. They suspected the likelihood of incomplete tooth fractures.

Clinically, symptomatic tooth infractions are confusing because they often mimic symptoms from other conditions such as earache, sinusitis, temporomandibular joint dysfunction, and even trigeminal neuralgia and other neurological pain conditions.^{4,7,8,16} When the problem is difficult to identify, it can lead to a long-standing pain condition that becomes more diffuse and makes localization of the offending tooth very difficult.^{8,13} Many reported cases of problematic infraction diagnosis are usually long-standing, from months to many years.^{8,17}

Because infractions typically originate internally and extend peripherally,¹³ a tooth with infraction is not likely to be identified by percussion until the fracture extends to involve the periodontal ligament (PDL).¹⁸ Further, since most infractions are situated in a mesiodistal direction, radiographs are not very diagnostic.¹³ Also, it can be challenging to differentiate between masticatory pain from infractions and similar pain from microleakage associated with restorations.¹² Finally, without magnification, infractions are not readily visualized, unless they are at least 20 μm .⁷ Fortunately, most instances of tooth infractions can readily be diagnosed using various diagnostic aids, to be described later.

DISTRIBUTION

The incidence of tooth infractions is not extensively reported. Two studies^{16,19} indicate that 2% to 3% of dental patients have infractions in their molars and premolars; most are asymptomatic, so the incidence of symptomatic teeth may be less than 1%. The low incidence may contribute to the difficulty many dentists seem to have in identifying this condition.

Molars and premolars appear to be the teeth almost exclusively involved.^{4,8,17,19–21} The location of fractures occurs overwhelmingly in the mesiodistal direction, with only a few in the buccolingual direction, and some in a combination of both.^{4,8,12,17,20}

Brynjulfson et al.⁸ noted that 10% of the infractions were centrally located, meaning pulpal involvement. It is interesting that in their study, in maxillary teeth, the majority (70%) of fracture lines were toward the buccal tooth surface, while in the mandibular teeth they were toward the lingual, also at 70%.

Many reports appear to point to mandibular teeth, in particular the second molar as being most frequently involved,^{4,14,17} but other studies identify maxillary molars more frequently.^{8,21} Both of the latter studies involved specific groups of patients: the first, a group of patients that had long histories of undiagnosed infractions and the second group, exclusively Korean. How much such factors influence incidence is not entirely clear.

In the rare case, when an fractured anterior tooth is involved, it is probably the result of a sudden traumatic blow to the tooth. Makkes and Folmer²² described a situation in which a central incisor suffered a luxation injury when the patient was very young. The immature root fractured vertically, but the fracture was not detected until years later because the split was not visible on radiographs.

The question has been raised about which tooth is more likely to fracture—one with or without a restoration? As with other aspects of tooth infraction, the available evidence is not conclusive. Most investigators agree that teeth with restorations are more likely to develop infractions,^{12,13,16,19,23–26} but there are also reports about non-restored teeth with infractions.^{20,21} Hiatt,²⁰ however, selectively chose teeth with no proximal restorations, and Roh and Lee²¹ studied a group of elderly Korean patients in which the majority of teeth were non-restored. They speculated that diet and racial anatomical characteristics as well as restorative procedures contribute to the development of infractions.

When looking at the total picture of cracked teeth—infractions and VRFs—it appears that clinicians encounter VRFs more often than infractions.^{15,27} But because of the rather minimal epidemiological evidence, one cannot be certain about which type of fracture is more common.

PAIN CHARACTERISTICS

Pain is generally a complaint that draws patients' attention to problem teeth. This is also true with respect to tooth infractions.^{2–5,8,9,12,13,20,28–31} All of the authors cited pointed out that pain to chewing is the most common finding in symptomatic tooth infractions.

Brännström³⁰ has proposed that the masticatory pain is due to sudden movement of dentinal fluid when the fractured tooth portions move independently, activating myelinated A- δ fibers in the pulp and creating a rapid, acute pain response. Stimulation of the A- δ fibers does not require inflammation of pulp tissue, which explains why chewing discomfort occurs in the very early stages of infraction and appears to be a symptom common to all infractions, both cuspal infractions and those involving the pulp. Sutton⁵ also suggested that the occasional sharp, momentary lancinating masticatory pain was due to bending and rubbing of dentin along fracture lines.

A unique pain response to chewing experienced by many patients is the pain that occurs when they release the pressure of biting, variously referred to as "rebound" or "relief" pain.^{9,12,13} This response can be duplicated diagnostically by having the patient bite on a moist cotton roll and if "rebound" pain occurs on release, it is very likely that one of the two teeth, maxillary or mandibular, has an infraction¹² (Figure 7).

Pain that is stimulated by temperature changes, particularly with application of cold stimuli, is also a common feature of teeth with infractions, but less common than chewing discomfort.^{3,4,12,13,17,18,20,29,30}

Figure 7 Clinical test for detecting tooth infraction. The patient bites on a moist cotton roll and on release, pain will often be quite noticeable ("rebound" or "relief" pain).

Ritchey et al.³ noted an elevated response to cold, a condition attributed to pulpal inflammation caused by the infractions communicating with the pulp and likely containing bacteria^{13,18,29,30} (Figure 8). Brännström³⁰ proposed that the inflammation sensitizes the pulpal C-fiber receptors that respond to temperature changes. While hot stimuli are not often mentioned as producing symptoms, they no doubt can cause pain, particularly as pulpal inflammation increases, making C-fiber receptors more sensitive and lowering threshold levels to both cold and hot stimuli.

One would think that teeth, painful due to masticatory forces, would be uniformly hypersensitive to percussion stimuli. This does not appear to be the case in tooth infractions.²¹ Swepston and Miller³¹ have suggested that sensitivity to percussion occurs when the pulp becomes involved, which is not always the case in tooth infractions, at least not initially. Rosen¹⁸ pointed out that until the infraction has propagated all the way from the pulp to the PDL, localization of an infractioned tooth by percussion is very difficult. Thus, in cases of cuspal infractions in which the pulp is not directly involved, percussion may not produce a painful response.

It is well known that teeth with infractions are associated with unusual pain conditions.^{3,4,7,8,13,18} Ritchey et al.³ described the patients' chief complaint as vague discomfort to mastication, and Cameron⁴

Figure 9 A 78-year-old patient mistakenly diagnosed with trigeminal neuralgia. **A**, Patient was referred from neurology service for dental evaluation for complaint related to typical symptoms of neuralgia: excruciating, lancinating pain to touch (mandibular right side). Initial dental examination revealed no dental pathosis. **B**, Four months later, the patient returned with a “sore tooth.” The initial symptoms had subsided within a few days and he had taken only one carbamazepine (Tegretol) tablet. In retrospect, it was most likely that the initial symptoms he had were related to tooth infraction (arrow) that was not evident on the first examination.

observed that in addition to being vague, the pain complaint could mimic other conditions, such as trigeminal neuralgia (Figure 9A,B). This was also reported by Caufield.⁷ Further confounding pain description in tooth infraction is that the resultant pulpal inflammation tends to refer pain responses to other areas served by the fifth cranial nerve¹⁸ with the result that pain can be experienced in other noninvolved teeth, and adjacent anatomical locations. Both Kahler et al.¹³ and Brynjulfson et al.⁸ have made a point of the fact that tooth infraction pain is associated with protracted histories of pain. The latter reported a range of 3 months to 11 years in a group of 32 patients with undiagnosed long-standing orofacial pain from tooth infraction. They indicated that such protracted histories could lead to development of chronic orofacial pain with hyperalgesia. Another observation by Brynjulfson et al.⁸ was that in some cases the symptoms of pain were not provoked by chewing or application of cold stimuli, but rather were spontaneous pain experiences involving diffuse orofacial areas. Often, the pain would be felt anterior to the tooth responsible for the symptom when not referred to an anatomical area apart from teeth. The pattern of pain referral noted by Brynjulfson et al.⁸ was that pain from mandibular teeth was frequently distributed to maxillary teeth, the neck, ear, muscles of

mastication, and temporomandibular joint (TMJ). Pain from maxillary teeth seldom projected to the mandible. An important observation was that the longer the duration of pain, the more diffuse it became and often led to headaches.

Pain response to sweets has been reported;^{13,20,26,28} likely the response is from pulps that have become inflamed due to exposure to infractions with bacteria present. While pain responses in teeth with infractions can mimic many other conditions, such as cariously affected teeth, it is prudent to maintain a high degree of suspicion when symptoms and examination findings do not match.

ETIOLOGY

Considering that restored teeth are more often associated with infractions than non-restored teeth,^{12,13,16,19,23–26} it would not be surprising that investigators have looked at a number of restorative factors for clues to the etiology of tooth infractions. In fact several aspects of restorative dentistry have been identified as potential culprits. Most often mentioned are excessively large and incorrectly designed restorations.^{12,16,18,23–25,32} Another contributing factor has been the use of pins for supporting large restorations, especially self-threading and friction-lock pins^{18,23,32–34} (Figure 10).

Figure 10 The use of pins for coronal buildup can be detrimental if the friction-grip or self-locking types are used (arrows). This tooth had developed infractions, but it was difficult to determine if they were connected with the pin placements.

Abrasion, erosion, and caries may also contribute to the development of infractions,²⁵ along with age changes in dentin,¹² oral habits,^{12,18} and thermal cycling.^{35,36} The latter is suspected of initiating infractions near the dentin–enamel junction and leading to breakdown of the dentin–enamel bond. Resisting these damaging forces is the dentin’s collagenous structure that prevents fractures from forming and propagating. As the dentin loses the ability for plastic deformation, it becomes more inclined to develop infractions, evidenced by the increase in infractions with age.¹³

In addition to cavity designs and size, the act of preparing a tooth for restoration can also be hazardous. It is suspected that the use of both high-speed handpieces³⁴ and coarse diamond burs³⁷ can lead to infractions. When coarse diamond burs are used, subsurface cracks develop from enamel into dentin. It is not clear if such infractions are more likely to progress further than the frequently observed enamel infractions. These craze lines can range from 1 to 20 μm in size and are usually filled with an organic material that appears to stain quite readily³⁶ (see Figure 1B).

Figure 11 Vertical fracture (arrow) of the crown, running mesiodistally and resulting from traumatic injury.

The act of chewing is also implicated in the development of infractions.^{9,13–15,18,20,21,26,32} Masticatory forces from repeated occlusal loads and perhaps certain types of foods can contribute to this problem.^{9,13–15,21,26,32} Certainly, accidental biting on hard objects, such as bird shots and hard candy, has resulted in tooth infraction and VRFs^{9,18} (Figure 11), and bruxism and clenching often combined with a wedging effect of cusps in opposing fossae can be stressful on teeth.^{14,15,20,21} Considering a biting force of up to 90 kg on first molars,²⁶ it is obvious that these teeth are subjected to extensive stress. Yeh¹⁴ coined the term “fatigue root fracture” to describe the stress on teeth that can be very damaging when combined with a course diet.

Acute trauma to teeth is also responsible for tooth infractions,¹⁸ and Makkes and Folmer²² described a situation in which an injury to a central incisor in a child resulted in a VRF that was not discovered until years later. Because anterior teeth are subjected to acute trauma more than posterior teeth, trauma is likely to be the etiology of vertical fractures in anterior teeth (Figure 12A,B).

Figure 12 **A**, Traumatic injury to the mandibular incisors resulted in a vertical fracture (arrow). **B**, Another view of small fracture (arrow).

Teeth are subjected to a variety of traumatic and stressful events, many resulting in damage such as infractions and fractures. In contrast to bones where repair of such injuries can readily take place, in dentin and enamel, similar repair following development of fracture lines does not occur.

Diagnosis of Tooth Infractions

Diagnosis of symptomatic tooth infractions is usually quite easily made based on symptoms, clinical and radiographic findings, and history. A suspicion of infraction is raised when symptoms of toothache are not readily connected to evidence of caries, periodontal disease, or recent trauma. If the initial examination fails to provide a definitive diagnosis, it can be difficult to proceed and also becomes more likely that an incorrect diagnosis will be made. Many patients with infractioned teeth may suffer symptoms for long periods

of time before a correct diagnosis is made.^{8,13,17,22} Brynjulfson et al.⁸ pointed out that the longer it takes to make a diagnosis, the more diffuse the pain becomes.

SYMPTOMS

The most common symptoms associated with symptomatic tooth infractions are pain to chewing,^{2,4,5,12,13,17,21,26} followed by pain to exposure to cold food,^{3,4,12,13,21,26,29} and in some cases to sweets.^{13,26,28}

It should be noted that not all teeth with infractions are symptomatic.¹⁹ Symptoms probably develop when infractions involve the pulp, especially when the infractions become populated with bacteria,^{13,29,31} and localization may also be possible when infractions reach the PDL, usually starting in the area of the crestal ligament.¹⁸

The history of a patient's symptoms can be helpful in forming a diagnosis. Diffuse, protracted pain, not associated with more easily diagnosed conditions of

caries-induced pulpitis, should at least attract a suspicion of tooth infraction.^{8,13,16–18} Considering that symptomatic infractions are in fact not a common dental condition, it is prudent for the careful diagnostician to keep this option as a possibility, when other definitive diagnoses are not applicable.

CLINICAL EXAMINATION

As with other dental diagnoses, making a definitive diagnosis of symptomatic tooth infractions requires obtaining adequate information, both from the patient's history and from clinical examination. It usually begins with a chief complaint of pain to chewing, possibly elevated sensitivity to cold food and sweets. The absence of an obvious carious etiology should trigger a suspicion of a possible infraction and in most cases the following clinical examination procedures should identify teeth with infractions.

Visual examination should reveal many instances of infractions, especially when aided by the use of transillumination^{8,12} (Figure 13) and a dye such as methylene blue^{8,12,17,38} (Figure 14). The use of transillumination is dependent on the part of the tooth to be examined to be without restoration to allow the light beam to pass through the tooth; when it encounters a fracture line

Figure 13 Clinical illustration of the use of fiber optic light source (arrow) to identify an infraction. Note that the light beam does not cross the infraction.

Figure 14 Removal of restoration and highlighting with a dye to detect infraction (arrow).

in the dentin, the light beam will bend and not pass through the fracture line and the opposite tooth structure will be dark.¹² Additionally, to aid in visualization, the use of a microscope can be very valuable,^{8,12} although magnification alone may not be a predictable way of detecting infractions.³⁹ But in combination with the application of a dye, infractions become quite visible.⁸

Because existing restorations in a tooth with infractions may hide infractions, it is often necessary to remove the filling materials to reveal infraction lines^{8,12} (see Figure 14). This becomes an important step in the clinical examination when the symptoms are vague and the location of pain is diffuse and not localized. Brynjulfsen et al.⁸ methodically removed restorations, one tooth at a time, to locate teeth with infractions in patients with long-standing, undiagnosed orofacial pain.

An important step in clinical examinations is the application of a *biting test*. Various techniques have been recommended, such as biting on burlew wheels,¹⁷ rubber wheels,¹¹ cotton tip applicators,¹¹ moist cotton rolls¹² (see Figure 7), and commercial biting applicators such as Tooth Slooth (Professional Results Inc., Laguna Niguel, CA) and Fracfinder (Svenoka Dental Instruments, Vasby, Sweden). To differentiate between biting pain from restorations with microleakage and pain from tooth infraction, a Tooth Slooth can be

Figure 15 The use of Tooth Slooth to test biting sensitivity to differentiate between pain from infraction and pain from microleakage related to a restoration.

positioned so that pressure is first placed on the filling and then on the tooth cusps¹² (Figure 15).

A very significant response to biting is when pain is experienced on release of biting pressure^{9,12,13} and is referred to as either “rebound pain”¹³ or “relief pain.”⁹ Kahler et al.¹³ explain the pain associated with the release of pressure as resulting from fluid movement as the crack rapidly closes. For the author, the moist cotton roll has been very effective in stimulating rebound pain, providing a good clue to the tooth in question.

Cold stimulus application and electric pulp testing (EPT) will provide information about the status of the

pulp, and there is evidence that teeth with infractions respond at lower threshold levels to cold and EPT stimulation compared to noncracked teeth.^{3,29} Since any tooth with pulpal inflammation is likely to have a lowered pain threshold, it is not particularly significant that teeth with infractions also do. But it can add to the total information about the tooth.

Percussion sensitivity in teeth with infractions is not as frequent as biting sensitivity²¹ and appears to require pulpal involvement.³¹ One could speculate that if the infraction is a cuspal infraction and not directly involving the pulp, percussion may not be as likely to produce a symptomatic response as percussion of teeth with infractions in direct contact with the pulp.

Cameron¹⁷ has suggested the use of a thin sharp explorer to probe around the cervical circumference of teeth suspected of having infractions, particularly in interproximal areas not readily visible if the tooth crown has a large or full coverage restoration. Both the “click” of the explorer tip encountering the crack and perhaps the patient’s response can provide a clue.

Periodontal probing has been recognized as an indispensable part of clinical dental examinations in general and also when examining teeth with potential infractions.^{12,20} Hiatt²⁰ described the result of probing to be narrow pockets adjacent to fracture lines, and Ailor¹² has suggested that if the probing extends below the alveolar crest, the tooth is not suitable for restoration (Figure 16A,B). Since the pockets adjacent to infractions are extremely narrow—in contrast to those adjacent to

Figure 16 Periodontal probing of a tooth with infraction. Anesthesia is necessary because the pocket is very narrow. **A**, Radiograph shows periodontal probe extending well below the alveolar crest. **B**, Extracted tooth shows infraction (arrow).

VRFs in endodontically treated teeth—it is usually necessary to anesthetize the tissues surrounding the tooth prior to probing.

RADIOGRAPHIC EXAMINATION

It is generally recognized that radiographic examination, while obviously necessary for a number of reasons, does not provide much information with respect to tooth infractions.^{8,12,13,40} This is because the infraction lines usually run mesiodistally in the majority of cases¹⁷ and the X-ray beam travels perpendicular to the fracture lines. If, however, the tooth infraction is located in a buccolingual direction, the X-ray beam may produce a clear image of the fracture line on the film or the sensor (Figure 17). If computed tomography technology continues to improve with respect to imaging smaller and smaller entities, one may expect that in the future, infractions in the size of 5 μm may be detectable.^{40–42}

One aspect of tooth infractions that can be detected radiographically is the rare instance in which bacteria in the infraction has stimulated clastic activity in the pulp, resulting in internal resorptive lesions.⁴³ This type of internal resorption is unique in many respects in that it appears to occur adjacent to the pulp space and may be mistaken for invasive external resorption. The presence of an infraction in connection with the resorption defect, and no communication of the resorptive defect with the periodontal tissues, confirms the diagnosis (Figure 18).

Figure 17 Radiograph of a maxillary molar with a buccopalatal infraction. Because of the fracture direction, it is readily identified radiographically (arrow).

Figure 18 Radiograph of a tooth with internal resorption (arrow) as a consequence of an infraction. The pulp was vital and the infraction was in the mesiodistal direction, communication with the pulp in the distal aspect of the crown.

FUTURE DIRECTION

Some tooth infractions can be diagnosed quite readily with just a few examination steps, while other cases are very difficult to solve and require extensive efforts.⁸ There is a need for additional means of detecting infractions and fractures in teeth; various avenues are being explored including the application of *ultrasound* to this problem. Ultrasound may have the potential to complement radiography as an imaging technique by identifying physical discontinuances (cracks) in hard tissues such as enamel and dentin. The application of ultrasound is used in industry for a similar purpose and would, if developed in dentistry, be of great help in the detection of tooth infractions.⁴⁴

Treatment

Any discussion of the treatment of tooth infractions must include an acknowledgement that neither dentin nor enamel can be permanently reunited once a fracture line develops. All treatment efforts therefore are attempts—some better than others—at preventing separation of the hard tissue entities, and perhaps keeping bacteria from colonizing the space caused by infractions. Further, root canal therapy, while contributing to reductions or elimination of symptoms, also will not change the fact

that a tooth with infraction is a weakened tooth that likely will not last as long as a non-infracted tooth.

Endodontists appear to be in agreement that teeth with infractions can be treated,⁴⁵ but it is not clear if all teeth with infractions need root canal therapy. The lack of clear understanding in this regard is probably related to the difficulty in determining if an infraction communicates directly with the pulp (in which case endodontic treatment would reasonably be a part of the overall treatment for the tooth), or the infraction is a cuspal infraction that may not communicate with the pulp.

One approach to the question of treating endodontically or not is that used by the author and also recommended by Ailor¹² and Brynjulfson et al.⁸:

Stabilize the tooth with an orthodontic band before beginning root canal therapy. If the initial pulpal diagnosis is less than irreversible pulpitis (no lingering pain to cold or spontaneous, severe pain), wait for about 2 weeks before scheduling root canal therapy. If all the symptoms have subsided after the placement of the orthodontic band, the patient may be offered the option of only placing a restoration that binds the tooth crown together, with the understanding that the tooth may later need root canal therapy (Figure 19A–C). If a full coverage crown is the recommended restorative procedure, it may be wise to include the root canal treatment prior to crown placement to avoid having to make an access through a prosthetic crown later. The reason for waiting a while after placement of the

Figure 19 Initial treatment of a tooth with infraction to determine pulpal involvement **A**, Radiograph of a tooth that was painful to chewing and slightly sensitive to cold. **B, C**, Orthodontic band placed to bind the crown together. After 3 weeks the tooth was completely asymptomatic and the patient chose to have it restored with a crown.

Figure 20 Tooth with infracture that did not respond to treatment. **A**, Radiograph of a tooth that was painful to chewing and had lingering pain to ice. Orthodontic band was placed and the pulp was extirpated. The tooth continued to be painful to chewing and the patient chose extraction. **B**, Photo of the extracted tooth shows infracture (arrow).

orthodontic band is that it takes some time before cold sensitivity subsides. Davis and Overton¹¹ found that it took 2 weeks for cold sensitivity to subside after binding infracted teeth with bonded amalgam restorations.

When teeth with infractures also have pulps that are irreversibly involved or necrotic, the need for root canal treatment is self-evident if the tooth is to be retained. Root canal treatment will obviously eliminate pulpal pain and sensitivity to temperature changes and to sweets; one should not, however, expect all infracted teeth to be free of chewing pain after root canal therapy. Pain to mastication forces is associated with inflammation in the PDL and one can expect such inflammation to be generated by bacteria-containing infractures that extend from the coronal area apically.^{13,18,20} The problem of not being able to predict if pain to chewing will cease after root canal treatment and restoration can be addressed again by the recommendation made above to first place an orthodontic band to measure the response to binding the crown together, followed by root canal therapy or possibly just pulp extirpation if the pulpal symptoms persist. If the patient is comfortable with the tooth, the treatment can be completed; if not, extraction becomes the alternative treatment (Figure 20A,B).

Treatments designed to bind infracted teeth together include the use of adhesives,⁴⁶⁻⁴⁹ amalgam with retention on both sides of the infractures,¹¹ and full coverage crowns.^{8,11,12,50,51} Experimental approaches using lasers (CO₂, Nd:YAG) have not yet produced any promising results.⁵²

PROGNOSIS

The outcome of the treatment for teeth with infractures is not extensively reported. Cameron¹⁷ reported a 75% success after 10 years following placement of crowns, and Guthrie and DiFiore⁵⁰ found that 24 of 25 teeth restored with acrylic crowns were asymptomatic after 1 year. Brynjulfson et al.⁸ achieved pain relief in 90% of their patients after protective restorations of teeth with infracture (endodontic therapy was included when indicated), and Tan et al.⁵¹ had an 85% survival rate 2 years after protective crowns were placed. The available data is insufficient to use as a basis for giving individual patient's odds on tooth survival for a specific number of years. It is important to inform the patient that the teeth need to be monitored so that when bone resorption becomes evident, the tooth should be extracted to prevent alveolar bone

Figure 21 Long-term follow-up of an endodontically treated tooth with infraction. **A**, The diagnosis and endodontic treatment was done in 1987 for the mandibular first molar. **B**, The tooth was monitored yearly and this radiograph shows the tooth in 1992 (at the time of treatment of the second molar that did not have infraction but pulpitis due to recurrent decay). The first molar continued to be asymptomatic, and the patient missed the following year recall. **C**, Radiograph in 1994 (17 years after original treatment) shows bone loss associated with the development of vertical root fracture (VRF) as a result of the initial infraction. The tooth was extracted and the patient chose to replace it with an implant.

loss (Figure 21A–C). In the author’s clinical experience, a 5-year survival prediction appears reasonable in most cases. Patients must be fully informed of the uncertainty based on the lack of data. What one can recognize is that in some situations the prognosis is poor: terminal teeth, teeth with periodontal involvement related to infractions, and teeth with multiple infractions.⁵¹ As with other dental treatment recommendations, clinicians can provide advice based on what is available in the literature and the clinician’s own experience, and the patient can contribute his/her preferences.

Prevention

A number of factors have been recognized as steps that can be taken to reduce the incidence of tooth infraction. They include cavity design and size,^{11,12,18,23,24,32} proper design of intracoronal cast restorations,^{24,32} avoiding the use of self-threading and friction-lock pins,^{18,23,32,33} avoiding extensive use of coarse diamond burs and vibrating high-speed handpieces,^{12,37} and restoring teeth with attention to occlusion to avoid interference from working premature contacts.^{12,18} It may also be beneficial to advise patients about potential damage

from oral habits (pipes, pencils, carpenter nails)^{12,18} and the stress excessive repetitive heavy mastication can produce in teeth.^{14,15,26} Yeh¹⁴ coined the term “fatigue root fracture” to describe the result of a coarse Chinese diet in patients who usually used heavy mastication over the years of their lives. Many often developed VRFs in non-restored teeth with no endodontic treatment history. The biting force on first molars is up to 90 kg²⁶ and if there is sudden external trauma, such as biting unexpectedly on something hard in the food, an infraction may result. Kahler et al.¹³ described how infraction can occur from “cyclic fatigue”—repeated occlusal loads. As with all body parts, teeth are not indestructible and care in the use of one’s teeth is advised.

With respect to care of teeth, a question sometimes raised is, is it damaging to chew on ice? The dental literature is not very informative on this topic; Brown et al.³⁵ in 1972 used thermal cycling—alternating exposure to very cold and very hot stimuli to extracted teeth—and reported extensive cracking in the teeth. It is not clear if this information can be applied to the question of ice chewing, but until more information becomes available, it seems reasonable to advise against chewing on ice.

Summary

Tooth infraction in dentistry is not a major problem in terms of incidence,^{16,19} but it is a problem in diagnosis when the symptoms and clinical findings are not definitive.^{3,4,7,8,12,13,17,20} Current information supports the notion that tooth infraction is an incomplete fracture of the tooth, most often starting in the crown, but sometimes in the root.^{4,6,11–13,15,18,21} Tooth infractions may be cuspal infractions that usually do not communicate directly with the pulp. They may, however, propagate from the pulp toward the dentin–enamel and dentin–cementum junctions. In the former situation, treatment may not need to include endodontic therapy, while in the latter situation, the pulp is likely to be at least irreversibly involved and root canal treatment is included with the restorative procedure.^{1,11,21,51} Restorative treatment involves procedures that provide a binding effect on the tooth infraction; this can be accomplished by using amalgam restorations that incorporate retention on both sides of the infractions,¹¹ amalgam in combination with bonding agents or full coverage crowns.^{8,11,12,51,53}

Adequate data is not available to determine prognosis for teeth with infractions; symptomatic teeth that have received treatment—either restorative alone

or in combination with root canal therapy—have been reported to survive for many years,^{17,50,51} but patients need to be informed that long-term retention is questionable. In spite of probable unfavorable long-term outcome, retaining a tooth with infraction may still be an excellent option in many instances.

CHAPTER 20

VERTICAL ROOT FRACTURES OF ENDODONTICALLY TREATED TEETH

AVIAD TAMSE

Vertical root fractures (VRFs) occur mainly in endodontically treated and restored teeth, but have been found in mesial roots of mandibular molars in nonendodontically treated teeth in a Chinese population.¹ According to the American Association of Endodontists,² “a vertical root fracture is a longitudinally oriented fracture of the root that originates from the apex and propagates to the coronal part.” From a horizontal aspect, the fracture initiates in the root canal wall and extends to the root surface,³ involving either one side (incomplete) or both sides (complete fracture)^{3,4} (Figure 1A,B).

VRFs present numerous problems for both patients and clinicians. VRFs can be difficult to differentiate from failing endodontically treated teeth or teeth associated with periodontal disease.^{5–8} Often the definitive diagnosis is made years after

extensive treatment.^{9,10} The etiology tends to be multifactorial^{6,10,11} and the need to extract the tooth or the root when the definitive diagnosis is made is disappointing.^{3,12}

Endodontically treated teeth may need to be extracted if they cannot be restored or have become periodontally involved; both causes are unrelated to the endodontic treatment itself. Survival rate studies have shown VRF to be one reason to extract endodontically treated teeth,^{13–15} but only a few studies show the prevalence of VRF teeth. Gher et al.¹⁶ suggest a low incidence (2.3%), similar to the 2 to 5% prevalence found in retrospective “success and failure” studies on prosthetic reconstructions.^{17,18} However, the percentage of extracted teeth with VRF can be much higher, between 10 and 20%.^{19,20}

Clinical Diagnosis

Arriving at the correct diagnosis for VRF of endodontically treated teeth based on clinical and radiographic findings can be challenging for any clinician. There are several reasons for this diagnostic difficulty.

1. It is often difficult radiographically to make an early detection of a crack.
2. Signs and symptoms, such as spontaneous dull pain, mastication pain, tooth mobility, presence of sinus tracts, osseous defects, periodontal-type abscesses, and bony radiolucencies, are often similar to those found in failed root canal treatment or in periodontal disease.^{5,6,21–23}
3. Often an existing crack or an incomplete fracture is not visually detected when intraradicular procedures are performed (instrumentation, obturation, or dowel preparation), and tooth restoration is completed over the existing crack or fracture. A

definitive diagnosis may not be made for years after treatment has been completed.^{10,21}

To complicate matters even more, early diagnosis needs to be made because of the direct correlation between bone resorption around a root with VRF and time.²⁴ That is, the longer the inflammatory process continues, the more bone resorption occurs.

The typical bone loss associated with VRF is loss of the alveolar bone buccal to the affected root (Figure 2A,B), a process that continues until the tooth or the root is removed.²⁴ Common clinical signs that can help clinicians make the correct diagnosis are a deep osseous defect (Figure 3A,B) and a sinus tract located near the cervical area (Figure 4A,B). In four retrospective clinical surveys of teeth with VRFs, deep osseous defects were found between 64 and 93% of the time, and cervically located sinus tracts between 13 and 35% of the cases.^{5,6,8,22}

When a root fracture line propagates coronally and laterally to the periodontal ligament (PDL), local

Figure 4 **A**, Coronally located sinus tract near a maxillary premolar. **B**, Buccal and lingual sinus tracts from a complete vertical root fracture (VRF) of a second maxillary premolar. The lingual sinus tract is located mesially to the fractured tooth.

inflammation develops in the PDL associated with the crack. It is caused by bacteria from the oral cavity and the root canal space penetrating into the crack.³ The local inflammatory process leads to periodontal breakdown followed by development of a deep osseous defect. An abscess forms when this chronic situation exacerbates over time and is similar to periodontal disease

Figure 5 **A**, Late diagnosis of a vertical root fracture (VRF) showing separated root segments and inflammatory process around them. **B**, Axial computed tomography (CT) scan showing complete bone loss on the buccal aspect.

abscesses.^{5,6,8,22,25} An exploratory surgical procedure to visualize the VRF allows definitive diagnosis.²⁴⁻²⁷

Lustig et al.²⁴ have described the typical bone resorption patterns in teeth with VRF. In 90% of teeth with VRF extracted during exploratory surgery, buccal bone dehiscence along the entire root length was noted. There is a direct correlation between the amount of bone resorbed facing the fracture line and time (Figure 5A,B). A

fenestration type of bone loss (Figure 6A-D) was found in only 10% of maxillary premolars and mesial roots of mandibular molars. Walton and Torabinejad²⁸ described the fracture initiation as apicocoronal propagation of initial bone resorption. In a later stage, when the

fracture extends to the gingival margin, resorption is more oblong, with resorption rapidly progressing apically and laterally to the interproximal areas. Radiographically, even if the buccal plate is completely resorbed, with no interproximal involvement, a single

Figure 6 **A**, Vertical root fracture (VRF) in a maxillary premolar. New restorative treatment was needed for the posterior segment. **B**, Periapical radiograph shows the “halo” radiolucency around the root. **C**, Exploratory flap procedure reveals buccal fenestration filled with granulation tissue **D**, Removal of the soft tissue reveals fracture line from apical to cervical root area. Methylene blue dye helped to demonstrate the fracture.

periapical view would, most likely, not reveal the bone loss (Figure 7A, B).

On the lingual aspect of a tooth with VRF, the bone resorbs into a shallow, rounded U-shaped defect because spongy bone is much thicker and resorbs away from the root, and only later extends laterally. It is interesting to note that in 10% of the fenestrations, an abscess similar to a chronic apical abscess of endodontic origin, with no probable osseous defect on the buccal side, was the only clinical sign.²⁴

During exploratory surgery, when the typical dehiscence appearance combined with a visible fractured root is seen, the root or the tooth can be extracted to prevent further bone loss.²⁴ Sinus tracts associated

with VRF, unlike those from a chronic apical abscess, are usually not located in the apical area. They tend to be within several millimeters of the gingival margin.^{8,21} This type of sinus tract has been found in 14 to 42% of the VRF cases.^{5,6,8,10,22} A deep osseous defect, a cervically located sinus tract, and typical bone loss upon exploratory surgery are very helpful in making a diagnosis.

Radiographic Diagnosis

It is possible to detect a VRF in an endodontically treated tooth radiographically in only two instances.

Figure 7 A, Periapical radiograph of a mandibular premolar reveals widening of the periodontal ligament (PDL) on the mesial tooth aspect. **B**, Change of horizontal angulation reveals radiolucency along most of the distal aspect from the coronal aspect, not involving the periapical area—periodontal radiolucency.

Figure 8 *A*, Separation of root segments of a maxillary premolar and a mandibular incisor *B*.

The first is when there is evidence of separation of the root segments (Figure 8A,B), usually accompanied by a large radiolucency surrounding the bone between the roots that is actually inflammatory tissue separating the segments.^{7,21,29} The second is when a “hair-like” fracture line radiolucency can be detected in a periapical radiograph (Figure 9). Rud and

Figure 9 “Hair-like” radiolucent line can be seen at the distal aspect of a fractured mandibular premolar.

Omnell²¹ claimed that it was possible to see fracture lines in 35.7% of the cases in their study. However, many of their cases were not true VRF cases. In clinical practice, it is still rare, when only a single periapical radiograph is taken, to have the X-ray beam lined up with the fracture line. Two or three periapical radiographs should be taken from different angulations when a fracture is suspected. Often the clinician can speculate, from bony radiolucencies surrounding or between the roots, whether or not there is a root fracture. Since some of these radiolucencies are similar to those in “endodontic”- or “periodontal”-type lesions,^{8,21,23,30,31} the correct diagnosis based on radiographs is often difficult and can delay the definitive diagnosis.

The appearance of a radiolucency associated with a VRF is influenced by the extent of bone destruction, direction and location of the fracture, and time elapsed since the initiation of the fracture.^{5,21} A possible helpful diagnostic factor is the observation that some radiolucencies have been found to be more often associated with VRFs than with cases of failed root canal treatment or periodontal disease.^{23,31–33}

The most frequent feature in VRFs, both in maxillary premolars and in mesial roots of mandibular

Figure 10 **A**, “Halo” appearance radiolucency around the apical and mesial aspects of a maxillary premolar. **B**, “Halo” type radiolucency including the mesial and distal aspects of the apical third of the root. **C**, Isolated lateral radiolucency in a maxillary premolar. The apical and coronal areas are not involved.

molars, is the “halo” appearance, a combined periapical and periradicular radiolucency on one or both sides of the involved root^{23,33} (Figure 10A-C). In mandibular molars, in addition to the “halo” appearance of the lesion, typical in these roots, a bifurcation radiolucency is also found in 63.3% of the cases²³ (Figure 11A-D). Observing such radiolucencies can help clinicians make the correct diagnosis of VRF teeth, especially when combined with the other signs and symptoms.

With digital radiography, it is possible to acquire, enhance, store, retrieve, and transfer radiographic information with reduced radiation dosage compared to conventional radiography. When digital radiography was compared with analog radiography in detecting VRF, neither had any advantage over the other.^{34,35}

The use of tomography to detect root fractures is not new,³⁶ and recently additional imaging techniques to detect and visualize root fractures have been introduced.³⁷⁻⁴⁰ These new techniques could be in clinical

use in the near future, providing opportunities for early detection of VRFs.

Etiology

Since VRFs occur mostly in endodontically treated and restored teeth, some root canal procedures, such as excessive removal of dentin during canal preparation^{19,22} and post space preparation and post placement,⁴¹ have been identified as causes of VRF.

These VRF etiologies are iatrogenic.¹⁰ There are also several predisposing factors to fractures, making VRF etiology more complex and multifactorial. Understanding the etiological factors may help clinicians better understand how to prevent and manage VRFs.

PREDISPOSING ETIOLOGIC FACTORS

Predisposing factors for VRF are root anatomy, amount of remaining sound tooth structure, loss of moisture in the dentin, amount of bony support,

Figure 11 Typical bony periradicular radiolucencies around mesial roots of mandibular molars. **A**, Lateral radiolucency on the mesial aspect and at the bifurcation area of a mandibular first molar. **B**, Periapical and bifurcation radiolucency around a second mandibular molar. **C**, Extracted tooth from **D**, shows the fracture line on the buccal aspect of the mesial root. **D**, Angular and bifurcation radiolucency.

pre-existing cracks, and biochemical properties of root dentin.

The most susceptible roots to fracture are those in which the mesiodistal diameter is narrow compared to the buccolingual dimension (oval, triangular, kidney-shaped, ribbon-shaped).⁴² Examples of such teeth would be maxillary and mandibular premolars, mesial roots of mandibular molars, and mandibular incisors.⁴³ In a retrospective study of fractured roots, Tamse et al.⁸ found that these were the most frequently fractured roots and teeth (79%). To minimize the risk of VRF, familiarity with the root anatomy and morphology is essential for appropriate root canal treatment and restoration of endodontically treated teeth.⁴²

Root curvature⁴⁴ and root depressions in the mesial root of mandibular molars and the buccal root of bifurcated maxillary premolars are anatomical entities that can predispose the roots to fracture and perforation^{42,44-46} (Figure 12).

The canal and root shape, combined with dentin thickness, affect tensile stress distribution during intracanal procedures.⁴⁷ Canal shape is the most important factor of the two since the area of reduced curvature radius (the buccal and lingual areas) is strongly influenced by stress concentrations. More than likely, this is the reason these roots fracture in a buccolingual direction and not mesiodistally, although more tooth structure is removed from the mesial and distal aspects at the stage of canal instrumentation and post space preparation.^{48,49}

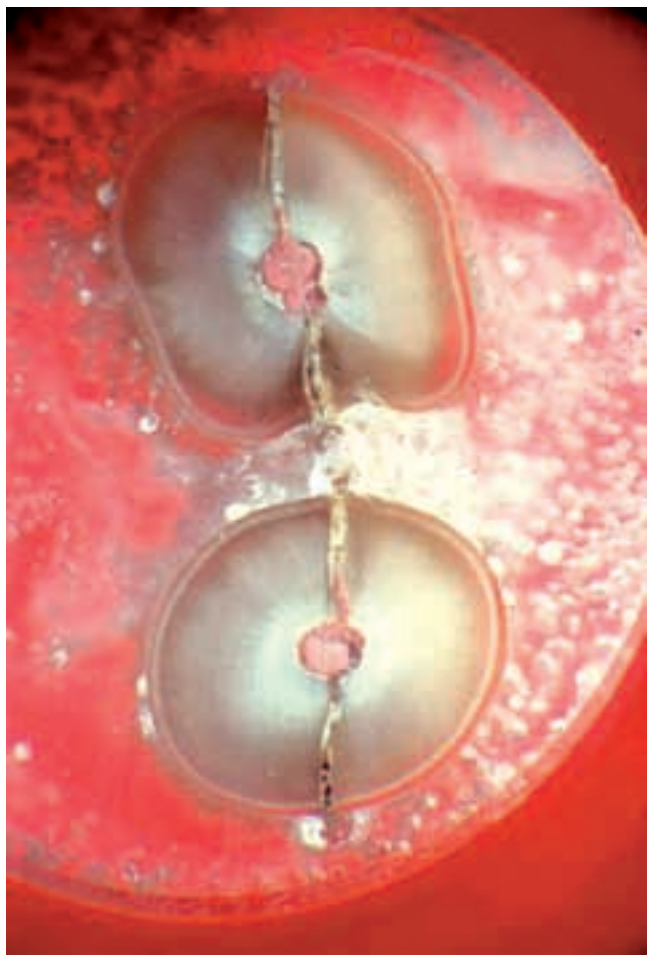

Figure 12 Complete vertical root fracture (VRF) in buccal and lingual roots of a maxillary bifurcated premolar. Note the depression on the bifurcation aspects of the buccal root.

Another important predisposing factor for VRF is the amount of tooth structure missing due to caries or trauma. Combined with the reduced amount of radicular dentin, the result of various intracanal procedures (initial root canal therapy, retreatment, post space preparation), the remaining tooth structure is directly related to the ability of endodontically treated teeth to resist fracture^{42,48-53} (Figure 13A,B). A common clinical speculation is that an endodontically treated tooth is more brittle compared to one with a vital pulp, and that the dentin undergoes changes in collagen cross-linking after root canal treatment.⁵⁴ However, this has not been validated.⁵⁵⁻⁵⁷ Moisture loss in endodontically treated teeth, compared with teeth with vital pulps, is not a major etiological factor but rather a predisposing one for fracture.⁵⁸

Small cracks are often present in dentin, parallel or perpendicular to the root canal space in intact teeth.^{3,59-61} During intracanal procedures when dentin is removed, especially in the mesiodistal areas, such cracks may be exposed (incomplete fractures or infractions), and then later may propagate in buccal and/or lingual directions (complete fracture).⁶¹

The specific biochemical properties of dentin are also predisposing factors in VRFs. In a study on the stress-strain response in human dentin, Kishen et al.⁶² found that the dentin adaptation to functional strain-stress distribution results in greater mineralization in the buccolingual areas. This may increase the likelihood for a fracture to propagate in this direction, compared with the less mineralization and more collagen in the mesiodistal areas.

Figure 13 A, Thin dentin walls after excessive preparation of a post in a maxillary premolar. **B**, Complete vertical root fracture (VRF) in the buccal part of a single-rooted maxillary premolar. Excessive preparation of the root canal space is evident.

Figure 14 Endodontically treated maxillary premolars as abutments. **A**, Typical periradicular radiolucencies around two premolars serving as abutments. **B**, Six months after the diagnosis of vertical root fracture (VRF).

Reinhardt et al.⁶³ found, by evaluating radiographs, a correlation between the height of the alveolar crest and the stress in the apical part of a post. One may assume that loss of bone support due to periodontal disease, pre-endodontic and prosthetic treatment, can result in reduced ability of the tooth to withstand functional stresses.

IATROGENIC ETIOLOGICAL FACTORS

Iatrogenic factors contribute to the susceptibility of a root to fracture. These factors are a combination of the residual tooth structure after dentin removal from the coronal area⁶⁴ and residual dentin thickness after completion of all intracanal procedures combined, along with the stress generated during these procedures, such as lateral condensation of gutta-percha, followed by post placement.^{5,10,65–67} A common procedure is the enlargement of the coronal third of the root canal as an early step in root canal preparation. The result is loss of tooth structure that may weaken the root. Obviously, enlargement of the coronal third of the root canal enables better access to the apical part of the canal, but excessive removal of dentin during root canal and post space preparation can leave thin dentin walls^{48,49} (see Figure 13A).

The risk of root fracture may increase as well with the use of spreaders during gutta-percha obturation. The stress generated during lateral condensation of gutta-percha may be from the wedging effect of the spreader, either on the canal walls or through the gutta-percha.⁶⁶ The spreader design or the metal used can also be a contributing factor for a VRF.⁶⁸ Since

the introduction of NiTi instruments for canal preparation, a NiTi spreader has been designed that is more elastic than stainless steel spreaders; it exerts less strain in the root canal during lateral condensation.⁶⁹ The exact contribution of stress to the inception of a fracture in clinical situations is not known. What is known is that the vertical load during obturation is only between 1 and 3 kg.^{65,66,70}

An important correlation has been shown by Sathorn et al.^{71,72} between the anatomy of the root canals, as a major predisposing factor, and major operative factors, such as stress distribution, residual dentin thickness, and types of canal preparation. Canal diameter, along with shape and proximal concavity, even plays a more major role in fracture susceptibility. On the other hand, residual dentin thickness, although an important factor in itself, does not appear to increase the susceptibility for fracture.

Another factor playing a major role in fracture susceptibility is canal irregularities. Their removal will decrease VRF susceptibility. Recently, Zandbiglari et al.⁷³ addressed the correlation of canal preparation to fracture susceptibility and stated that roots may be weakened significantly by preparation with greater taper instruments. Rundquist and Versluis⁵³ have shown that although more dentin may be removed, increased taper of the root canal causes less stress during obturation. However, this stress increases during masticatory loading.

Restorative procedures after root canal therapy, such as post space preparation, selection of tapered posts, traumatic seating of the post creating hydrostatic pressure, and expansion of posts due to corrosion, are additional iatrogenic causes for VRF.^{5,29,74–76} Post space preparation and post selection are of

utmost importance, especially in VRF-susceptible teeth because of their specific cross-section contours and curvatures.^{42,43,77}

Retrospective surveys of success and failure of restored endodontically treated teeth have shown that 10% of failures are due to root fractures.^{78,79} The percentage of failures by root fracture is much higher with threaded posts.⁸⁰ The selection of VRF-susceptible teeth, such as maxillary premolars as post-retained bridge abutments, should also be considered with caution^{9,81,82} (Figure 14A,B).

Treatment

The constant ingress of bacteria into VRFs provides an open pathway from the oral cavity to the supporting periodontal and alveolar tissues. Various treatment modalities have been suggested to save vertically fractured roots, but all of them have proved to be ineffective in the long run.^{7,83–88} In posterior teeth, a fractured root can sometimes be amputated and the other roots retained with a new coronal restoration, or partially resected to provide some additional use of the tooth. In recent *in vitro* studies, some epoxy resin sealers have shown a positive effect in increasing the resistance of roots against fracture.^{52,89}

Prevention

As described above, a fractured root cannot be repaired despite some anecdotal sporadic attempts. Prevention, knowledge, and appreciation of the multifactorial etiology of fractures in endodontically treated teeth are the best solutions that the clinician can accomplish by

1. recognizing the roots and teeth susceptible to fracture;
2. preserving as much tooth structure as possible, thus finding the necessary “golden path” between the need to achieve canal cleanliness and removing only the amount of dentin necessary for the specific intracanal procedure;
3. judicious use of force during obturation of the root canal space;
4. placing a post only when necessary for additional core support;
5. using dowels with a parallel wall with passive fit and round edges, or fiber-reinforced resin-based composite posts when indicated^{90,91}; and
6. preparing coronal restoration ferrules with a vertical length of 1.5 to 2 mm on sound dentin.

MANAGEMENT

CHAPTER 21

TREATMENT OF ENDODONTIC INFECTIONS, CYSTS, AND FLARE-UPS

J. CRAIG BAUMGARTNER, PAUL A. ROSENBERG, MICHAEL M. HOEN, LOUIS M. LIN

Periapical abscesses and cellulitis occur when microbes invade these tissues. The severity of the periapical infections is related to the virulence of the organisms and host resistance. An abscess is a localized collection of pus within a tissue or confined space.¹ Cellulitis is a symptomatic edematous inflammatory process that spreads diffusely through connective tissue and fascial planes.¹ Clinically, cellulitis and the associated abscess should be considered a continuum of the infectious inflammatory process.

After bacteria have invaded periapical tissues, an otherwise healthy patient will eventually exhibit clinical signs and symptoms of infection. The patient may experience swelling and mild to severe pain. As the infection and inflammatory response spreads further, the patient may experience systemic signs and symptoms such as chills, fever, lymphadenopathy, nausea, and headache. The tooth that is the reservoir of the endodontic infection will usually be sensitive to biting and percussion (touch), and eventually the overlying tissues will be sensitive to palpation. There may or may not be radiographic evidence of periapical disease. The pulp cavity of an infected tooth is the source of the infection spreading to periapical tissues and for secondary (metastatic) infection that may spread to facial spaces of the head and neck. Appropriate treatment includes removing the reservoir of infection either by debridement of the infected root canal system or removal of the tooth, along with drainage from swollen tissues. Adjunctive pharmacotherapeutics may also be indicated with cellulitis, progressive swellings, and systemic signs and symptoms of infection.

The spread of infection into facial spaces may be life-threatening. There are potential spaces between anatomic structures of the head and neck which may be involved in infection and inflammation. These facial spaces are recognized by their anatomic boundaries.² An anatomic space that may be involved in mandibular infections is the mandibular buccal vestibule. The swelling occurs between the cortical plate and the buccinator muscle in the posterior of the mandible and the mentalis muscle in the anterior. Mandibular anterior teeth may produce swelling of the mental or submental spaces (Figure 1). The mental space is located between the mentalis muscle and the

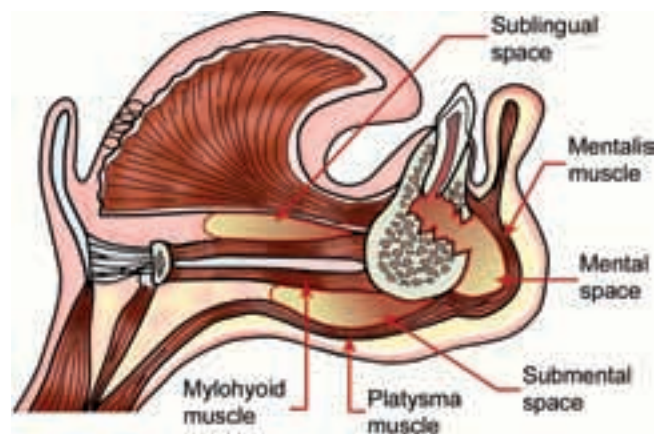

Figure 1 Mental, submental, and sublingual spaces. Courtesy Dr. Wm. Girsch.

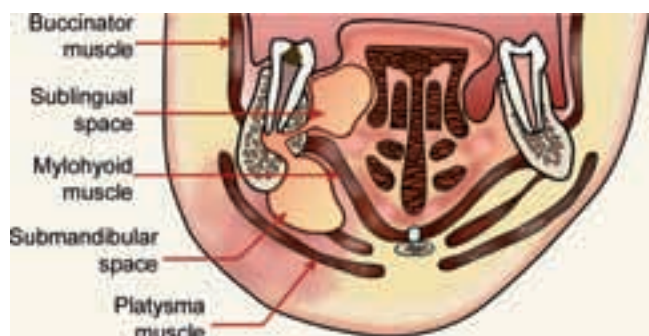

Figure 2 Submandibular and sublingual spaces. Courtesy Dr. Wm. Girsch.

platysma muscle. The submental space is between the mylohyoid muscle and the platysma muscle. Mandibular anterior teeth may also lead to swelling in the sublingual space (see Figure 1) located between the floor of the mouth and the inferiorly located mylohyoid muscle. The submandibular space (Figure 2) is between the mylohyoid and the platysma muscles. The source of infection in this space is usually a mandibular posterior tooth. Ludwig's angina is an infection that includes the submental, sublingual, and submandibular spaces. Cellulitis may extend to the pharyngeal and cervical spaces and produce airway obstruction.

Anatomic spaces involved in lateral face swelling include the maxillary buccal vestibule. This space is located between the cortical plate of the maxilla and the superior attachment of the buccinator muscle and associated with infections of maxillary posterior teeth. The buccal space (Figure 3) is between the lateral surface of the buccinator muscle and the overlying skin of the cheek. The source of the infection may

Figure 3 Buccal, submasseteric, pterygomandibular, and parapharyngeal spaces. Courtesy Dr. Wm. Girsch.

be either a maxillary or a mandibular posterior tooth. The submasseteric space (see Figure 3) lies between the lateral surface of the ramus of the mandible and the masseter muscle. The source of the infection is usually the mandibular third molar. The deep temporal space is between the lateral surface of the skull and the medial surface of the temporal muscle while the superficial temporal space lies between the temporal muscle and the overlying fascia.

Anatomic spaces involved in the pharyngeal and cervical areas include the pterygomandibular space (see Figure 3). That space is usually associated with infection of the mandibular second or third molars. The pterygomandibular space is bounded by the lateral surface of the medial pterygoid muscle and the medial surface of the mandible. The bilateral parapharyngeal space is between the medial surface of the medial pterygoid muscle and the superior constrictor muscle. The superior border is the base of the skull and the inferior border is the hyoid bone. The carotid space contains the carotid artery, internal jugular vein, and the vagus nerve. The retropharyngeal space (Figure 4) is posterior to the superior constrictor muscle and extends to the mediastinum. The pretracheal space surrounds the trachea and extends from the thyroid cartilage to the level of the aortic arch. The retrovisceral space extends from the base of the skull into the posterior mediastinum. The danger space (see Figure 4) extends from the base of the skull into the posterior mediastinum. The prevertebral space surrounds the vertebral column.

The anatomic spaces involved in midface swellings are the palate, the base of the upper lip, the

Figure 4 Pretracheal, prevertebral, and danger spaces. Courtesy Dr. Wm. Girsch.

Figure 5 Periorbital and canine spaces. Courtesy Dr. Wm. Girsch.

infraorbital (canine) space, and the periorbital spaces. The source of infection for the palate is the maxillary teeth. Swelling of the base of the nose is typically caused by a maxillary central incisor with its root apex above the attachment of the orbicularis oris muscle. The infraorbital space (Figure 5) is between the levator anguli oris muscle and the levator labii superioris muscle. The source of the infection is usually the maxillary cuspid or first premolar. The periorbital space lies deep to the orbicularis oculi muscle and becomes involved as a result of the spread of infection from the buccal or infraorbital space. Infections of the midface are of special concern because of the possibility that they may result in cavernous sinus thrombosis. If the inflammation and resulting edema cause blood to back up into the cavernous sinus, the infected thrombi may escape into circulation and produce a life-threatening event.

Treatment of Endodontic Abscesses/Cellulitis

Prompt diagnosis and removal of the reservoir of infection are important for the successful treatment of endodontic infections. Drainage of infectious material and inflammatory mediators associated with endodontic infections may be established through the tooth, soft tissues, or alveolus. Surgical methods for drainage include incision for drainage (I&D), needle aspiration, and trephination. In otherwise healthy patients, chemo-mechanical debridement of the root canal system and drainage of an associated swelling will lead to rapid improvement of the patient's signs and symptoms. Tooth extraction is the alternative treatment to removal of the reservoir of infection. After debride-

Figure 6 Drain sutured in place. Courtesy Dr. Craig Baumgartner.

ment of the root canal system, I&D is indicated for periapical swellings. A recent study found that even with drainage through the access opening into the pulp cavity, there was not a significant reduction in pain, percussion pain, swelling, or number of analgesics taken.³

INCISION FOR DRAINAGE

Successful resolution of an infection requires removal of the source of infection and drainage of the accumulated exudate. Drainage from a swelling caused by an abscess/cellulitis decreases the number of bacteria, bacterial by-products, and inflammatory mediators associated with the swelling. The removal of pockets of purulence and edematous fluid also improves circulation and allows delivery of prescribed antibiotics in a minimum inhibitory concentration. An I&D or needle aspiration of a swelling associated with cellulitis will often reveal accumulations of purulence consistent with an abscess. An incision provides a pathway for additional drainage to prevent the further spread of the abscess/cellulitis. Nerve block anesthesia should be used and if necessary supplemented with local infiltration (see Chapter 22).

To achieve drainage from a swelling, a stab incision through the periosteum is made at the most dependent site of the swelling. A periosteal elevator or hemostat is then used for blunt dissection to allow drainage of any accumulated exudate and inflammatory mediators. Except for very small localized swellings, a drain should be sutured into place (Figure 6).

Figure 7 Top drain is a capillary drain, middle is a penrose drain, bottom is a rubber dam drain. Courtesy Dr. Craig Baumgartner.

Drains may be a piece of rubber dam, a Penrose drain, or a capillary drain (Figure 7). The latter is ribbed and seems to stay under the tissues better than the non-ribbed drains. Non-latex drains should be used for those allergic or sensitive to latex. A sutured drain keeps the incision open for continued drainage and encourages compliance by the patient to return for follow-up evaluations. The use of warm intraoral rinses may help promote drainage. The drain can usually be removed in 1 or 2 days when there is improvement in the patient's clinical signs and symptoms. Consultation with, and referral to other specialists in the management of facial infections, is indicated for severe or persistent infections.

NEEDLE ASPIRATION

Needle aspiration may be described as the use of suction to remove fluids from a cavity or space. It is a surgical procedure that may provide information as to the presence and volume of exudate, cystic fluid, or blood. Aspirated samples may be used for microbial isolation and identification, using either culturing or molecular methods⁴⁻⁶ (Figure 8). In addition, the sample may be used for immunohistochemical analysis (Figure 9). In 1995, Simon et al.⁷ described the clinical use of needle aspiration for intraoral swelling as an alternative technique to I&D. Following regional and local anesthesia, the technique involved the use of a syringe with an 18-gauge needle to aspirate the contents of a swelling. Clinical advantages of needle aspiration over I&D include reduced scarring, evaluation of volume and character of the aspirate, use of

Figure 8 Aspirate from abscess/cellulitis. Courtesy Dr. Mike Hoen.

the aspirate for culture and sensitivity testing, and the lack of postoperative drain removal.

ANTIBIOTICS IN ENDODONTICS

The vast majority of infections of endodontic origin can be effectively managed without the use of antibiotics. Systemically administered antibiotics are not a substitute for timely endodontic treatment. Chemo-mechanical debridement of the infected root canal system with drainage through the root canal and by incision and drainage of swollen tissues will decrease the bioburden so that a normal healthy patient can

Figure 9 The aspirated sample is injected through the stopper into an anaerobic transport vial. Courtesy Dr. Craig Baumgartner.

Table 1 Conditions not Requiring Adjunctive Antibiotics

1. Pain without signs and symptoms of infection
 - a. Symptomatic irreversible pulpitis
 - b. Symptomatic apical periodontitis
2. Teeth with necrotic pulps and a radiolucency
3. Teeth with a sinus tract (chronic apical abscess)
4. Localized fluctuant swellings

begin the healing process. Antibiotics are not recommended for healthy patients with symptomatic pulpitis, symptomatic apical periodontitis, a draining sinus tract, a localized swelling of endodontic origin, or following endodontic surgery⁸⁻¹³ (Table 1). An antibiotic regimen should be prescribed in conjunction with endodontic treatment when there are systemic signs and symptoms of infection or a progressive/persistent spread of infection. The presence of a fever (>100°F), malaise, cellulitis, unexplained trismus, and progressive swelling are all signs and symptoms of systemic involvement and spread of infection (Table 2). Under these circumstances, an antibiotic is indicated in addition to debridement of the root canal harboring the infecting microbes and drainage of any accumulated purulence. Patients with serious endodontic infections should be closely followed on a daily basis. Their conditions will usually improve rapidly once the source of the infection is removed. Because of the lack of circulation, systemically administered antibiotics are not effective against a reservoir of microorganisms within an infected root canal

Table 2 Indications for Adjunctive Antibiotics (Antimicrobial Therapy)

1. Systemic involvement

3. Persistent infections

system. Furthermore, a minimum inhibitory concentration of an antibiotic may not reach an anatomic space filled with purulence and edematous fluid because of poor circulation and the diffusion gradient that it must traverse. Pus consists mainly of neutrophils, cellular debris, bacteria, bacterial by-products, enzymes, and edematous fluid. An I&D will allow drainage of the purulent material and improve circulation to the area. Drainage provides a pathway for removal of inflammatory mediators and helps prevent further spread of cellulitis.

Empirical selection of an antibiotic (antimicrobial agent) should be based on knowledge of which bacteria are most commonly associated with endodontic infections and their antibiotic susceptibility.^{4,5,14-18} The clinician must be knowledgeable about the antibiotic and inform the patient of its benefits, possible side effects, and possible sequelae of failing to take the recommended dosage. A loading dose is important to provide an initial adequate therapeutic blood level of antibiotic. It should generally be continued for 2 to 3 days following resolution of the major clinical signs and symptoms of the infection. Following removal of the source of the infection and adjunctive antibiotic therapy, significant improvement in the patient's status should be seen in 24 to 48 hours. A prescription written for a 7-day regimen of antibiotic therapy is usually adequate.

Penicillin VK is the antibiotic of choice because of its effectiveness against both facultative and anaerobic microorganisms commonly found in polymicrobial endodontic infections.^{4,5,14,17-19} However, up to 10% of the population may be allergic to this medication, so a careful history of drug hypersensitivity is important. A loading dose of 1,000 mg of penicillin VK should be orally administered followed by 500 mg every 4 to 6 hours.

Amoxicillin has an expanded spectrum of activity that includes bacteria not routinely associated with infections of endodontic origin.^{4,5,15,16} It is rapidly absorbed and provides sustained serum levels which make it ideal for use with medically compromised patients who require antibiotic prophylaxis. The usual oral dosage for amoxicillin to treat infections is 1,000-mg loading dose followed by 500 mg every 8 hours. An alternate dosage for amoxicillin is 875 mg every 12 hours.

Clavulanate is a competitive inhibitor of beta-lactamase. Antibiotic susceptibility tests have shown excellent results against bacteria isolated from endodontic infections when clavulanate is used in combination with amoxicillin (Augmentin).^{4,5,15,16} This combination should be considered for patients who

are immunocompromised. The usual oral dosage for amoxicillin with clavulanate is 1,000-mg loading dose followed by 500 mg every 8 hours. An alternate dosage is 875 mg every 12 hours.

Erythromycin has traditionally been the alternative choice for patients allergic to penicillin, but it is not effective against anaerobes associated with endodontic infections. Clarithromycin and azithromycin are macrolides like erythromycin, with some advantages over the latter. They have a spectrum of antimicrobial activity that includes facultative bacteria and some anaerobic bacteria associated with infections of endodontic origin. They also have less gastrointestinal upset than erythromycin. The oral dosage for clarithromycin is a 500-mg loading dose followed by 250 mg every 12 hours. The oral dosage for azithromycin is a 500-mg loading dose followed by 250 mg once a day.

Clindamycin is effective against both facultative and strict anaerobic bacteria associated with endodontic infections. It is well distributed throughout the body, especially to bone, where its concentration approaches that of plasma. Both penicillin and clindamycin have been shown to produce good results in treating odontogenic infections.^{4,5,20} Clindamycin is rapidly absorbed even in the presence of food in the stomach.²¹ The oral adult dosage for serious endodontic infections is a 600-mg loading dose followed by 300 mg every 6 hours.

Metronidazole is a nitroimidazole that is active against parasites and anaerobic bacteria. However, it is ineffective against facultative bacteria.^{4,5,22} It is a valuable antimicrobial agent in combination with penicillin when penicillin alone has been ineffective.²² The usual oral dosage for metronidazole is a 1,000-mg loading dose followed by 500 mg every 6 hours. Consultation with, and referral to other specialists in the management of facial infections, is indicated for severe or persistent infections.

Cephalosporins are usually not indicated for the treatment of endodontic infections. First-generation cephalosporins do not have activity against the anaerobes usually involved in endodontic infections. Second-generation cephalosporins have some efficacy for anaerobes, however, there is a possibility of cross-allergenicity of cephalosporins with penicillin.

Doxycycline occasionally may be indicated when the above antibiotics are contraindicated. However, many strains of bacteria have become resistant to the tetracyclines.

Ciprofloxacin is a quinolone antibiotic that is not effective against anaerobic bacteria usually found in endodontic infections. With a persistent infection, it may be indicated if culture and sensitivity tests demonstrated the presence of susceptible organisms.

PROPHYLACTIC ANTIBIOTICS FOR MEDICALLY COMPROMISED PATIENTS

Prophylactic antibiotic coverage may be indicated for medically compromised patients requiring endodontic treatment. The American Heart Association (AHA) and the American Academy of Orthopaedic Surgeons have made guidelines for prophylactic antibiotic coverage.^{23,24} The guidelines are meant to aid practitioners but are not intended as the standard of care or as a substitute for clinical judgment. The incidence of endocarditis following most procedures on patients with underlying cardiac disease is low (see Chapter 7 “Microbiology of Endodontic Disease”).

A reasonable approach for prescribing prophylactic antibiotics considers the degree to which the underlying disease creates a risk for endocarditis, the apparent risk for producing a bacteremia, adverse reactions to the prophylactic antibiotic, and the cost-benefit aspect of the regimen.²³ Antibiotic prophylaxis is employed to prevent surgical infections or their postoperative sequelae, to prevent metastatic bacteremias, and to prevent accusation that “all was not done for the patient.”²⁵ It is suspected that antibiotic prophylaxis is often prescribed to prevent malpractice claims.²⁵

How antibiotics quickly kill bacteria in the blood is difficult to answer when many antibiotics are only effective with actively dividing bacteria. It is speculated that antibiotics may reduce metastatic infections by preventing adhesion of bacteria to tissues or inhibiting growth after attachment.²⁶ The principles of antibiotic prophylaxis state that the antibiotic must be in the system prior to an invasive procedure. If a patient has not taken the prescribed antibiotic, he or she should be rescheduled or wait an hour after administration of the antibiotic for treatment. However, there is data to support the use of an antibiotic up to 2 hours after the onset of bacteremia.²⁵

The incidence of bacteremia has been shown to be low during root canal therapy. A transient bacteremia can result from the extrusion of microorganisms from the root canal to the periapical tissues of the tooth.^{27–31} In addition, positioning rubber dam clamps and accomplishing other dental procedures may produce bleeding and can lead to a bacteremia. Medically compromised dental patients who are at risk of infection should receive a regimen of antibiotics that either follows the recommendations of the AHA or an alternate regimen determined in consultation with the patients’ physicians.²³ Chapter 24 gives the antibiotic regimens recommended for dental procedures. It is believed that amoxicillin,

ampicillin, and penicillin V are equally effective against alpha-hemolytic streptococci; however, amoxicillin is recommended because it is better absorbed from the gastrointestinal tract and provides higher and more sustained serum levels.²³

For cardiac conditions associated with endocarditis, prophylaxis is recommended for both non-surgical and surgical endodontic procedures.²³ Antibiotic prophylaxis is recommended for cardiac conditions associated with endocarditis at a high or moderate risk category (see Chapter 24). Dental procedures for which antibiotic prophylaxis is recommended (see Chapter 24) include endodontic instrumentation beyond the apex or surgery, but not intracanal endodontic treatment, post-placement and buildup.²³ From a practical standpoint, it is difficult to determine with certainty that endodontic instruments do not pass beyond the apical foramen. Also included for prophylaxis antibiotics is intraligamentary periodontal ligament (PDL) local anesthetic injections, but not non-intraligamentary ones.²³

In 2003, a joint committee of the American Dental Association and American Academy of Orthopaedic Surgeons published their first advisory statement on antibiotic prophylaxis for patients with prosthetic joints. The dental procedures of concern and the antibiotic regimens are the same as for endocarditis Chapter 24. Patients of potential increased risk of having a hematogenous total joint infection include all patients during the first 2 years following joint replacement, immunocompromised/immunosuppressed patients, and patients with comorbidities as shown in Chapter 24.³²

COLLECTION OF A MICROBIAL SAMPLE

Adjunctive antibiotic therapy for endodontic infections is most often prescribed empirically based on knowledge of the bacteria most often associated with endodontic infections. At times, culturing may provide valuable information to better select the appropriate antibiotic regimen. For example, an immunocompromised/immunosuppressed patient (not immunocompetent) or patients at high risk of developing infections (e.g., history of infective endocarditis) following a bacteremia require close monitoring. These patients may have an infection caused by bacteria usually not associated with the oral cavity. Other examples include a seemingly healthy patient who has persistent or progressive symptoms following surgical or non-surgical endodontic treatment. An aseptic microbial sample from a root canal is collected by first isolating the

tooth with a rubber dam and disinfecting the tooth surface and rubber dam with sodium hypochlorite or other disinfectant. Sterile burs and instruments must be used to gain access to the root canal system. Intracanal irrigation should not be used until after the microbial sample has been taken. If there is drainage from the canal, it may be sampled with a sterile paper point or aspirated into a sterile syringe with a sterile 18- to 25-gauge needle, depending on the viscosity of the exudate. The aspirate should either be taken immediately to a microbiology laboratory in the syringe or injected into pre-reduced transport media. To sample a dry root canal, a sterile syringe should be used to place some pre-reduced transport medium into the canal. A sterile endodontic instrument is then used to scrape the walls of the canal to suspend microorganisms into the medium.

To prevent contamination by the normal oral flora, a microbial sample from a soft tissue swelling should be obtained before making an I&D. Once profound anesthesia is achieved, the surface of the mucosa should be dried and disinfected with an iodophor swab. A sterile 16- to 20-gauge needle and syringe is used to aspirate the exudate. The aspirate should be handled as described above. A sample can be collected on a swab after the I&D has been made, but great care must be taken to prevent microbial contamination with normal oral flora. After collecting the specimen on a swab, it should be quickly placed in pre-reduced medium for transport to the laboratory.

Good communication with the laboratory personnel is important. The sample should be Gram-stained to demonstrate which types of microorganisms predominate. The culture results should show the prominent isolated microorganisms and not just be identified as "normal oral flora." Antibiotics can usually be chosen to treat endodontic infections based on the identification of the prominent microorganisms in the culture. With persistent infections, susceptibility testing can be undertaken to establish which antibiotics are the most effective against resistant microbial isolates. At present, it may take 1 to 2 weeks to identify anaerobes using conventional methods. Some laboratories may have molecular methods available to rapidly detect and identify known opportunistic bacteria.

CORTICAL TREPHINATION

Cortical trephination is defined as the surgical perforation of the alveolar cortical plate to release accumulated tissue exudates.¹ Its use is indicated for patients with severe pain of endodontic origin without intraoral or

extraoral swelling and when drainage cannot be accomplished through the root canal, for example, in the presence of posts, filling material, or ledging. Cortical trephination involves exposing the cortical bone, making an opening in the bone, and making a pathway through the cancellous bone to the root end.³³⁻⁴⁰ Occasionally, an instrument may be used to penetrate the mucosa and cortical plate without an incision (Figure 10A,B). Several studies have demonstrated that a patient with severe periapical pain without swelling will have significant relief following trephination.^{34,41-43} A technique for trephination recommended by Henry and Fraser⁴¹ involves a submarginal horizontal full thickness flap to access the

Figure 10 **A**, Trephination using a #3 spreader. **B**, Radiograph showing tip of a #3 spreader near root end. Courtesy Dr. Craig Baumgartner.

alveolar bone, the use of a surgical high speed round bur to access the involved root apex and abscessed area, and the placement of a sutured drain.

Some studies have shown cortical trephination may not be predictable in relieving periapical pain.³⁶⁻³⁸ A prospective randomized blinded clinical trial raised concern about the assumed clinical effectiveness of trephination.³⁸ In that study, pain logs were evaluated after non-surgical endodontic treatment and either real or simulated trephination. It was found that the routine use of trephination for the reduction of pain or swelling in symptomatic necrotic pulps in teeth with periapical radiolucencies was not predictable. A systematic review of the literature concerning the emergency management of acute apical periodontitis in the permanent dentition also concluded that routine cortical trephination did not show significant benefit.⁴⁴ While there is no higher level of evidence justifying the routine use of surgical trephination, there are limited instances in which it is a reasonable treatment alternative. Patients with severe periapical pain of endodontic origin without swelling may benefit from the procedure.

DECOMPRESSION: ASPIRATION AND IRRIGATION

The terms decompression and marsupialization are often used interchangeably. Decompression is the surgical exposure of a cyst wall and insertion of a tube or other type of drain to decompress the lesion during healing.¹ It is not uncommon for chronic periapical pathosis to remain clinically asymptomatic and develop a bony defect of significant size. If left undiagnosed and untreated, periapical pathosis may develop into self-perpetuating entities that erode osseous supporting structures and encroach on adjacent teeth, sinus cavities, neurovascular bundles, and even the nasal cavity. Bony lesions radiographically exceeding 200 mm² have a higher statistical chance of being cystic.⁴⁵ There are radicular cysts that may have progressed to the extent that they are truly independent, and non-surgical endodontic treatment may no longer be enough to result in bony healing.^{46,47} When non-surgical endodontics does not resolve apical pathosis, surgical intervention is an alternative treatment recommendation.

Surgical treatment, including the enucleation of extensive bony lesions, may involve unintentional interruption of periapical vascular and neural structures, development of soft tissue defects, and damage to adjacent anatomic structures. Decompression is a more conservative treatment option that allows the progressive reduction in lesion size and may eliminate

the necessity for surgical enucleation. Decompression is intended to disrupt the integrity of the lesion wall, reduce the internal osmotic pressure, and permit osseous regeneration (Figure 11).

In 1982, Suzuki⁴⁸ suggested treating jaw cysts using an irrigational technique. In that study, the contents of 36 cysts were irrigated weekly for months and even years. This irrigation method involved the use of Ringer's solution, glucose, and antibiotics. The fluids aspirated from the cysts were quantitatively analyzed for electrolytes, inorganic substances, proteins, and lipids. Irrigation of the lesions eventually resulted in the reduction in the volume and size of the cysts. The irrigation method is effective for the treatment of cysts in jaws.⁴⁸ Large cysts have been decompressed using acrylic stents, obturators, and tubing that extends into the lesion.^{49–53} Acrylic stents or tubing was often left in for months with irrigation of the lesion. Neaverth and Berg⁵² described several cases of large lesion decompression that lasted from several weeks to more than a year. The method used radiopaque tubing in conjunction with water irrigation by the patient. The tube was removed once there was evidence of elimination of the cystic lesion.

A surgical technique was described in case series format by Wong⁵⁴ in 1991. After flap reflection, a surgical fenestration was used to obtain some tissue for biopsy, but the majority of bony defect was left intact. Copious drainage was accomplished and the defect irrigated with saline prior to suturing. This surgical treatment was effective in producing healing while avoiding potential complications.⁵⁴ Rees⁵⁵ in 1997 reviewed and highlighted the treatment of large maxillary cysts by root canal treatment and subsequent decompression. The described technique used a drain made from surgical suction tubing. This seems to be the consensus treatment sequence currently in the dental literature. Figure 12 shows the radiographic and clinical appearance of decompression tube that was left in position for 1 week and the 6-month follow-up radiograph after non-surgical root canal filling.

A 20-patient cohort study of decompression results by Enislidis et al.⁵⁶ is perhaps the best evidence of the technique's effectiveness. The authors described the advantages as ease of treatment, confirmed diagnosis with biopsy, low morbidity, and low incidence of complications. The quickest evidence of successful decompression was related by Loushine et al.⁵⁷ in 1991. This case report related the removal of the decompression tube after only 2 days with follow-up examinations showing progres-

sive osseous repair at 3, 6, and 12 months. The use of decompression to treat odontogenic keratocyst (OKC) has been reported by August et al.⁵⁸ A pediatric nasal airway was modified and placed in 14 OKCs for an average of 8.4 months. They were irrigated twice a day with chlorhexidine. At the time of cystectomy, 9 of 14 no longer showed histological features of OKCs. The epithelium had dedifferentiated and lost cytokeratin 10 production in 64% of the patients.

Mejia et al.⁵⁹ reported, in a case series format, the use of a vacuum system within the root canal system. The technique produced a vacuum effect capable of removing copious amounts of exudate and inflammatory fluids. Perhaps, the removal of the rather high osmolarity fluid and disruption of the bony defect lining is the impetus for subsequent healing.

The combination of aspiration and irrigation as an alternative to surgical endodontic treatment was reported by Hoen et al.⁶⁰ in 1990. This case series demonstrated successful outcomes using a single-visit aspiration and saline irrigation of non-healing bony lesions associated with previously endodontically treated teeth. Following profound anesthesia, mucosa disinfection and aspiration of the cyst contents was accomplished using a 16- or 18-gauge needle attached to a syringe. Several milliliters of viscous aspirate was routinely obtained. The aspirates were submitted for aerobic and anaerobic culturing, Gram-staining, and immunoglobulin quantification. The level of immunoglobulin (Ig) G was significantly elevated in each specimen. Above normal levels of IgG have been shown to be consistent with cyst fluid.⁶¹ It has also been shown there is a high level of albumin and globulin in cysts compared to "granulomas".⁶² No bacteria were seen or cultured from any of the aspirates. At the 1-year follow-up appointments, the patients were asymptomatic and significant bony healing was seen on radiographs. It is important to develop a clear differential diagnosis and to have timely re-evaluations of the patient's signs and symptoms to determine if further treatment is needed.⁶⁰

An additional use of aspiration is to obtain a biopsy sample. August et al.⁵⁸ concluded that the use of needle aspiration for biopsy is a useful technique to distinguish between malignant and benign intraosseous jaw lesions. The described technique involved the use of a 10-mL syringe containing 1 or 2 mL of air attached to 23- or 25-gauge needles. Once within the lesion, suction was applied and several quick passes were performed to obtain cellular

material. The specimens were then placed on glass slides for smear preparation. The authors suggested that aspiration may be the diagnostic tool of choice in a hospital setting due to its simplicity, suitability as an outpatient procedure, rapidity of interpretation, and minimal morbidity.⁶³ The accuracy of fine-needle aspiration biopsy of head and neck tumors has been reviewed in 218 patients.⁶⁴ The technique was determined to be a useful modality for the diagnosis of head and neck tumors. The use of such a technique requires coordination with a pathologist familiar with needle biopsy specimens.

Endodontic Flare-ups

The American Association of Endodontics' *Glossary of Endodontic Terms* offers the following definition: "A flare-up is an acute exacerbation of an asymptomatic pulp/or periapical pathosis after the initiation or continuation of root canal treatment."¹ Treating similar teeth in patients with comparable medical and dental histories is no assurance of a common outcome. While one patient remains asymptomatic, another may have a flare-up. The contrasting clinical outcomes may seem to occur in a random manner or lead to erroneous

conclusions about the cause–effect relationship of endodontic procedures to the flare-up. The development of moderate to severe inter-appointment pain, with or without swelling, is an infrequent but challenging problem. The severe pain and swelling associated with flare-ups represent the clinical manifestation of complex pathologic changes occurring at a cellular level. There is increasing evidence pointing to multiple complex factors involved in producing a flare-up. These factors include mechanical, microbial, chemical, immunological, gender, and psychological components. The regulation of periapical inflammation is highly complex and is another factor in patients' response to endodontic procedures.^{22,65–70}

The reported incidence of inter-appointment emergencies ranges from 1.4 to 19%.^{66,69–74} While one study found pain and swelling occurred in as many as 20 to 40% of patients,⁷⁵ the incidence of severe pain conditions is most frequently reported at less than 5%.^{65,70,76,77} Variations in the findings are the result of a number of factors. For example, differences exist in the definition of a flare-up. Some investigators have used swelling as the sole criteria for a flare-up after treating asymptomatic teeth with pulp necrosis and chronic apical periodontitis.⁷¹ Others have used broader definitions of a flare-up which do not require swelling.^{65,66,69,70} Some investigators used a retrospective approach in their research,^{69,73} while others used prospective methodologies.^{65,66,70} There have also been variations in sample size, treatment procedures, number of visits, endodontic medications, and other variables that are neither well-defined nor controlled.

AGE OF PATIENT

There is a lack of agreement concerning the influence of age on the incidence of flare-ups. Prospective studies assessing the incidence of flare-ups in endodontic patients found no correlation between flare-ups and the age of the patient.⁷⁰ However, a large retrospective study reached a different conclusion. Records of 2,000 patients were examined, and it was determined that when age was evaluated (20–39, 40–59, over age 60), a significant difference was found among age groups ($p = 0.0001$). Patients in the 40- to 59-year range had the most flare-ups and those under the age of 20 had the least.⁶⁹ Conflicting conclusions regarding the influence of age on the incidence of flare-ups can be attributed to variations in research methodologies, definitions, sample size, and clinical procedures.

GENDER AND FLARE-UPS

An extensive review concerning gender variation in clinical pain experience reported that women are more likely than men to experience a variety of recurrent pain.⁷⁸ In most studies, women have reported more severe levels of pain, more frequent pain, and pain of longer duration than men.⁷⁹ While a number of studies found a significantly higher percentage of females than males had postoperative pain,^{69,70,75,80} others have not found gender to be a significant factor.^{66,81} It should be noted that there are considerable variations between different types of clinical pain.⁸² Experimental pain, produced under controlled conditions by brief, noxious stimuli, differs from procedural and post-surgical pain. These differences make the study of pain more complex.⁷⁹

SYSTEMIC CONDITIONS

It seems reasonable to assume that host resistance, for example, medical status of the patient, is an important variable in the occurrence of flare-ups. Unfortunately, there is little conclusive evidence concerning the relationship between host resistance and flare-ups. One study found a highly significant association between flare-ups and the presence of allergies to various substances (sulfa medication, pollen, dust, and foodstuffs) and the frequency of inter-appointment pain.⁶⁹ It was suggested that this could have been due to an immediate hypersensitivity reaction occurring in the periapical tissues in response to the egress of antigens from the root canal. Although the components of the immediate hypersensitivity reactions (IgE, mast cells, and mast cell-derived mediators) have been found in periapical lesions, evidence is lacking as to whether these reactions actually occur in the periapical tissues and are responsible for inter-appointment pain.⁶⁸ An association between allergy and inter-appointment pain has not been confirmed.⁷⁰

ANATOMIC LOCATION

Examining the incidence of flare-ups by tooth groups or between arches (maxillary versus mandibular) has usually shown no significant difference.^{66,70,80} An exception was a retrospective study of 2,000 patients who had received root canal treatment for necrotic pulps. Mandibular teeth were associated with more inter-appointment emergencies than their maxillary counterparts ($p = 0.0247$). Mandibular premolars followed by mandibular incisors were the most

problematic teeth after cleaning and shaping of their root canals.⁶⁹

ANXIETY

A high incidence of fear and anxiety among patients concerning an endodontic procedure may have a marked effect on the patient's intra-operative and postoperative response to treatment. It has been shown that if a patient expects pain to occur during dental treatment, this increases the likelihood of pain being perceived.⁸³ An anxious patient with a previous memory of dental pain is more likely to expect pain during subsequent treatment. The slightest pressure on the tooth can be interpreted as pain and initiate a pain reaction. Anxiety may also lead to increased sympathetic activity and muscle tension that may cause more pain.⁷⁹ Patients' descriptions of their pain can be influenced by their level of anxiety and complicate the diagnostic process.⁷⁹

A multivariate analysis of the effectiveness of local anesthesia in pediatric patients indicated anxiety as the strongest predictor of poor pain control.⁸⁴ A large retrospective study noted an association between apprehension and postoperative pain.⁷² The dental procedures causing the highest levels of stress and anxiety are oral surgery and endodontics. There is a high probability that endodontic patients are anxious and expect to experience pain during treatment⁷⁹ (see Chapter 22).

PREOPERATIVE HISTORY OF THE TOOTH

Most studies have found a highly significant relationship between the presence of preoperative pain and/or swelling and the incidence of inter-appointment emergencies.^{65,66,69,70} Studies have also shown a statistically significant higher incidence of flare-ups in patients taking analgesics and anti-inflammatory drugs.^{66,70} It is reasonable to assume that patients taking those drugs were having preoperative pain.

PULP/PERIAPICAL STATUS

There is no universal agreement concerning the influence of pulp status and/or the presence of a periapical lesion on the incidence of inter-appointment emergencies. A prospective study found that teeth with vital pulps resulted in relatively few flare-ups, with an overall percentage of 1.3%.^{66,70} In contrast, pulp necrosis correlated to an incidence of flare-ups of 6.5%, a statistically significant increase when compared to vital pulps. A low number of flare-ups following root canal

treatment of teeth with vital pulps is consistent with findings in other studies.^{73,74}

The periapical diagnosis of acute apical abscess was also related to significantly greater incidence of flare-ups when compared with less symptomatic or less severe apical pathosis.⁷⁰ As one might expect, the presence of a sinus tract did not correlate with flare-ups.^{69,70} Investigators found the presence of a periapical radiolucency was significantly related to inter-appointment flare-ups.^{65,66,71,74} These findings are in contrast to others who found a higher incidence of inter-appointment emergencies in teeth without apical radiolucencies.^{69,81,85,86} The differences in findings may be attributable to variations in research methodologies, sample size, clinical procedures, patients studied, and definition of flare-ups.

NUMBER OF TREATMENT VISITS

A number of studies have determined that less postoperative pain results from a single-visit approach to endodontics than a multi-visit course of treatment.^{66,87,88} Other investigators concluded that little or no difference occurred between single- and multiple-visit endodontic therapy.^{70,89-91} Significant variables exist among the studies that may account for the different conclusions.

CAUSES OF INTER-APPOINTMENT PAIN

Inter-appointment pain is caused by mechanical, chemical, and/or microbial injury to the pulp or periapical tissues that are induced or exacerbated during endodontic treatment.^{68,69,92} The cause of injury may vary, but the intensity of the inflammatory response is usually directly proportional to the intensity of tissue injury.⁹³ Mechanical and chemical injuries are often associated with iatrogenic factors, but microbial-induced injury is a major cause of inter-appointment pain.^{68,92,94} Microbial factors may be combined with iatrogenic factors to cause inter-appointment pain. Even when endodontic procedures are performed within accepted guidelines, microbes can cause a flare-up.⁶⁸ Development of pain precipitated by microbial factors can depend on the interrelationship of several factors that are discussed in Chapter 7.

TREATMENT OF TEETH WITH VITAL AND NON-VITAL PULPS

Treatment of teeth with vital (pulpitis) and non-vital (necrotic) pulps represent pathological conditions that require different approaches to therapy.⁹⁵ It has been suggested that if the pulp is free of infection, the

endodontic treatment should be completed in one visit if other factors permit. Temporization after removal of a vital pulp entails the risk of micro-leakage and contamination of the canal.⁹⁵ A high level of asepsis during pulpectomy and subsequent obturation is an essential part of treatment. Although asepsis is also an important part of treating a tooth with a non-vital pulp, the principle concern is the presence of bacteria in the root canal system. Infected canals may contain 10 to 100 million bacterial cells.⁹⁵⁻⁹⁷ Clinicians are faced with the challenge of disinfecting the canal system through instrumentation, irrigation, and medication without pushing debris into the periapical tissues.

RE-TREATMENT CASES

Re-treatment cases, in most studies, have had a significantly higher incidence of flare-ups than conventional cases^{69,70} (Figure 13). One study found an extremely high incidence of flare-ups (13.6%) in re-treatment teeth with apical periodontitis.⁷⁷ It can be hypothesized that re-treatment cases are often technically difficult to treat, and there is a tendency to push remnants of gutta-percha, solvents, and other debris into the periapical tissues. Microbes may also be pushed apically during the re-treatment process. Extrusion of infected debris or solvents into the periapical tissues during preparation of the canals is allegedly one of the principal causes of postoperative pain.^{92,96,98} Re-treatment cases are usually associated with a persistent or secondary root canal infection by therapy-resistant microorganisms that may be more difficult to eradicate when compared to primary infections.^{67,98,99} In contrast, others have found

no statistical significance in the relation of re-treatment to flare-ups.⁷⁰

WORKING LENGTH

The apical portion of the root canal system has been considered the most critical anatomic area with regard to the need for cleaning, disinfection, and sealing.^{67,100}

Overextension should be avoided as it can result in postoperative pain.⁶⁷ Teeth with non-vital (necrotic) pulps associated with a periapical lesion, as well as root-filled teeth with recalcitrant lesions, represents a different biological challenge.⁶⁷ In these cases, microorganisms may be at or near the apical foramen and accessory foramina that are in close contact with the periapical tissues.^{67,101-104} Thus, correct working length in infected teeth is essential.^{67,105} Inaccurate working length or inadvertent over- or under-instrumentation can result in negative outcomes for the patient. Over-instrumentation may force infected debris into the periapical tissues eliciting a severe inflammatory response and pain. Under-instrumentation will leave microorganisms in close proximity to the apical foramina where they or their virulence factors can gain access to the periapical tissues^{67,106} (see Chapter 7). Incomplete instrumentation can disrupt the balance within the microbial flora and allow previously inhibited species to overgrow.¹⁰⁷ If those strains of bacteria are virulent and/or reach sufficient numbers, damage to the periapical tissues may be intensified and result in an exacerbation of the lesion. Furthermore, environmental changes, induced by incomplete debridement, have the potential to activate virulence genes.⁶⁸

Figure 13 Swelling associated with flare-up following revision of previous endodontic treatment. Courtesy Dr. Paul Rosenberg.

A change in host resistance or microbial virulence may allow a previously asymptomatic situation to become symptomatic.⁶⁸ Clinical studies, however, have not linked incomplete canal preparation to flare-ups.^{70,91,108,109}

OBTURATION

Overfilling can cause postoperative pain particularly when a substantial amount of filling material extrudes through the apical foramen. Gross overfilling involves the introduction of excess sealer (and its cytotoxic components) into the periapical tissues causing tissue damage and inflammation.⁶⁷ A recent study found that overfilling was significantly associated with increased rate of pain and percussion sensitivity in 1-week follow-up examinations in comparison with teeth not overfilled.¹¹⁰ Scheduling of the obturation visit in relation to instrumentation may be another important factor. Obturation in the presence of acute apical periodontitis can be considered to be a predictor of postoperative pain. In order to avoid increased postoperative pain, patients who present for obturation but have significant acute apical periodontitis should have the procedure postponed until the tooth is more comfortable. Relief of pain can be achieved by treatment directed at reducing tissue levels of factors that stimulate peripheral terminals of nociceptors or by reducing mechanical stimulation of sensitized nociceptors (e.g., occlusal adjustment). Thus by deferring obturation of a tooth with pericementitis, further stimulation of sensitized nociceptors is avoided.^{111,112}

Strategies to Prevent Flare-ups

ANXIETY REDUCTION

The causes of endodontic flare-ups are varied, and an effective preventive strategy must be multifaceted (see Chapter 23). There is a well-documented relationship between anxiety, pain threshold, and postoperative pain.^{72,79,83,84}

BEHAVIORAL INTERVENTION

In preoperative patients, high levels of stress, anxiety, or pessimism predict poor outcomes in measures that range from speed of wound healing to duration of hospital stay. Over 200 studies indicate that preemptive behavioral intervention, to decrease anxiety

before and after surgery, reduces postoperative pain intensity and intake of analgesics improves treatment compliance, cardiovascular and respiratory indices, and accelerates recovery.¹¹³ In a landmark study, it was found that preoperative discussion of likely post-surgical treatments and associated discomfort halved the requirement for postoperative morphine and reduced time to discharge. Patients in that study also received instructions in a relaxation technique.¹¹⁴

Providing information about the procedure is an important step in preparing patients for endodontic treatment. Information about profound dental anesthesia and preventive pain strategies is an important anxiety reduction technique. Perhaps most importantly, the dentist should assure the patient that pain prevention is a primary concern. It was determined that patients given a running commentary concerning procedures and associated sensations rated themselves as less anxious and experiencing less pain than a normal control group.¹¹⁵ Information about sensations experienced during treatment as well as a description of procedures appears to have a significant impact in reducing patient anxiety.¹¹⁵ Patients should not be allowed to watch surgical procedures in a mirror.

OCCLUSAL REDUCTION

Occlusal reduction is a valuable pain preventive strategy in appropriate cases.^{116,117} Some earlier studies raised questions concerning the value of prophylactic occlusal reduction as a pain preventive measure.^{118,119} The results of a more recent study indicated that occlusal reduction should result in less post-treatment pain in patients whose teeth exhibit pulp vitality, preoperative pain, percussion pain, or absence of a periapical radiolucency.¹²⁰ While the presence of all four conditions is the strongest predictor, the presence of any one or more of the conditions is enough to indicate the need for occlusal reduction (Figure 14).

Occlusal reduction when performed in appropriate cases is a highly predictable, simple strategy for the prevention of postoperative pain and relief of pain due to acute apical periodontitis. There is a biologic rationale for the relief of pain provided by the occlusal reduction. Mechanical allodynia (i.e., sensitivity to percussion or biting forces) is due to tissue levels of mediators that stimulate peripheral terminals of nociceptors. Occlusal adjustment, in either arch, reduces mechanical stimulation of sensitized nociceptors.^{120,121}

Figure 14 Effect of occlusal reduction on pain. Courtesy Dr. Paul Rosenberg.

Pharmacologic Strategies for Flare-ups

ANTIBIOTICS

Antibiotics are frequently prescribed to endodontic patients without a rational biologic basis.^{122,123} An evidence-based review determined that the use of systemic antibiotics for the prevention of post-treatment endodontic pain should be discouraged.¹²⁴ Antibiotic treatment is generally not recommended for healthy patients with localized endodontic infections. Systemic antibiotics should be considered if there is a spreading infection that indicates failure of local host responses to control bacterial irritants or the patient has a medical condition that compromises defense mechanisms and could expose the patient to higher systemic risks.¹²⁴

NSAIDS AND ACETOMINOPHEN

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been shown to be effective for managing pulpal and periapical pain.^{111,125} However, due to the renal effects of NSAIDs as well as interactions with many anti-hypertensive drugs, acetaminophen should be considered for post-treatment pain in patients with known sensitivity to NSAIDs or aspirin. Acetaminophen should also be considered for those with the following disorders: ulcers, ulcerative colitis, asthma, or hypertension. Pretreatment with NSAIDs or acetaminophen has also been shown to be effective for reducing postoperative pain.^{68,121} Pretreatment with NSAIDs for irreversible pulpitis should have the effect of reducing pulpal levels of the inflammatory mediator prostaglandin E2 (PGE2).^{68,71}

It is advisable to have endodontic patients take their analgesics “by the clock” rather than on an “as needed basis”.¹²¹ Patients should take an NSAID or acetaminophen just prior to, or immediately after, treatment. If they wait to take medication until after the onset of pain, there is usually a delay of up to 1 hour before they experience pain relief. It has been suggested that instructing patients to take their analgesics by the clock for the first few days provides a more consistent blood level of the drug and may contribute to more consistent pain relief.¹²¹ The combination of ibuprofen and acetaminophen taken together has been shown to produce additive analgesia when treating dental pain.^{111,121,126–128} Opioids may be added when indicated (see Chapter 22).

LONG-ACTING LOCAL ANESTHETICS

Long-acting local anesthetics (e.g., bupivacaine) can provide an increased period of post-treatment analgesia beyond the usual duration of anesthesia.^{129,130} By blocking the activation of unmyelinated C-fiber nociceptors, the anesthetic decreases the potential for central sensitization.¹²¹ Long-acting local anesthetics can provide a period of analgesia for up to 8 to 10 hours following block injections and may reduce pain even 48 hours later.^{121,129} Use of long-acting local anesthetics is a valuable biologically based strategy that provides analgesia during the immediate postoperative period.¹²¹ Endodontic treatment by itself can be expected to provide significant pain relief (see Chapter 22).

Treatment of Endodontic Flare-ups

Selecting the appropriate treatment after an endodontic flare-up is dependent upon understanding its biological cause. For example, the clinician must determine if a flare-up is primarily iatrogenic in nature, as in the case of inaccurate measurement control, or microbiologically based, as in an infected necrotic situation.

DIAGNOSIS AND DEFINITIVE TREATMENT

History of the onset of pain is important in determining if the pain is spontaneous or provoked by a specific stimulus. For example, if a tooth had a history of acute apical periodontitis and its occlusion had not been reduced, that could be identified as a probable cause of postoperative pain,

appropriate treatment should be provided.¹²⁰ In contrast, a complaint of swelling, pressure, and throbbing in the interproximal area might suggest a periodontal component of the problem that should be explored. If inaccurate measurement control was used or proper measurement not maintained, the clinician must determine if the canal was under- or over-instrumented. Working length should be reconfirmed, patency to the apical foramen obtained, and thorough debridement with copious irrigation completed. Remaining tissue, microorganisms and their products, and extrusion beyond the apex are major factors responsible for post-treatment symptoms.⁹⁴ Pain relief in the over-instrumented case is often dependent on an analgesic strategy. The under-instrumented case may require further instrumentation to the correct measurement, as well as the use of analgesics.

Drainage Through the Coronal Access Opening

A cardinal principle in the treatment of suppurative lesions is the establishment of drainage (Figure 15). Drainage, upon access to the pulp cavity, releases purulent or hemorrhagic exudate from the periapical tissues and may reduce periapical pressure in symptomatic teeth with radiolucent areas.¹³¹ Obtaining

drainage through the coronal access opening has been advocated as a means of reducing pain following treatment in some necrotic cases.¹³² Interestingly, a retrospective study examined the effect of drainage upon access on postoperative endodontic pain and swelling in symptomatic necrotic teeth. It was determined that drainage upon access (average of 1.85 minutes) did not significantly ($p > 0.05$) reduce pain, percussion pain, swelling, or the number of analgesic medications taken, for symptomatic teeth with periapical radiolucencies.¹³¹ It is possible that pre-existent apical periodontitis was a factor in the cases studied and was not addressed by the establishment of drainage. Occlusal relief may also have been required to address that symptom.

I&D

The goal of emergency treatment for an endodontic flare-up with a swelling is to achieve drainage.¹³² The object of drainage is to evacuate exudate from the periapical spaces (Figure 16). Drainage is best achieved through a combination of canal instrumentation and I&D. Even in cases where an I&D is to be implemented, the canal should be accessed, instrumented, irrigated, medicated, and closed as soon as active drainage stops. Systemic antibiotics can be expected to be more effective once the canal has been debrided, medicated, and closed.^{133,134}

Figure 15 Purulent drainage upon access to the pulp cavity. Courtesy Dr. Craig Baumgartner.

Figure 16 Purulent drainage following incision of a fluctuant abscess involving a mandibular anterior tooth (Courtesy Dr. John Ingle).

INSTRUMENTATION

After considering the biological cause of the flare-up, the clinician may decide to re-enter the symptomatic tooth. Profound local anesthesia is necessary before re-entry. Enhanced magnification and illumination are helpful in reassessing the chamber morphology for canals that might have been missed at the prior visit.^{135–137} Working lengths should be reconfirmed, patency to the apical foramen obtained, and a thorough debridement with copious irrigation performed.⁶⁸ Remaining necrotic tissue, microorganisms, and toxic products are important factors responsible for flare-ups.⁹⁴ Enlarging the apical constriction has been advocated to encourage drainage.¹³⁸ Others have found that instrumenting through the apical foramen does not ensure drainage of periapical exudation.^{68,138}

In some cases, however, drainage may be established through the root canal system upon instrumentation. Drainage allows for exudate to be released from the periapical tissues thus reducing localized tissue pressure and pain.¹³¹ Leaving a tooth open after drainage is complete will result in re-infection from oral microbes.^{73,94}

TREPINATION

As discussed earlier in the chapter, trephination is the surgical perforation of the alveolar cortical plate over the root end, to release accumulated tissue exudate that is causing pain.¹ It may be indicated for patients with a flare-up when there is exquisite pain, no swelling, and drainage cannot be accomplished through the tooth.

COMPLEX DIAGNOSES

The clinician must be sensitive to the potential of non-odontogenic pain being confused with a flare-up. For example, the words “tingling” or “burning” when used as descriptors of pain are signals of non-odontogenic pain rather than a flare-up. Similarly, although rare, it is possible for a tooth, other than one undergoing endodontic treatment, to suddenly become painful and confuse the diagnosis. A previously undetected periodontal component may also pose a diagnostic problem.

Bacterial Factors Associated with Flare-ups

Bacteria are capable of acting as irritants and induce non-specific innate or specific adaptive immune responses in the host.^{139,140} The host's responses to a bacterial challenge depend largely on virulence factors and the numbers of pathogens, as well as the host's innate and adaptive immunity. If the host's defense mechanisms are capable of overcoming a bacterial challenge, bacteria will be eliminated. In contrast, if the bacterial challenge overwhelms the host's defense mechanisms, an inflammatory response, as a result of innate or adaptive immunity, will occur. Microorganisms have been suggested as the major causative agents of flare-ups.^{68,92,94} Unlike elsewhere in the body, bacteria in the root canal system are well protected from the host's immune defenses and antimicrobial agents. The microbes and virulence factors associated with pulpal and periapical infections are discussed in Chapter 7 “Microbiology of Endodontic Disease.”

The bacterial community in an infected root canal is closely related to the nutrient supply, bacterial interaction, and oxidation–reduction potential.¹⁰⁷ Endodontic procedures cause changes in the root canal environment, favoring growth of some pathogens remaining in the incompletely instrumented canals, thus predisposing the patient to a flare-up.⁹⁴ Some bacterial species may, under certain conditions such as changes in oxidation-reduction potential, bacterial interaction, or environmental stresses, become more virulent and induce higher concentrations of inflammatory molecules and/or cytokines from damaged periapical tissues, thus intensifying the inflammatory response.^{68,94} This is exemplified in some asymptomatic infected teeth with pulpal and/or periapical pathosis, as well as some asymptomatic re-treatment cases with periapical pathosis. After initiation or continuation of root canal treatment, those cases suddenly develop a flare-up. Preoperative symptomatic teeth have been

shown to produce a higher incidence of flare-ups than asymptomatic teeth,^{69,70} although the mechanism is not clear. It is possible, in teeth that are symptomatic, the canals are dominated by pathogens often found associated with pain or an acute periapical abscess. Therefore, these cases are predisposed to flare-up if the canals are not completely debrided or critical numbers of pathogens are forced into the apical tissues to overwhelm the host's defenses. A shift in the microbial community in the root canal may occur before the appearance of a flare-up.⁹⁴

Therapeutically, it is easier to reduce the intracanal bacterial count than to control specific pathogens in the infected root canals. Mechanical instrumentation and antiseptic irrigation have been shown to greatly reduce bacterial count in infected root canals.¹⁴¹ Intracanal medication between visits with calcium hydroxide may further reduce the bacterial count.^{97,142} However, studies have not demonstrated an ability to eliminate all bacteria in infected root canals using contemporary endodontic procedures. Usually, the pathogenicity of microorganisms is related to their virulence factors and numbers. Although complete chemo-mechanical preparation, in combination with intracanal medication, may not eliminate specific pathogens and their virulence factors, the procedures will significantly reduce the intracanal bacterial count and the nutrient supply, thus possibly preventing critical numbers of pathogens from causing a flare-up. Many species of bacteria have been demonstrated in teeth with clinical signs and symptoms; however, the cause of a flare-up by a specific species of bacteria or combinations of bacteria requires further clarification. The presence of specific species of bacteria in teeth with clinical symptoms does not necessarily imply they are the cause of a flare-up.

CHAPTER 22

PHARMACOLOGIC MANAGEMENT OF ENDODONTIC PAIN

KENNETH M. HARGREAVES, AL READER, JOHN M. NUSSTEIN, J. GORDON MARSHALL, JENNIFER L. GIBBS

The management of pain represents both a challenge and an opportunity for the endodontist. It is a challenge due to pharmacological (e.g., reduced anesthetic success), behavioral (e.g., patient apprehension), and practice management (e.g., relationship with referring practitioner) issues. Many of these factors can increase the stress of providing high-quality clinical care to our patients. However, effective pain management also represents a unique opportunity to integrate pharmacological, procedural, and behavioral skills in providing outstanding pain control to grateful patients. A tremendous increase in our knowledge of the pain system and its dynamic plasticity in response to tissue inflammation occurred over the last decade (Chapter 10, “Mechanisms of Odontogenic and Non-Odontogenic Pain” and Chapter 11, “Non-Odontogenic Toothache and Chronic Head and Neck Pains”). Equally important, a commensurate increase in analgesic clinical trials provides the clinician with a unique opportunity to develop biologically and evidence-based strategies for effectively treating endodontic pain patients. This chapter contributes to that skillset by comprehensively reviewing this clinical literature and formulating strategies based on the latest results from clinical research. To accomplish this goal, the chapter will sequentially review major drug classes available to the practitioner and then use this information to summarize evidence-based approaches for pain control.

Local Anesthesia

Profound pain control starts with effective local anesthesia. In addition to the obvious ethical and moral obligation of providing appropriate high-quality care, the technical challenges of endodontic procedures are greatly increased without effective anesthesia. Background reviews on local

anesthetic techniques and pharmacology should be reviewed as needed by the reader. This section provides an evidence-based rationale of various local anesthetic agents and primary and supplemental routes of administration, with an emphasis on clinical implications.

Before reviewing the clinical trial literature, several preliminary factors should be considered. First, subjective approaches for assessing the depth of anesthesia (“are you numb?”) are fraught with a lack of sensitivity and specificity.¹⁻⁴ Instead, testing for pulpal responses in vital teeth, by an application of a cold refrigerant or by using an electric pulp tester (EPT), are effective methods for evaluating anesthesia in pain-free⁵⁻⁹ or symptomatic vital teeth^{5,9-11} in nearly^{5,9,10} all patients. Simply put, the lack of profound anesthesia after an initial injection becomes a major indication for supplemental injection of local anesthetic solutions. Second, a prior history of incomplete anesthesia often predicts subsequent problems with obtaining complete anesthesia.¹² This issue should be considered when reviewing the patient’s dental history. Third, preoperative pain is a risk factor for incomplete local anesthesia, with up to an eight-fold increase in the prevalence of incomplete anesthesia observed in patients with irreversible pulpitis.¹³ Although the mechanism(s) mediating this clinical problem is incompletely understood, several hypotheses have been advanced including (1) ion trapping of local anesthetic molecules due to lower pH (only possible for infiltration injections; block injections are not likely to involve acidotic tissue); (2) altered membrane excitability of peripheral nociceptors^{14,15}; (3) increased activity of the tetrodotoxin-resistant (TTXr) class of sodium channels that may also be resistant to the action of local anesthetics¹⁶; (4) increased overall

expression of sodium channels in pulps diagnosed with irreversible pulpitis¹⁷; and/or (5) central sensitization that amplifies peripheral input from afferent neurons. Importantly, supplemental techniques such as intraosseous^{9,10,18,19} or periodontal ligament (PDL)¹¹ injections have been demonstrated to increase anesthetic efficacy when an inferior alveolar nerve (IAN) block fails to provide effective anesthesia. Fourth, preoperative apprehension, possibly due to previous dental procedures including injections,^{20–22} may contribute to patient management issues. Topical anesthetics have been reported to be effective in reducing injection discomfort in some,^{23–26} but not all,^{27–29} studies, and both pharmacological and psychological components may contribute to the effectiveness of topical anesthetics.²⁹ Fifth, a slow rate of injection (60 versus 15 seconds) reduces patient discomfort³⁰ and can be accomplished either manually or by a computer-controlled anesthetic delivery system. Automated anesthetic delivery systems have been shown to produce less pain in some studies,^{31–36} or either no difference or greater pain in other studies^{37,38}; at least some discomfort has been noted in most studies.^{32–38} Sixth, epinephrine-containing local anesthetics, with their associated lowered pH, are thought to be associated with more injection discomfort in some^{39,40} but not all⁴¹ studies. As noted in Chapter 10, “Mechanisms of Odontogenic and Non-Odontogenic Pain,” the TRPV1 “capsaicin receptor” is expressed on pain neurons and is profoundly activated by pH solutions of <6.0, which might provide a biological basis for this observation. Seventh, permanent damage to the lingual nerve and IANs are very rare, with a calculated incidence of about 0.0006 to 0.3%.⁴² Of these reported injuries, the lingual nerve is affected ~70 to 79%, while the IAN is affected ~21 to 30% of these cases.^{42,43} In one case series, the lingual nerve was affected in 18 out of 12,104 patients (~0.1%), with 17 of these 18 cases resolved within 6 months.⁴⁴ Collectively, these general principles of local anesthesia provide foundation knowledge when using this important class of drugs.

Mandibular Anesthesia

Numerous studies have evaluated pulpal anesthesia using a standardized testing protocol involving repeated application of an EPT using a 0–80 scale of current.^{1–4,45–49} This method permits controlled clinical trials in which either normal healthy control subjects or odontogenic pain patients using the same dependent measure for study outcome. In these studies, anesthetic success is defined as the percentage of subjects who achieve two consecutive 80 readings

Figure 1 Time–response curve for the development of pulpal anesthesia (defined as no response on Analytical Technologies EPT at setting = 80) of mandibular first molars following inferior alveolar nerve (IAN) block injection of 1.8 mL of 2% lidocaine with 1:100,000 epinephrine. Data courtesy of Dr. A. Reader et al.

(EPT) within 15 minutes and continuously demonstrate a lack of responsiveness for 60 minutes. Conversely, anesthetic failure is defined as the percentage of subjects who never achieved two consecutive 80 EPT readings at any observation time. In general, studies performing IAN block injections with one cartridge of 2% lidocaine with 1:100,000 epinephrine report different proportions of anesthetic success/failure for the mandibular first molar (53% success/17% failure), first premolar (61%/11%), and the lateral incisor (35%/32%)^{1–4,45–49} (Figure 1). It is important to note, however, that 100% of the subjects^{1–4,45–49} reported profound lip numbness. Therefore, this outcome has no predictable value for determining the depth of pulpal anesthesia. Although the presence of lip sign does not indicate effective pulpal anesthesia, the absence of a lip sign indicates a failed IAN block injection and should prompt a second injection of local anesthetic before treatment begins.

Several local anesthetics have been compared in clinical trials using designs similar to that described above. As summarized in Table 1, these studies have demonstrated that many local anesthetics produce similar levels of anesthesia for IAN block injections. In particular, the equivalency of 3% mepivacaine and 2% lidocaine with 1:100,000 epinephrine, in patients with irreversible pulpitis, is an important finding. It provides a vasoconstrictor-free alternative when medical conditions or drug therapies suggest caution in administering epinephrine-containing solutions.

Mepivacaine is available in a formulation containing levonordefrin, an adrenergic agonist with 75% α

Table 1 Comparison of Local Anesthetics for Inferior Alveolar Nerve Anesthesia

Local Anesthetic I	Local Anesthetic II	Patient Population	Finding	Reference
3% Mepivacaine plain	2% Lidocaine with 1:100,000 epinephrine	Healthy volunteer subjects	I = II	2
3% Mepivacaine plain	2% Lidocaine with 1:100,000 epinephrine	Irreversible pulpitis	I = II	11
2% Mepivacaine with 1:20,000 levonordefrin	2% Lidocaine with 1:100,000 epinephrine	Healthy volunteer subjects	I = II	4
4% Prilocaine plain	2% Lidocaine with 1:100,000 epinephrine	Healthy volunteer subjects	I = II	2
4% Prilocaine with 1:200,000 epinephrine	2% Lidocaine with 1:100,000 epinephrine	Healthy volunteer subjects	I = II	4
4% Articaine with 1:100,000 epinephrine	2% Lidocaine with 1:100,000 epinephrine	Healthy volunteer subjects	I = II	71
4% Articaine with 1:100,000 epinephrine	2% Lidocaine with 1:100,000 epinephrine	Irreversible pulpitis	I = II	72
4% Articaine with 1:100,000 epinephrine	4% Articaine with 1:200,000 epinephrine	Healthy volunteer subjects	I = II	73

activity and only 25% β activity, making it seem more attractive than epinephrine (50% α activity and 50% β activity).⁵⁰ However, levonordefrin is marketed as a 1:20,000 concentration in dental cartridges.⁵⁰ Clinically, the higher concentration of levonordefrin makes it equipotent to epinephrine in clinical and systemic effects.^{4,51} Therefore, 1:20,000 levonordefrin offers no clinical advantage over 1:100,000 epinephrine.

Articaine is available in the United States as a 4% solution containing 1:100,000 and 1:200,000 epinephrine.⁵² Articaine is an amide anesthetic that contains a thiophene ring and an ester linkage unlike other amide local anesthetics.⁵² The extra ester linkage is susceptible to hydrolysis by plasma esterases.⁵² Several studies have reported that articaine is safe when used in appropriate doses.^{52–60} Although lidocaine and articaine have the same maximum 500 mg dose for the adult patient,⁵⁰ the manufacturer's recommended maximum dose for a healthy 70 kg adult would be 7 cartridges of 4% articaine solution compared to 13 cartridges of 2% lidocaine solution.⁵⁰ Articaine, like prilocaine, has the potential to cause methemoglobinemia and neuropathies.⁵² While the incidence of methemoglobinemia is rare, dentists should be aware of this complication in patients who are at an increased risk of developing this condition.⁶¹ The incidence of neuropathies (involving the lip and/or the tongue), associated with articaine and prilocaine, is approximately five times more than that found with either lidocaine or mepivacaine.^{62,63} In one retrospective study, the incidence of paresthesia was approximately one in 785,000 injections.⁶² Therefore, while the paresthesia incidence is statistically higher for articaine and prilocaine, it is a clinically rare event that nevertheless imposes some medicolegal implications. Available literature indicates that articaine is equally effective when statistically compared to other local anesthetics,^{60,64–71} with relatively few studies demonstrating a statistical superiority of articaine over lidocaine for nerve blocks. Recent

studies have reported that articaine was significantly better than lidocaine for anesthesia after buccal infiltration of the mandibular first molar, with articaine producing a success rate of about 64 to 87%.^{72,73}

Long-acting local anesthetics, including bupivacaine and etidocaine, have been advocated for *prolonged* pain control, with support from several clinical trials.^{74–79} Recently, etidocaine has been withdrawn from the market by Dentsply Pharmaceuticals. Although bupivacaine exhibits sustained anesthesia and pain control, patients should be informed of prolonged soft tissue anesthesia (lip sign) since this may preclude their willingness to use this drug.⁷⁵ Bupivacaine has a somewhat slower onset than 2% lidocaine but almost twice the duration of pulpal anesthesia (approximately 4 hours) in the mandible⁴⁸ (Figure 2).

Ropivacaine is a structural homologue of bupivacaine that appears to have a lower potential for central

Figure 2 Time–response curve for the development of pulpal anesthesia (defined as no response on Analytical Technologies EPT at setting = 80) of mandibular first molars following inferior alveolar nerve (IAN) block injection of either 1.8 mL of 2% lidocaine with 1:100,000 epinephrine or 1.0 mL of 0.5% bupivacaine with 1:200,000 epinephrine. Data courtesy of Dr. A. Reader et al.

nervous system (CNS) and cardiovascular toxic effects.⁸⁰ Anesthesia from injection of 0.5% ropivacaine with 1:200,000 epinephrine was equivalent to 0.5% bupivacaine with 1:200,000 epinephrine. One study found that 0.5 and 0.75% concentrations of ropivacaine without epinephrine were effective for IAN blocks.⁸¹

IAN block injections are not always successful. As noted above, patients with preoperative pain are at risk for reduced rates of successful anesthesia. However, even in patients without pain, the IAN block injection is not always successful. Several hypotheses have been advanced for this lack of complete success.⁶⁹ First, the mylohyoid nerve has been suggested to provide accessory innervation that might contribute to the clinical failure of IAN block injections.^{82,83} However, clinical studies in which IAN block injections were compared to an IAN block as well as with mylohyoid nerve block failed to demonstrate any increase in anesthetic success. This led to the conclusion that the mylohyoid nerve is not a major contributor to failed IAN block injections.⁸⁴ Second, it is possible that inaccurate positioning of the needle might contribute to IAN block failures; however, confirming the needle position with either a medical ultrasound device⁴⁵ or radiographs^{85,86} failed to increase success rates of IAN injections. Third, it is possible that needle deflection might be a cause for IAN block failures.⁸⁷⁻⁸⁹ However, neither a bidirectional rotation method, using the Wand (CompuDent, Milestone Scientific Inc., Deerfield, IL),⁸⁹ nor insertion with the needle bevel oriented away from the mandibular ramus (so the needle would deflect toward the mandibular foramen)^{90,91} substantially improved anesthetic success. Fourth, it is possible that the contralateral IAN provides an accessory path for innervation. Cross-innervation occurs in mandibular incisors^{92,93} but likely does not contribute to most cases of IAN block failures. Fifth, it is very possible that anesthetic failure of mandibular anterior teeth might be due to the anatomical organization of the IAN where the “central core” of axons supplies the distal anterior teeth and the outer layer of axons supplies the posterior teeth.^{94,95} The well-described failure of the IAN block to anesthetize anterior teeth^{1-4,45-49,96} might be simply due to the lack of sufficient drug concentrations to block voltage-gated sodium channels (VGSC) in the central core axons. Of course, this hypothesis does not explain the failure to block posterior mandibular teeth. Collectively, these findings have prompted much research to increase the success of IAN nerve block injections.

Several procedures have been evaluated for increasing the rate of successful anesthesia of the IAN block. First,

increasing the volume of 2% lidocaine with epinephrine (from 1.8 to 3.6 mL) does not increase anesthetic success.^{1,49,84,97,98} Second, increasing epinephrine concentration (from 1:100,000 to 1:50,000) does not appear to increase anesthetic success in normal teeth.^{46,99} Third, hyaluronidase, an enzyme that reduces tissue viscosity¹⁰⁰ with favorable anesthetic enhancement properties,^{101,102} was not found to improve the success of lidocaine anesthesia in a recent double-blind, randomized clinical study.¹⁰³ Fourth, *carbonated* solutions are thought to trap the anesthetic within the nerve as well as impose a direct depressant action on nerves.³ Lidocaine hydrocarbonate, however, was no more effective for anesthetic success.³ Fifth, diphenhydramine, an antihistamine with reported local anesthetic properties,^{104,105} did not improve lidocaine anesthesia when injected as a combined solution.¹⁰⁶ Sixth, meperidine, an opioid analgesic with demonstrated anesthetic properties,¹⁰⁷ did not improve the success of lidocaine anesthesia after coinjection.^{107,108} Although these experimental approaches using pharmacological methods were not successful in improving IAN block anesthesia, other studies evaluating alternative methods of drug delivery proved more successful in addressing this problem.

Alternative or supplemental injections are indicated when IAN block is not successful. One alternative approach is to reduce the speed of injection for an IAN block. A slow IAN block injection (60 seconds) significantly increases anesthesia success rates (electric pulp testing), compared to a rapid injection (15 seconds).³⁰ There are three supplemental routes of injection that will be discussed in the following sections, “The intraligamentary injection,” “The intraosseous injection,” and “The intrapulpal injection.” They are included in the section under “Mandibular anesthesia” because this is the major, though not exclusive, area for their clinical application.

THE SUPPLEMENTAL INTRALIGAMENTARY INJECTION

The technique of intraligamentary anesthesia can be reviewed in other published papers or textbooks. Studies have reported that about 0.2 mL of solution is delivered with each mesial and distal injection using a traditional or pressure syringe, that different needle gauges (25, 27, or 30 gauge) are equally effective,^{109,110} and that standard syringes are as effective as special ligamental syringes.¹¹⁰⁻¹¹² Several studies have shown that the intraligamentary injection produces initial success rates of about 63 to 74% and that, if needed, reinjections produce an overall success rate of about 92 to

96%.^{11,110–113} The intraligamentary injection will not be successful in mandibular anterior teeth.^{114,115} This route of injection should be considered a type of intraosseous injection since the solutions are forced through the cribriform plate into the marrow spaces around the tooth^{116–120} and *not* via the PDL. Although back-pressure upon injection is the most important factor for anesthetic success,^{116,118} this simply reflects forces necessary to penetrate the cribriform plate and does not produce pressure anesthesia^{121,122} like the intrapulpal injection.^{123,124} The presence of a vasoconstrictor significantly increases the efficacy of intraligamentary injection,^{122,125–128} and anesthetic solutions with reduced vasoconstrictor concentrations (e.g., bupivacaine with 1:200,000 epinephrine) are not very effective with this technique.^{128,129} The onset of anesthesia is immediate^{110–112,114,121,122} and if anesthesia is still not adequate, reinjection is indicated. Since the duration of pulpal anesthesia in asymptomatic cases following the IAN nerve block plus supplemental intraligamentary injections is only about 23 minutes,¹¹³ the operator must work fairly quickly and be prepared to reinject if profound anesthesia is lost. Although it has been reported that the intraligamentary injection can be used in the differential diagnosis of pulpally involved teeth,^{130,131} experimental studies have demonstrated that adjacent teeth also become anesthetized with the intraligamentary injection of a single tooth.^{114,121,122} Therefore, the intraligamentary PDL injection should *not* be used for differential diagnosis.

Several studies have evaluated potential adverse effects that may occur with the intraligamentary route of injection. First, intraligamentary injections are more painful when anesthetizing teeth with irreversible pulpitis, as compared to normal teeth,^{5,111,114,122} and this may be due to the mechanical allodynia that often occurs in cases of irreversible pulpitis.¹³² The patient should be made aware of this possibility. Second, intraligamentary injections typically produce mild postinjection pain in the majority of patients for 14 to 72 hours after injection,^{111,114,122} and this would be additive to any postendodontic pain. Third, about 40% of the patients will report that their tooth feels high in occlusion.^{114,122} Fourth, although a letter to the editor reported avulsion of a tooth following intraligamentary injections,¹³³ no clinical or experimental study has reported avulsion or loosening of teeth with this technique,^{114,121,122} and therefore, avulsion should not be a concern when using the intraligamentary injection technique. Fifth, initial studies in dogs reported cardiovascular responses to intraligamentary injection of epinephrine-containing solutions¹³⁴; however, this has not been confirmed in clinical studies evaluating tachycar-

dia.^{135,136} Sixth, minor damage to the periodontium does occur, but only at the site of needle penetration and this subsequently undergoes repair in nearly all cases. In very rare instances, periodontal abscesses and deep pocket formation^{113,114} or root resorption^{137,138} have occurred after intraligamentary injections. Seventh, clinical and animal studies have shown no effect on the pulp following intraligamentary injections^{114,121,122,138–140} other than a rapid and prolonged decrease in pulpal blood flow caused by epinephrine.¹²⁷ No histological induction of pulpal inflammation has been observed in studies comparing restorative procedures to restorative procedures combined with intraligamentary injections.¹⁴¹ Therefore, intraligamentary injections are unlikely to cause pulpal necrosis. Eighth, the intraligamentary injection of primary teeth may cause enamel hypoplasia of the developing permanent teeth.¹⁴² However, the effect was not due to the injection itself but due to the anesthetic agents used. The same effect would seemingly be produced by an infiltration injection next to the developing tooth. Ninth, intraligamentary injection has been reported to be safe in the presence of mild to moderate gingival inflammation or incipient periodontitis.¹⁴³ Taken together, the intraligamentary route of injection provides a useful supplemental route for increasing anesthesia success with minimal adverse events reported in the great majority of studies.

A recent modification of the intraligamentary supplemental injection is the computer-assisted local anesthetic delivery system such as the Wand or CompuDent (CompuDent, Milestone Scientific Inc.) that accommodates a standard local anesthetic cartridge that is linked by sterile microtubing to a disposable, pen-like handpiece with a Luer-Lok needle attached to the end. The device is activated by a foot control that automates the infusion of local anesthetic solution at a controlled rate. A slow or fast flow rate may be initiated and maintained by a foot pedal control. A 1.4-mL aliquot of solution is delivered in 1 minute in the fast mode and in about 4 minutes and 45 seconds in the slow mode. The slow rate is used for the intraligamentary injection.

A recent study,¹⁴⁴ using experimental subjects, demonstrated that the Wand method of primary intraligamentary injection of 1.4 mL of 4% articaine with 1:100,000 epinephrine, versus injection of 1.4 mL of 2% lidocaine with 1:100,000 epinephrine, produced similar rates of successful anesthesia of the mandibular first molar (86 versus 74%, respectively, using EPT). The duration of anesthesia (31–34 minutes) was much longer than that reported previously using a pressure syringe and 0.4 mL of a lidocaine solution

(10 minutes).¹¹⁴ Another study evaluated patients with irreversible pulpitis and a failed IAN block. Success of the intraligamentary injection (none or mild pain upon endodontic access or initial instrumentation) was obtained in only 56% of the patients.¹⁴⁵ The results were somewhat disappointing because the computer-controlled anesthetic delivery system should have been capable of delivering approximately 1.4 mL of anesthetic solution via intraligamentary injection by consistently maintaining a precise flow rate. Thus, other supplemental injection procedures may be indicated in patients with irreversible pulpitis.

INTRAOSSEROUS ANESTHESIA

A second route for supplemental injection is the intraosseous injection. There are three intraosseous systems in the commercial market, including the Stabident system (Fairfax Dental Inc., Miami, FL), the X-tip system (Dentsply, Tulsa, OK), the IntraFlow (IntraVantage, Plymouth, MN). However, to date, most published clinical trials have used either the Stabident or X-tip systems. The Stabident system is comprised of a slow-speed handpiece-driven perforator, a solid 27-gauge wire with a beveled end that, when activated, drills a small hole through the cortical plate. The anesthetic solution is delivered to the cancellous bone through the 27-gauge ultra-short injector needle placed into the hole made by the perforator; the modified nonbevel needle is recommended for ease of negotiation. The X-tip anesthesia delivery system consists of a special hollow needle that serves as the drill penetrating the cortical plate, whereupon it is separated and withdrawn. The guide sleeve is designed to accept a 27-gauge needle to inject the anesthetic solution and is removed after injection (Figure 3).

Several characteristics are similar among the studied intraosseous delivery systems. First, anesthetic success is improved following injection into a site distal rather than mesial to the selected tooth.^{19,51,146–152} The exception to this rule is the maxillary and mandibular second molars where the mesial site should be selected.^{19,51,146–152} Second, the onset of anesthesia is essentially immediate.^{19,51,146–153} Third, manufacturer's instructions locate the perforation site in attached gingival, where the cortical bone is often thinner and one can inject at a site equidistant between adjacent root structures. However, two studies have successfully used the X-tip system, with its guide sleeve design, in alveolar mucosa at a more apical location,^{19,148} providing a potential clinical advantage over

the Stabident system when apical injections are considered.

As described above, a regular IAN block often provides poor anesthetic success in patients with irreversible pulpitis (i.e., only 19 to 56% of patients report no/mild pain upon access).^{9–11,19,71,153} Thus, several studies have evaluated whether supplemental intraosseous injections improve anesthetic success after IAN nerve block in odontogenic pain patients.

Several studies have evaluated the Stabident system in patients with irreversible pulpitis in mandibular posterior molars after failed conventional IAN nerve block injections. In general, these trials have demonstrated that a Stabident injection of 2% lidocaine with 1:100,000 epinephrine produced 79% anesthetic success at a volume of 0.45 to 0.9mL¹⁸ and 91% success rate at an intraosseous injection volume of 1.8 mL.⁹ The intraosseous injection was more successful than the PDL injection,¹¹³ probably due to the greater amount of anesthetic solution delivered with the intraosseous injection. Other studies using a similar patient population and experimental design have demonstrated that supplemental intraosseous injection of 3% mepivacaine produced 80% success after one cartridge and 98% success following a second intraosseous injection.¹⁰ Another study demonstrated that a supplemental intraosseous injection of 1.8 mL of 4% articaine with 1:100,000 epinephrine was 87% successful after the failure of IAN blocks for posterior teeth diagnosed with irreversible pulpitis.¹⁵³ Two conclusions are evident from this analysis. First, a supplemental intraosseous injection after a failed IAN nerve block significantly improves anesthetic success. Second, it appears that an intraosseous injection of one cartridge of 3% mepivacaine plain may not be as efficacious as one cartridge of 2% lidocaine with 1:100,000 epinephrine. However, as noted below, an advantage of mepivacaine is that 3% mepivacaine does evoke the tachycardia typically observed with epinephrine-containing anesthetic solutions.

Parallel studies have evaluated the X-Tip system in patients with irreversible pulpitis in mandibular posterior molars after failed conventional IAN nerve block injections. In one study evaluating apical positioning of the perforator, the X-tip injection site was 3 to 7 mm apical to the mucogingival junction of the mandibular molar or premolar tooth, and 1.8 mL of 2% lidocaine with 1:100,000 epinephrine was administered.¹⁹ The authors reported that in the absence of the backflow of anesthetic solution into the oral cavity, the success rate was 82%, but that in the presence of a backflow, the success rate dropped to 18%.¹⁹

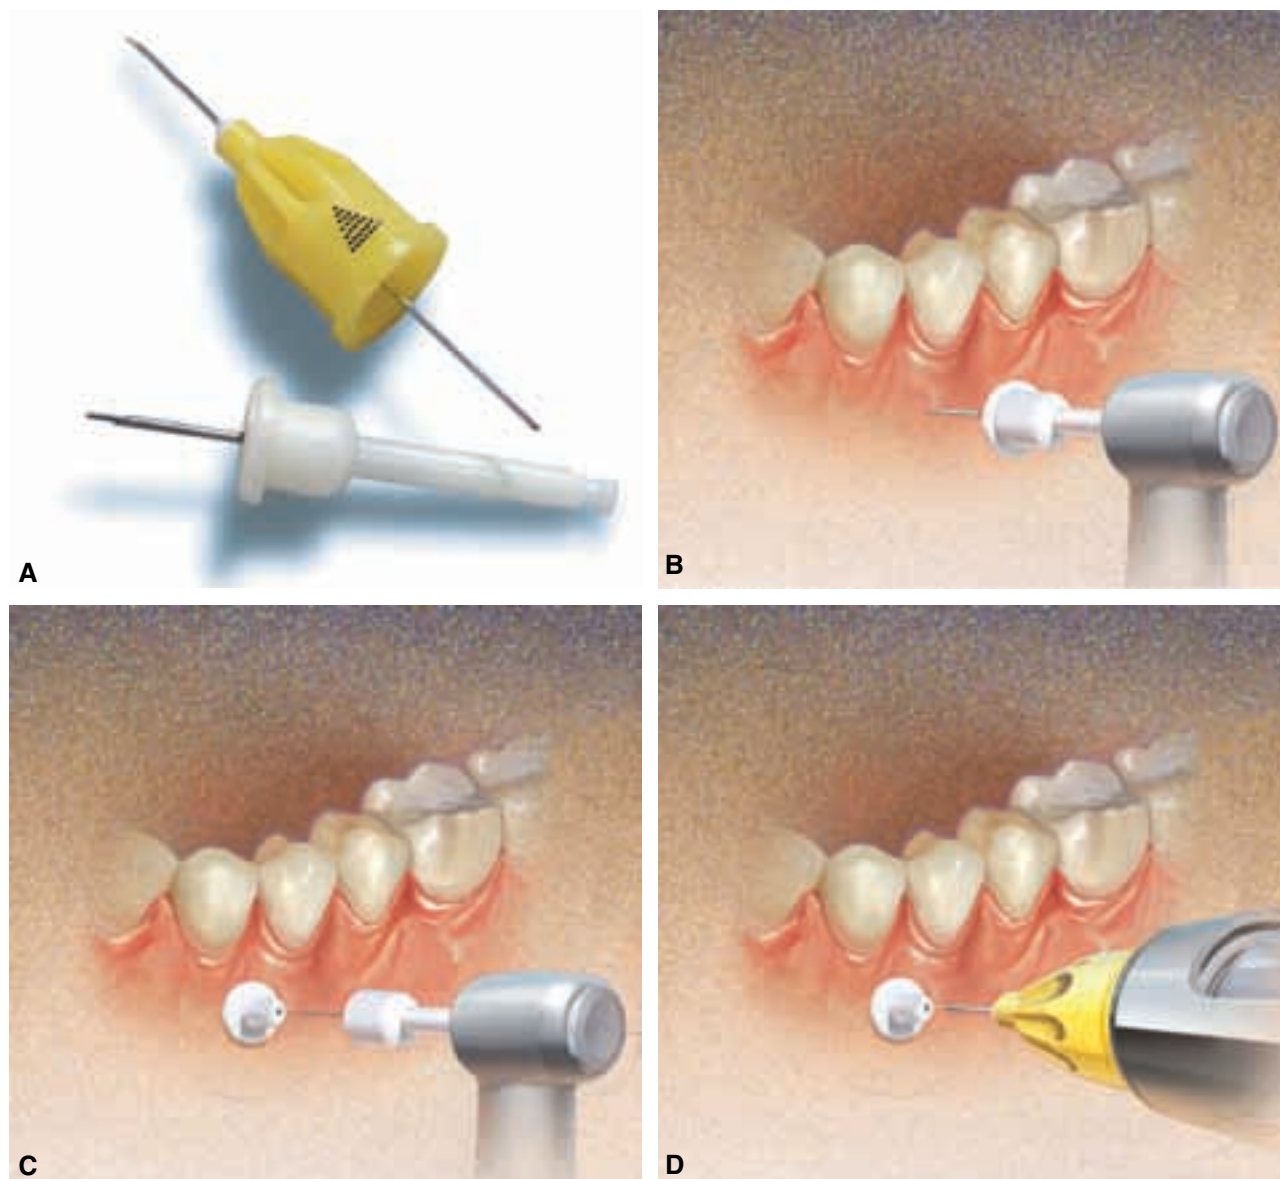

Figure 3 Intraosseous anesthesia delivery system X-tip. **A**, The X-tip system comes in two parts: the drill and the guide sleeve and special injection needle. First, anesthetize the mucobuccal fold and select a site 2 to 4 mm apical to the alveoli crest and between the roots. **B**, Place the X-tip drill in a slow-speed handpiece (15,000 to 20,000 rpm) and drill at maximum speed at 90° to the bone. In 2 to 4 seconds the drill will perforate the cortical bone into the cancellous bone. **C**, Hold the guide sleeve in place and withdraw the drill. **D**, Insert the special short needle into the hole in the guide sleeve and slowly inject a few drops of anesthetic solution. In the event, additional anesthesia is needed later; the guide sleeve can be left in place until the end of treatment.

Several clinical implications can be derived from these studies. First, given the relatively high failure rate of IAN blocks in patients with irreversible pulpitis, it would be prudent to consider using these combined methods in all patients with irreversible pulpitis. Second, anesthetic success requires deposition of the solution into the cancellous bone. If

backflow occurs, the clinician should consider reperi-
foration at the same or another site. A second intraosseous injection of 1.4 mL of 2% lidocaine with 1:100,000 epinephrine 30 minutes after the initial intraosseous injection provided an additional 15 to 20 minutes of pulpal anesthesia.¹⁵⁴ Third, in studies using either the Stabident or the X-tip system, the

duration of anesthesia was sufficient for the entire debridement appointment.^{9,19,153} Fourth, no clinical study has reported the anesthetic success rate or adverse events of supplemental intraosseous injection in painful teeth with necrotic pulps and periradicular radiolucencies. Therefore, no evidence-based clinical recommendations for necrotic cases can be made due to this lack of data. This is an area for future research.

Several studies have evaluated potential adverse effects that may occur with intraosseous injections. First, pain may occur during perforation and solution deposition when using the Stabident system, although the incidence of even a moderate transient pain is low in asymptomatic patients.^{146–151} In symptomatic teeth with irreversible pulpitis, the incidence of transient moderate–severe pain is about 0 to 16% during Stabident perforation and about 5 to 31% during injection of the anesthetic solution.^{9,10,153} For the X-tip system in patients with irreversible pulpitis, there is a 48% incidence of moderate to severe pain with perforation and a 27% incidence with injection of anesthetic.¹⁹ Second, it has been estimated that about 1% of perforators “separate” during use, requiring removal with a hemostat.^{19,146–151} Third, a transient tachycardia (12 to 32 bpm) can occur for about 4 minutes in 46 to 93% of patients after Stabident or X-tip intraosseous injection of epinephrine- and levonordefrin-containing solutions.^{9,19,51,146–150,152,153,155} No significant change in diastolic, systolic, or mean arterial blood pressure has been observed with the intraosseous injection of 2% lidocaine with 1:100,000 epinephrine.^{155,156} In one study, a slow intraosseous injection (over 4 minutes 45 seconds using a computer-assisted local anesthetic delivery system) was compared to a “fast” injection (45 seconds) of 2% lidocaine with 1:100,000 epinephrine. The slow infusion produced a significantly lowered magnitude of tachycardia (12 versus 25 bpm).¹⁵⁷ Although transient tachycardia is noticeable to the patient, it is thought to be not clinically significant in otherwise healthy patients.¹⁵⁵ Importantly, there is no significant increased tachycardia when 3% mepivacaine is used for intraosseous anesthesia.^{155,158} This represents an alternative approach for patients whose medical condition (moderate-to-severe cardiovascular disease) or drug therapies (patients taking tricyclic antidepressants or nonselective β -adrenergic blocking agents) suggest caution in administering epinephrine- or levonordefrin-containing solutions. Based upon these considerations, the intraosseous injection of 1.8 mL of 3% mepivacaine without a vasoconstrictor (e.g., 3% Carbocaine) could be recommended as a local anesthetic of first choice. This is not based on the potential cardiovascular risks associated

with a vasoconstrictor-containing anesthetic solutions, but instead is based on the avoidance of a transient tachycardia combined with its reasonably effective anesthesia.^{155,158} Fourth, the traditional long-acting local anesthetic (e.g., bupivacaine) did not demonstrate prolonged anesthesia after intraosseous or maxillary infiltration anesthesia.^{152,159–161} Given concerns about its potential for cardiotoxicity,¹⁶² bupivacaine should not be used for intraosseous anesthesia. Fifth, some authors have cautioned that administration of an overly large volume of local anesthetic with an intraosseous injection could lead to overdose reactions.¹⁶³ However, venous plasma levels of lidocaine were the same for maxillary anterior intraosseous and infiltration injections of 2% lidocaine with 1:100,000 epinephrine.¹⁶⁴ Therefore, the intraosseous technique should not be considered an intravascular injection. Sixth, about 2 to 15% of patients receiving Stabident injection have reported moderate pain on a postoperative day,^{51,146,149,150,155} although this is less than that reported after intraligamentary injection.¹²² Gallatin et al.¹⁶⁵ found that significantly more males experienced postoperative pain with the X-tip system than with the Stabident system. They felt that this was related to a denser and more mineralized bone in the posterior mandible in males and the fact that the X-tip perforating system diameter is larger than the Stabident perforator resulting in the generation of more frictional heat during perforation. Seventh, other postinjection problems can occur, including swelling and/or exudate at the site of perforations in <5% of patients after Stabident and possibly a slightly greater prevalence after X-tip injections.^{51,146,149,150,155,165} These slow-healing perforation sites may be due to overheating of the bone caused by pressure during perforation, warranting a slow gentle approach during perforation. To date, all such reported cases have healed without incidence.

THE INTRAPULPAL INJECTION

In about 5 to 10% of mandibular posterior teeth with irreversible pulpitis, supplemental intraosseous injections, even when repeated, do not produce profound anesthesia; pain persists when the pulp is entered. This is an indication for an intrapulpal injection. The advantage of the intrapulpal injection is that it works well for profound anesthesia if given under backpressure.^{123,124} Onset will be immediate and no special syringes or needles are required. The major drawback of the technique is that needle placement and injection are directly into a vital and very sensitive pulp; the injection may be moderately to severely painful and the patient should be warned of this potentiality.⁹

Maxillary Anesthesia

Descriptions of conventional techniques for maxillary anesthesia are available for review in numerous articles and textbooks. Clinically, maxillary anesthesia is more successful than mandibular anesthesia and the infiltration route is by far the dominant approach.¹² Numerous studies have demonstrated that infiltration injection of anesthetics such as 2% lidocaine with 1:100,000 epinephrine results in 90 to 95% successful pulpal anesthesia (obtaining an 80 reading) in anterior and posterior maxillary teeth.^{67,68,160,166–169} Although the onset of infiltration anesthesia usually occurs within 5 to 7 minutes, the duration is fairly short in both anterior (20 to 30 minutes) and posterior (30 to 45 minutes) maxillary teeth.^{160,166–169} This may require additional anesthetic injections depending on the length of the procedure. For maxillary infiltration injections, increasing the volume of 2% lidocaine with 1:100,000 epinephrine to 3.6 mL will increase the duration of pulpal anesthesia.¹⁶⁷ As with mandibular anesthesia, pulpal anesthesia does not last as long as soft tissue anesthesia.^{160,166–169} The infiltration injection of 4% prilocaine (1:200,000 epinephrine) is similar in action to an infiltration injection using 2% lidocaine (1:100,000 epinephrine).¹⁶⁹ In most,^{65–68} but not all,¹⁷⁰ studies, maxillary infiltration injections of articaine with 1:100,000 epinephrine were equivalent to both prilocaine and lidocaine with epinephrine. Although bupivacaine provides long-acting anesthesia in the mandible, it does not provide prolonged pulpal anesthesia in maxillary infiltration injections.^{80,159,160} The infiltration injection of anesthetics without vasoconstrictors, 3% mepivacaine plain and 4% prilocaine plain, produce a brief duration (15 to 20 minutes) of pulpal anesthesia and accordingly are generally used only for brief procedures.^{168,169}

Since many endodontic procedures are done on one tooth at a time, the infiltration route is most commonly employed. However, for the sake of completeness, major maxillary block injections that are effective for anesthetizing multiple teeth will be briefly reviewed. The posterior superior alveolar (PSA) nerve block anesthetizes some first molars, and all second and third molars.⁷ Generally, to ensure patient comfort for the first molar, an *additional buccal infiltration* injection after the PSA block may be needed. The *infraorbital nerve block* injection will anesthetize the first and second premolars and the lip, but not the central or lateral incisors.^{171,172} The *second division nerve block* will successfully anesthetize the pulps of molar teeth and about 50% of the second premolars.^{173,174} The high tuberosity approach is preferred over the greater palatine approach because the success rate is similar and it is less painful.¹⁷³ The *palatal-*

anterior superior alveolar (P-ASA) injection deposits the anesthetic solution into the incisive canal and derives its name from the injection's ability to supposedly anesthetize both the right and the left anterior superior alveolar nerves leading to bilateral anesthesia of maxillary incisors and canines.¹⁷⁵ However, needle insertion results in 54 to 58% of the subjects reporting moderate/severe pain following needle placement.^{34,176} The *anterior middle superior alveolar* (AMSA) injection is a new route for anesthetizing the maxillary central and lateral incisors, canines, and first and second premolars.^{177–179} The AMSA injection site is located palatally at a point that bisects the premolars and is approximately halfway between the midpalatine raphe and the crest of the free gingival margin. However, studies evaluating the AMSA route have reported rather modest to low success rates,^{180,181} and 32% to 38% incidence of moderate injection pain.³⁵

Non-Narcotic Analgesics: Nonsteroidal Anti-Inflammatory Analgesics and Acetaminophen

The major analgesic drug class for treating endodontic pain is the non-narcotic drugs, consisting of the non-steroidal anti-inflammatory analgesics (NSAIDs) and acetaminophen. The reader is referred to basic pharmacology texts for an overview of these drugs. The present review will instead focus on newer evidences and clinical implications from controlled clinical trials. The NSAID class of drugs are thought to produce their analgesic and anti-inflammatory effects by the inhibition of cyclooxygenase (COX).¹⁸² Other mechanisms such as inhibition of cell signaling molecules (e.g., NFκB) have also been proposed.¹⁸³ Two major isotypes of COX have been described,^{184,185} and NSAID drugs can be classified based upon their preference for blocking COX1 or COX2. NSAIDs such as ibuprofen should be considered “mixed COX” inhibitors since they can inhibit both enzymes at clinical dosages. Moreover, a recent study has reported that the analgesic efficacy of ibuprofen depends upon the genetic mutation of COX1, with patients having certain polymorphisms of COX1 displaying significantly better analgesic responses than patients having other polymorphisms.¹⁸⁶ If confirmed, then variations in patient responses to NSAIDs might be due to variations in the mutations on the gene encoding the COX1 enzyme. Blockade of COX1 is associated with increased risk for gastrointestinal side effects such as ulcers, whereas blockade of COX2 is associated with increased

Figure 4 Schematic illustration of the relationship between risk for adverse side effect profile of non-narcotic analgesics based on the relative inhibition of COX1 versus COX2. Adapted from FitzGerald GA.¹⁸⁷

cardiovascular risk such as thrombotic events.¹⁸⁷ Instead of a bimodal classification, the NSAIDs should be viewed as having an inhibitory continuum,¹⁸⁷ where drugs can have varying efficacy for inhibiting COX1 versus COX2, and accordingly would be expected to vary in their clinical side effect profile (Figure 4). Based upon findings demonstrating rapid upregulation of prothrombic enzymes¹⁸⁸ and cardiac events,^{189,190} it has been suggested that most patients would be best managed with the non-COX2-selective NSAIDs such as ibuprofen.¹⁹¹

Several systematic reviews have been published describing the efficacy and adverse effect profile of NSAIDs for treating both postsurgical pain^{192–194} and postendodontic pain.¹⁹⁵ In general, these studies have demonstrated that NSAIDs produce excellent analgesic responses in patients who can tolerate this class of drugs. For example, in a meta-analysis of >14,000 third molar patients,¹⁹² several NSAIDs were shown to produce a dose-related analgesic effect (defined as >50% pain relief). These data are summarized in Table 2. Since many clinicians were originally taught that acetaminophen/codeine combinations provide superior pain control, it is worth carefully reviewing these data. The lowest studied dose of ibuprofen (200 mg) actually has about the same analgesic response as acetaminophen 600 to 650 mg/codeine 60 mg. Moreover, the 400 mg and 600 mg doses of ibuprofen produce substantially greater levels of analgesia. Equally

Table 2 Meta-Analysis of Non-Narcotic Analgesics for Relief of Postoperative Pain

Drug	Percentage of Patients with $\geq 50\%$ pain relief	N (No. of patients)
Ibuprofen 200 mg	46	1,194
Ibuprofen 400 mg	56	3,402
Ibuprofen 600 mg	79	203
Diclofenac 50 mg	50	367
Diclofenac 100 mg	70	204
Acetaminophen 600–650 mg	36	1,265
Acetaminophen 600–650 mg plus codeine 60 mg	48	911
Placebo	-13	6,497

Data adapted from Barden J et al.¹⁹²

important, only the acetaminophen/codeine combination was associated with any significant increase in adverse effects.¹⁹² Fortunately, these findings mirror the responses of endodontists published in a recent survey¹⁹⁶ where non-narcotics, especially ibuprofen 600 mg, were dominantly selected for pain control over the acetaminophen/opiate combination drugs.

Other studies have evaluated the analgesic benefit of NSAIDs for treating pain after nonsurgical endodontic procedures.^{197–215} In general, the randomized placebo-controlled endodontic studies have demonstrated significant analgesic benefits for patients treated with flurbiprofen,²⁰² flurbiprofen/tramadol,¹⁹⁷ intracanal ketorolac,¹⁹⁸ IM ketorolac,²⁰⁸ intraoral ketorolac (in some,^{201,207} but not all²¹⁶ studies), piroxicam,²¹⁰ mefanamic acid,²¹¹ aspirin,²¹¹ diclofenac,²⁰⁹ ketoprofen (in some,^{199,209} but not all²⁰⁰ studies), ibuprofen,^{199,204} and ibuprofen/acetaminophen.²⁰⁴

Interestingly, ibuprofen 600 mg produced only a modest/moderate analgesic effect in several postendodontic studies.^{217–220} It is not clear if this modest analgesic effect reflects a non-COX pain mechanism in endodontic pain patients reflective of chronic inflammatory conditions (e.g., cytokines), or whether it represents a “floor effect” where nonsurgical root canal treatment by itself reduces pain to the extent that it is difficult to detect further reduction by the addition of an analgesic. This latter point has been observed in many endodontic trials where non-surgical root canal treatment (NS-RCT) plus a placebo pill resulted in a 50 to 80% pain reduction, 24 to 48 hours after treatment.^{197,199} However, the overall interpretation of these data provide strong support for the use of NSAIDs as a primary class of analgesics for treating acute inflammatory pain due to either surgical or nonsurgical procedures.

As noted in Chapter 10, “Mechanisms of Odontogenic and Non-Odontogenic Pain,” the VGSC play the dominant role in the signaling of nociceptor

activity from the periphery to the CNS. In particular, the TTX-resistant class of VGSCs expressed on nociceptors is relatively resistant to lidocaine and is sensitized by prostaglandins.^{16,221,222} One interpretation of these basic science findings is that NSAIDs would be expected to increase the effectiveness of local anesthetics by virtue of their ability to reduce prostaglandin levels in inflamed tissue. A preemptive approach to improve anesthesia in patients with irreversible pulpitis is to give ibuprofen 1 hour before anesthetic administration. A recent study²²³ evaluated ibuprofen given before local anesthetic injection in patients with irreversible pulpitis. It concluded that *it significantly improved the depth of anesthesia* using an EPT testing paradigm. Another study pretreated patients with either a placebo or with acetaminophen 650 mg or the combination of ibuprofen 600 mg with acetaminophen 650 mg. They concluded that the odds ratio for the *combination group* tended to favor successful anesthesia in the active groups as compared to the placebo.²²⁴ However, both of the studies have fairly small sample sizes, and further research is needed on this potentially important clinical finding.

Acetaminophen represents the second major member of the non-narcotic class of analgesics. Its utility is largely based on the finding that its side effect profile is less adverse than the NSAIDs, and that the drug can be used in patients for whom NSAIDs are contraindicated.²²⁵ Although acetaminophen has been used for nearly 100 years, its mechanism of action remains mostly unknown. Acetaminophen does inhibit peripheral COX activity in inflamed tissues but only at doses of about 1,000 mg.²²⁶ Recent studies have suggested additional mechanisms by which acetaminophen may act by metabolic conversion to a compound previously called AM404, which is a cannabinoid-like analgesic.²²⁷ Indeed, acetaminophen antinociception is reversed in mice by pretreatment with a cannabinoid receptor antagonist.²²⁸ However, other potential mechanisms have been proposed including modulation of the serotonin receptor 5HT1A.²²⁹

In humans, acetaminophen inhibits central sensitization under conditions that exclude a potential peripheral site of action,²³⁰ suggesting that this drug also has a CNS site of action. Interestingly, animal studies demonstrate that acetaminophen produces synergistic effects with a variety of NSAIDs (i.e., ibuprofen, diclofenac, ketoprofen, meloxicam, metamizol, naproxen, nimesulide, parecoxib, and piroxicam) using a mouse model of tissue hyperalgesia.²³¹ This finding appears to have clinical implications since acetaminophen/NSAID combinations appear to be very effective for pain control following surgical^{232,233} or endodontic²⁰⁴ procedures.

Steroids

Various classes of drugs have been studied for the management of endodontic posttreatment pain.¹⁹⁷ These include non-narcotic analgesics comprising NSAIDs and acetaminophen, opioids and glucocorticoids (steroids). This section will consider the use of glucocorticoids for the management of endodontic pain. For an in-depth description of the pharmacology, pharmacodynamics, mechanisms and sites of action, as well as their anti-inflammatory actions, the reader is directed to review articles.^{198,199,234–238}

The potent anti-inflammatory properties of glucocorticoids were first appreciated and utilized as an adjunct to endodontic therapy more than 50 years ago.^{239–241} Steroids have been used as a pulp-capping agent,²⁴² as an intracanal medicament either alone or in combination with antibiotics/antihistamines,^{198,240,241,243–247} and systemically^{199,248,234–236,239,249–253} as a means to decrease pain and inflammation in endodontic patients.

In critically evaluating the literature, it must be kept in mind that the most powerful conclusions are generated from studies that are prospective, randomized, double-blind, and placebo-controlled. However, none of the endodontic reports on the use of corticosteroids published prior to 1984 meets these criteria, and the results therefore should be considered as lower levels of evidence. Results from studies that used corticosteroids in combination with other agents (antibiotics and/or antihistamines) are also difficult to interpret, as results ascribed to one of the agents may reflect the activity of the combination.^{199,200} Equally difficult to interpret are results from studies using intracanal steroid delivery.^{198,240,241,243–247} The methodology in these studies cannot account for either the dosage or the delivery period of the intracanal medicament to reach the site of action (periapical tissues). In these studies, very small dosages of the steroid are placed into the canal(s). Even assuming apical patency of unknown size, the steroid must pass through the apical foramen via passive diffusion along a concentration gradient, and this may be opposed by a potential backpressure from periapical transudate or exudate. For a critical assessment of these studies, the reader is directed to review an article by Marshall.²³⁸ Studies evaluating the systemic administration of corticosteroid as the sole agent, in a known dose, are the critical ones in evaluating the efficacy of the steroid's ability to decrease endodontic posttreatment pain.

In a randomized, prospective, double-blind, placebo-controlled study, Marshall and Walton²³⁵ evaluated the effect of the intramuscular injection of dexamethasone on posttreatment endodontic pain when compared

to a placebo. After endodontic instrumentation and/or obturation, patients received an IM injection of 1.0 mL of either dexamethasone (4 mg/mL) or sterile saline. Pain levels of none, mild, moderate, or severe were recorded preoperatively at 4, 24, and 48 hours posttreatment. Teeth with vital and necrotic pulps as well as retreatment cases were included. No antibiotics were taken by the patients and no postoperative infections were reported. The amount of additional postoperative pain medication required was not recorded. Results indicated that dexamethasone significantly reduced both pain incidence and severity at 4 hours posttreatment. At 24 hours posttreatment, patients in the corticosteroid group showed a trend toward less pain.

Another double-blind study evaluated the effect of oral dexamethasone on posttreatment pain.²⁵² Fifty patients presenting for endodontic treatment were studied. Retreatment cases and patients presenting with purulent drainage or cellulitis were excluded. Teeth were instrumented and closed with no intracanal medication. Pretreatment, 8, and 24 hours posttreatment pain levels were recorded on a visual analog scale (0–100). Patients randomly received dexamethasone (0.75-mg tablet) or a placebo, with instructions to take three tablets immediately and then one tablet every 3 hours until bedtime for a total of seven tablets. Results showed that patients receiving dexamethasone had significantly less pain at 8 and 24 hours when compared to those receiving the placebo ($p < 0.01$)

A third study²⁵⁰ evaluated the effect of oral dexamethasone on endodontic interappointment pain, but at a much higher dosage than the preceding study.²⁵² Forty patients with “asymptomatic vital inflamed” pulps were evaluated. After endodontic instrumentation and temporization, alternate patients were given either dexamethasone (4 mg per tablet) or a placebo. Instructions were to take one tablet immediately and then one tablet at 4 and 8 hours posttreatment for a total dose of 12 mg in the dexamethasone group. Pain was recorded on a visual analog scale at 8, 24, and 48 hours posttreatment. Patients receiving dexamethasone had a statistically significant reduction in pain at all post treatment periods.

Liesinger et al.²³⁴ in a double-blind, randomized, prospective, placebo-controlled study evaluated the effect of four different dosages of dexamethasone on posttreatment endodontic pain. All patients ($N=106$) presented with pretreatment pain. Pulp status was recorded (vital and necrotic cases were included). Endodontic instrumentation and/or obturation was performed after which patients randomly received a 1.0-mL intraoral injection of either a placebo (sterile

saline) or dexamethasone (2, 4, 6, 8 mg/mL). The injection was given into the masseter, internal pterygoid, or buccinator muscle; preference was given to introoral muscles anesthetized for treatment. Patients recorded their pain levels on a 0 to 9 scale. Pretreatment and posttreatment (4, 8, 24, 48, and 72 hours) pain levels were recorded. The type and the amount of posttreatment analgesics taken were also recorded. No antibiotics were given at any time. Results showed patients receiving dexamethasone had significantly less severe pain at 4 and 8 hours postoperatively ($p < 0.05$) and took significantly less pain medication compared to the placebo (dexamethasone mean, 1.98 tablets; placebo mean, 4.64 tablets). When evaluated on a milligram per kilogram dosage basis, patients who received 0.07 to 0.09 mg/kg of IM dexamethasone had significantly less pain at 8 hours and required significantly less postoperative pain medication when compared to the IM placebo.

Kaufman et al.²⁵⁴ were the first to evaluate the effect of the *intraalimentary delivery* of dexamethasone on endodontic posttreatment pain. Forty-five patients were randomly assigned to one of three experimental groups. Endodontic treatment was completed in one appointment on both vital and necrotic pulps, with and without periapical radiolucencies. After the administration of local anesthesia, but prior to endodontic treatment, patients in Group 1 received 4 to 8 mg of slow-release methylprednisolone (Depo-Medrol) via an intraligamentary syringe. Single-rooted teeth received 4 mg, and multirooted teeth received 8 mg. Group 2 received a PDL injection of 3% mepivacaine in a similar fashion to Group 1. Patients in Group 3 received no PDL injection. Pretreatment pain levels were not recorded. Patients were telephoned at 24 hours posttreatment and reported their pain intensity on a 1–10 scale. The results showed a significant decrease in postoperative pain in the methylprednisolone group compared to the active and passive placebo groups ($p < 0.05$).

Gallatin et al.²⁴⁸ evaluated pain reduction in patients with untreated irreversible pulpitis using an intraosseous injection of methylprednisolone. Forty patients with a clinical diagnosis of irreversible pulpitis actively associated with moderate–severe pain participated in this prospective double-blind study. The involved tooth was anesthetized followed by an intraosseous injection of 1 mL of either methylprednisolone (Depo-Medrol 40 mg/mL) or saline. The blinded solutions were administered using the Stabident system (Fairfax Dental Inc.). No endodontic treatment was performed at this time. Patients were given a 7-day pain diary as well as analgesic medication. Over the 7-day

observation period, patients who received Depo-Medrol reported significantly less pain ($p < 0.05$) compared to a placebo while taking significantly fewer analgesics ($p < 0.05$).

Bramy et al.²³⁶ evaluated the intraosseous administration of corticosteroid for pain reduction in symptomatic necrotic teeth. Thirty-eight patients with a clinical diagnosis of pulpal necrosis with associated periapical radiolucency participated in the study. All patients experienced moderate–severe pain at the time of presentation with mild or no clinical swelling. After complete canal debridement, patients in a double-blind fashion randomly received an intraosseous injection of 1 mL of either methylprednisolone (Depo-Medrol 40 mg/mL) or sterile saline. All subjects received ibuprofen and Tylenol #3 (with codeine) and were instructed to take the medication as needed for pain. Patients recorded their pain levels and the type and amount of pain medications taken for 7 days postoperatively. The results showed that the steroid group had significantly less postoperative pain and took significantly less pain medication over the 7 days when compared to the placebo group ($p < 0.05$). No antibiotics were taken by patients at any time.

In a follow-up study, Claffey et al.²⁴⁹ evaluated pain reduction in symptomatic teeth with necrotic pulps using an oral dose regimen of methylprednisolone. The materials and methods were nearly identical to Bramy et al.²³⁶ except that no patient had clinical swelling, and after canal debridement, patients randomly received either oral methylprednisolone (48 mg/day for 3 days) or an oral placebo (lactose 48 mg/day for 3 days) in a double-blind fashion. All patients received ibuprofen and Tylenol #3 and a diary to record pain, percussion pain, swelling, and number and type of pain medication taken. Clinical success was defined as any patient who experienced only none–mild pain, none–mild percussion pain, none–mild swelling, and did not take any Tylenol #3. No antibiotics were prescribed or taken. The results showed that patients who received methylprednisolone had a significantly higher level of clinical success when compared to the placebo ($p < 0.05$).

Ouyang et al.²⁵³ evaluated the effect of submucosally injected dexamethasone on both the incidence and the severity of endodontic interappointment pain. Teeth with a diagnosis of asymptomatic pulpal necrosis were endodontically treated in one appointment. Eighty patients received a submucosal injection of 5 mg dexamethasone; the control group of 80 patients had endodontic treatment performed but no submucosal injection. Pain incidence and severity was evaluated for 3 days postoperatively.

Results indicated that the patients in the dexamethasone group had a statistically significant decreased incidence and severity of endodontic interappointment pain.

Prior to interpreting these studies,^{248,234–236,249–251,253} it is critical to remember that endodontic treatment has a major effect in reducing posttreatment pain regardless of pharmacologic intervention. As stated by Hargreaves,²⁵⁵ “This reduction in posttreatment pain, combined with variable levels of preoperative pain, reduces the statistical power of endodontic clinical trials for detecting active analgesics over time in all patient groups (the so-called floor effect). This limitation is a problem in interpreting clinical studies in general and may explain why some endodontic clinical trials fail to detect analgesic treatment or only detect it in those patients with moderate/severe pain.” This has been shown by Torabinejad et al.¹⁹⁹ and Rogers et al.¹⁹⁸ where various agents including corticosteroid significantly reduced posttreatment pain but only in those patients who presented for treatment with at least moderate/severe pretreatment pain. It would seem that the systemic administration of a corticosteroid to ameliorate endodontic posttreatment pain would be appropriate only for those patients who present with at least moderate levels of preoperative pain. Three independent studies^{234,236,249} meet the criteria of being prospective, randomized, double-blind, placebo-controlled with no drug combinations, and including patients who presented with the required level of pretreatment pain. Importantly, these studies showed that the systemic administration of corticosteroid not only significantly reduces posttreatment pain at various times but also significantly reduces the amount of additional pain medication required.

Interestingly, the reports by Bramy et al.²³⁶ and Claffey et al.²⁴⁹ show significant pain relief with the administration of a steroid for up to 7 days posttreatment, in contrast to Liesinger et al.²³⁴ who found significant differences in pain reduction only in the first 8 hours. It is possible that these findings are due to differences in dosages of different corticosteroids or due to the routes of administration. This is probably not the case, as dexamethasone is approximately five times as potent as methylprednisolone. The 6 to 8 mg intramuscular dosage used by Liesinger et al.²³⁴ would be equivalent to 30 to 40 mg of methylprednisolone. Intraosseous 40 mg of methylprednisolone was the dosage used by Bramy et al.²³⁶ It may be speculated that these differences in the duration of action might be related to differences in the preoperative pulpal and periapical status of the patient populations of these

studies. All of the patients in the studies by Bramey et al.²³⁶ and Claffey et al.²⁴⁹ presented for treatment with necrotic pulps, associated periapical radiolucencies, and either mild or no swelling. The majority of patients in the study by Liesinger et al.²³⁴ had a pre-operative diagnosis of irreversible pulpitis and acute apical periodontitis. Those patients with necrotic pulps had no associated periapical radiolucencies. It is plausible that corticosteroids may be more efficacious in attenuating the pain associated with pulpal necrosis and an associated radiolucency compared to pain associated with irreversible pulpitis. Necrosis/radiolucency is associated with a more complex chronic inflammatory process. Thus the efficacy of corticosteroids, in endodontic pain patients, may be related to variations in the periapical immunological/inflammatory dynamics of teeth with irreversibly inflamed pulps compared to necrotic pulps.

On the basis of the work of Bramey et al.²³⁶ and Claffey et al.,²⁴⁹ it is plausible that corticosteroids would have efficacy in cases of endodontic flare-up that result after treatment of previously asymptomatic teeth with necrotic pulps with or without associated periapical radiolucencies. This premise has not been investigated. The low incidence of this type of flare-up²⁵⁶ would require a multicenter study over a period of years to achieve an adequate sample size.

It appears that the route of systemic administration of a steroid is not a determinant in the efficacy of action.^{234,236,249} When given in equivalent dosages, agents such as dexamethasone and methylprednisolone appear to be interchangeable. If a systemic steroid is to be administered, an intraoral IM injection or an intraosseous injection would seem to be preferable over an extraoral IM injection. Clinicians are familiar with intraoral and intraosseous injections, and the site of injection is already anesthetized. Intraoral injection of steroid would be preferable to a written prescription for glucocorticoid as no assumption to patient compliance is required. An injection dosage of 6 to 8 mg of dexamethasone or 40 mg of methylprednisolone appears to be appropriate for the adult patient. If an oral route is chosen, 48 mg of methylprednisolone per day for 3 days and by extrapolation 10 to 12 mg of dexamethasone per day for 3 days should provide significant posttreatment pain relief.

It has been stated that antibiotics must be given in conjunction with steroids to prevent an infection secondary to a decrease in the inflammatory response.^{239,257–259} The implication is that suppression of inflammation also means a decrease in local defenses permitting unchecked proliferation of

pathogenic microorganisms. None of the studies published since 1984 supports this premise, including those cases with a diagnosis of pulpal necrosis with periapical radiolucency where the potential for dissemination of an infectious process might be expected.^{236,249} Antibiotics were not given or needed at any time during these studies nor were the steroids associated with any increase in infection rate compared to the control groups. It can be concluded that antibiotics are not routinely required or recommended in conjunction with corticosteroids for the management of endodontic posttreatment pain in the otherwise healthy patient.

Opioid Analgesics

Because opioids are not anti-inflammatory, nonopioids with anti-inflammatory efficacy (e.g., aspirin, ibuprofen) are the analgesics of first choice for endodontic pain.²⁶⁰ It has been shown that codeine in a 30 mg dose provides no more analgesia than a placebo.^{261,262} However, a 60 mg dose of codeine produces significantly more analgesia than a placebo. Thus, opioids in the appropriate dosage may be of benefit when additional pain control is needed. For example, if an NSAID is not controlling a patient's discomfort, an opioid combination such as acetaminophen/hydrocodone may be prescribed in addition to the NSAID. Opioids in combination with an NSAID produce additional analgesia beyond the ceiling effect of the NSAID. Opioid analgesics activate mu receptors that inhibit the transmission of nociceptive signals from the trigeminal nucleus to the higher brain centers and activate peripheral receptors to reduce pain.^{263,264} Although opioid analgesics may be effective for the relief of moderate to severe pain, their use is limited by adverse side effects that include nausea, vomiting, drowsiness, dizziness, constipation, and respiratory depression. In addition, chronic use is associated with tolerance and dependence. Because of the numerous side effects, opioids are usually used in combination with other analgesics to manage endodontic pain. Table 3 has a list of opioids

Table 3 Opioid Analgesic Combinations

Opioid Combination	Usual Dose
Acetaminophen (300 mg) and codeine (30 mg)	2 tablets q4h
Aspirin (325 mg) and codeine (30 mg)	2 tablets q4h
Acetaminophen (500 mg) and hydrocodone (5 mg)	1-2 tablets q6h
Acetaminophen (325/500 mg) and oxycodone (5 mg)	1 tablet q6h
Aspirin (325 mg) and oxycodone (5 mg)	1 tablet q6h
Ibuprofen (200 mg) and hydrocodone (7.5 mg)	1 tablet q6h

in combination with aspirin, acetaminophen, and ibuprofen that may be used to alleviate pain of endodontic origin. Clinicians must be aware of drug-seeking patients who request a specific opioid.

Conclusions

A thorough knowledge of the biological (Chapter 10, “Mechanisms of Odontogenic and Non-Odontogenic Pain”) and pharmacological aspects of odontogenic pain reveals several important conclusions that are summarized as follows:

- There is no single magic bullet for treating pain. Clinicians need to develop skills for differential diagnoses of pain disorders, delivering positive behavioral management strategies, identifying risk factors for postprocedural pain, effective intraosseous injection of local anesthetics (particularly in cases of painful mandibular teeth, especially irreversible pulpitis), using combinations of an NSAID with acetaminophen (in patients who can tolerate these drugs), delivering effective and appropriate dental treatment, and following up all patients to ensure their appropriate response.
- The intensity of preoperative pain is a useful predictor of post-endodontic pain,^{199,202,265} and this risk factor should be considered when developing the pain treatment plan before treatment commences.
- Preoperative pain in a mandibular tooth is a risk factor for anesthetic failure of IAN block injections. The best evidence to date, which balances efficacy with minimal adverse effects, would support treating patients with an irreversible pulpitis of a mandibular tooth first with an IAN block injection, followed immediately by an intraosseous injection of 3% mepivacaine. Little is known about benefits/risks of an intraosseous injection of symptomatic mandibular teeth with pulpal necrosis and periapical radiolucencies.
- Emerging clinical evidence provides qualitative support that a preoperative NSAID would be expected to enhance the magnitude of anesthesia, although additional research is needed.
- In patients who can tolerate the drug classes, there is strong preclinical and clinical trial data demonstrating that the combination of an NSAID with acetaminophen provides effective pain control in both postsurgical and postendodontic patients. One possible strategy to treat patients in moderate-to-severe pain would be to consider combinations of up to ibuprofen 600 mg and acetaminophen

1,000 mg, four times a day for no more than 2 to 3 days after the procedure. This combination of analgesics provides a useful alternative to the classical use of narcotic-containing analgesic drugs.

- It is our belief that the integration of high-quality clinical research findings together with the clinician’s own skills, the patient’s desires and the particulars of each case, represents the highest level of clinical care. From this perspective, this chapter represents an important contribution, but is only one source of information on the pharmacology of pain control. Clinicians must supplement this information and evaluate its application to any particular clinical case.

CHAPTER 23

ANXIETY AND FEAR IN THE ENDODONTIC PATIENT

STANLEY F. MALAMED

Fear and anxiety is far from being a uniquely endodontic problem; it is, however, a more significant problem within because of the commonplace nature of the patients' underlying problem: pain. Dentistry consistently appears in lists of our most common fears along with fear of heights, flying, mice, and public speaking.¹ Common dental fears include fear of the unknown, fear of pain, and, perhaps most commonly, fear of the "shot."

Studies over the years have evaluated the incidence of dental phobia (odontophobia) in the general population.²⁻⁴ They indicate that between 10 and 30% of the adult population suffer from moderately severe to extreme odontophobia. Chanpong et al.⁴ in a survey ($n = 1101$) of Canadian adults found 7.6% stating they had "missed, cancelled or avoided a dental appointment because of fear or anxiety." In response to the question "How would you assess your feelings towards having dental treatment done?", 5.5% assessed themselves as either "very afraid" (2.0%) or "terrified" (3.5%). In this "high fear" group, 49.2% had missed, cancelled, or avoided a dental appointment because of fear or anxiety compared with only 5.2% of the "low or no fear" group.

Enkling et al.⁵ reported that in 67% of odontophobic patients a prior painful dental or medical experience was the primary cause of their fear, followed by fear of needles (33%).

Dental fear is real and it hurts. For the patient, it is palpable. For the doctor and office staff, it stands as a barrier to the delivery of quality dental care. Within the realm of endodontics, many patients requiring treatment do so as a result of their extreme odontophobia. The first endodontic appointment, during which access will be gained and pulpal tissues removed, provides the greatest challenge to the

endodontist, confronted with a patient who is in pain and having possibly been in pain for several months, and who is fearful not just of the local anesthetic injection but of "root canal work" itself.

Other chapters have information on the management of endodontic infection (Chapter 20, "Treatment of Endodontic Infections, Cysts, and Flare-Ups") and endodontic pain (Chapter 10, "Mechanisms of Odontogenic and Nonodontogenic Pain") and pain of nonendodontic origin (Chapter 11, "Nonodontogenic Toothache and Chronic Head and Neck Pains").

Fear and pain are a potent combination capable of provoking some of the most catastrophic situations imaginable in the dental office, such as cardiac arrest. Surveying the incidence of medical emergencies in the dental environment, Malamed⁶ found that 54.9% occurred during the administration of the local anesthetic with an additional 22.0% occurring during dental treatment. When a medical emergency arose during dental treatment, 65.8% occurred either during extirpation of the pulp (26.9%) or extraction of the tooth (38.9%).⁷ Over three-quarters of medical emergencies seen in dentistry are stress-related. Potentially stress-related medical emergencies include syncope, angina pectoris, bronchospasm, seizures, hyperventilation, and the so-called "epinephrine reaction."

Recognition of Fear and Anxiety

Recognition of dental fear should not be left until the patient is seated in the dental chair. Quite often the receptionist is asked revealing questions by patients, such as "Is the doctor gentle?", "Does the doctor give good shots?" Patients in the reception area may converse amongst themselves, discussing their upcoming

treatment, perhaps in lurid ways. This invaluable information must be relayed to chair-side personnel who can now act to prevent a “problem” from developing.

Once seated in the dental chair, the patient’s fears usually become more obvious. Fearful patients simply do not “look” comfortable. Legs remain crossed and fingers clutch the armrest of the dental chair, the so-called “white-knuckle syndrome.” The patient closely watches everything, not wanting to be “snuck up on” by the doctor. Responses to questions are unusually prompt; speech is rapid. Perspiration may be observed on the patient’s forehead, upper lip, and perhaps underarms.

If any of the above is noted, it is important for the doctor to confront the patient, asking them “if anything about the upcoming procedure bothers them.” Once the patient admits to having fears and once the fears are out in the open, the “problem” should be manageable.

Management problems occurring during the local anesthetic administration can be almost entirely prevented by taking a patient’s “feelings” about receiving “shots” into consideration. Most people do not relish the thought of receiving intraoral local anesthetic injections as demonstrated by the high incidence of adverse reactions occurring at this time. Fifty-five percent of all medical emergencies reported by Malamed⁶ were fainting, and over 54% of all emergencies occurred during administration of the local anesthetic. Syncope accounted for 61.1% of dental office medical emergencies reported during a 1-year period in New Zealand.⁸

Fainting during injection is preventable by following a few simple steps aimed at making all local anesthetic injections as comfortable (atraumatic) as possible: (1) placing the patient about to receive an intraoral injection into a supine position *prior* to injection, (2) slow administration of the local anesthetic solution, and (3) use of sedation, if warranted, prior to the administration of the local anesthetic.

Management of Fear and Anxiety

The concept behind the successful use of sedation is that fearful patients are overly focused on everything that happens around them, and to them, in the dental environment. Administration of a central nervous system (CNS)-depressant drug lessens the patients’ awareness, moving their minds away from the dental chair. They no longer over-respond to stimulation. They no longer care about the procedure and, in effect, become more “normal” patients. Stated even more simply, sedation is about distraction.

DEFINITIONS

Sedation occurs as a result of depression of the CNS. Although various levels of CNS depression will be discussed, one is in fact dealing with a continuum, from the earliest manifestations of a drug’s action, *anxiolysis*, through the controlled loss of consciousness, *general anesthesia*. As most jurisdictions require a licensed dentist to obtain a permit before being allowed to administer CNS-depressant drugs via various routes and to varying levels of CNS depression, a number of dental (and medical) organizations have published guidelines for the safe and effective use of these drugs.^{9–11}

When describing, and defining, the various levels of CNS depression, the precise wording of the definition may vary slightly from state to state and organization to organization, but the essence of the definitions is the same. The reader is strongly advised to adhere to those definitions that have been established in the jurisdiction in which he/she is licensed. Until recently, the terms used to describe the levels of CNS depression were (in order of increasing levels of depression): *anxiolysis* → *conscious sedation* → *deep sedation* → *general anesthesia*. New definitions, first proposed by the American Society of Anesthesiologists, describe the degree of CNS depression ultimately achieved (Table 1).¹² The definitions that follow are taken from the American

Table 1 Continuum of Depth of Sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia

	Minimal Sedation (Anxiolysis)	Moderate Sedation/Analgesia (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful* response to verbal or tactile stimulation	Purposeful* response after repeated or painful stimulation	Unarousable, even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

*Source: American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists.¹²

Dental Association's (ADA's) Guidelines for the Use of Sedation and General Anesthesia by Dentists.¹¹

Minimal Sedation

Minimal sedation was previously associated with *anxiolysis*—a minimally depressed level of consciousness that retains the patient's ability to independently and continuously maintain an airway and respond appropriately to physical stimulation or verbal command, and that is produced by a pharmacologic or nonpharmacologic method or a combination thereof. Although cognitive function and coordination may be modestly impaired, ventilatory and cardiovascular functions are unaffected.^{11–12} In accord with this particular definition, the drug(s) and/or techniques used should carry a margin of safety wide enough to render unintended loss of consciousness unlikely. Furthermore, patients whose only response is a reflexive withdrawal from repeated painful stimuli would not be considered to be in a state of minimal sedation.

When the intent is minimal sedation for adults, the appropriate dosing of enteral drugs is no more than the maximum recommended dose of a single drug that can be prescribed for unmonitored home use.

Nitrous oxide/oxygen (N₂O–O₂) when used in combination with sedative agents may produce minimal, moderate, or deep sedation or general anesthesia.

The following definitions apply to administration of *minimal sedation*:

Maximum recommended therapeutic dose (MRTD): maximum FDA-recommended dose of a drug approved for unmonitored home use. *Incremental dosing*: administration of multiple doses of a drug until a desired effect is reached, but not to exceed the MRTD. *Titration*: administration of incremental doses of a drug until a desired effect is reached. Knowledge of each drug's time of onset, peak response, and duration of action is essential. Although the concept of titration of a drug to effect is critical, when the intent is minimal sedation, one must know whether the previous dose has taken full effect before administering an additional drug dose.

Moderate Sedation

This was previously associated with *conscious sedation*—a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually

maintained.^{11,12} In accord with this particular definition, the drugs and/or techniques used should carry a margin of safety wide enough to render unintended loss of consciousness unlikely. Repeated dosing of an agent before the effects of previous dosing can be fully appreciated may result in a greater alteration of the state of consciousness than is the intent of the dentist. Furthermore, a patient whose only response is a reflexive withdrawal from a painful stimulus is not considered to be in a state of moderate sedation.

Deep Sedation

This is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.^{11,12}

General Anesthesia

This is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.^{11,12} Because sedation and general anesthesia are a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to diagnose and manage the physiologic consequences (rescue) for patients whose level of sedation becomes deeper than initially intended.¹²

For all levels of sedation, the practitioner must have the training, skills, and equipment to identify and manage such an occurrence until either assistance arrives (emergency medical service) or the patient returns to the intended level of sedation without airway or cardiovascular complications.

REGULATION

Through the 1960s, upon receiving a dental degree and a license to practice dentistry, the dentists were allowed to administer any form of anesthesia (from local anesthesia to sedation to general anesthesia). No prohibitions, except for common sense, existed. As no formal training had been received in these techniques (aside from local anesthesia) in dental

school, most new doctors prudently avoided their use, managing fearful patients as best they could. Some, however, felt that they could easily administer anesthesia (in the broad sense) to their patients. Although some were successful, a large enough number became involved in serious untoward events, leading to death or severe neurologic damage, that governmental agencies (state dental boards and/or legislatures) began to seriously question whether dentists should be allowed to perform these techniques.

In the early 1970s, an Alaskan dentist had several deaths occur under halothane general anesthesia. As this dentist had little or no formal training in general anesthesia, Alaska became the first state to ban the administration of general anesthesia in the dental office. In 1974, in response to four patient deaths under general anesthesia in a short span of time in the office of an untrained dentist, Ohio became the first state to limit the use of general anesthesia to dentists who could prove adequate training, either through an oral surgery program or a 1-year anesthesiology residency¹³ (J. Weaver, personal communication, January 2006).

As of 21 December 2006, all 50 states have enacted regulation governing the administration of general anesthesia and deep sedation in dental offices.¹⁴ Deep sedation, by virtue of the fact that the patient's ventilatory status and ability to maintain an airway may be impaired, requires a level of training equal to that of general anesthesia. Education and training in general anesthesia requires a minimum of a 1-year or 2-year, full-time residency in anesthesiology.

Some dentists, untrained and now unable to administer general anesthesia, began administering CNS-depressant drugs parenterally, either intramuscularly or intravenously, as these techniques had not yet been regulated. Not surprisingly, a number of deaths occurred, as well as other serious morbidities over the ensuing years. And also, not surprisingly, legislative bodies began to regulate parenteral sedation. All 50 states now regulate the administration of parenteral conscious sedation.¹⁵ (Intranasal [IN] sedation, a relatively new approach to CNS-depressant drug administration in dentistry, is classified as a parenteral route of drug administration.)

The oral route, the least effective and least controllable common mode of drug delivery, had always enjoyed a somewhat limited use in dentistry. As other routes of drug delivery and levels of sedation encountered increased scrutiny and regulation, interest burgeoned in this, as yet, unregulated mode of drug administration.

Orally administered drugs had always been an important management technique within the specialty practice of pediatric dentistry, with chloral hydrate, hydroxyzine, and promethazine forming a triad of oft-used drugs. In 1985 the American Academy of Pediatric Dentistry developed guidelines for the use of sedation by pediatric dentists who received adequate clinical and didactic experience in this technique during their residencies. These guidelines have been reevaluated several times with the most recent version accepted and published in 2006.¹⁶

Unfortunately, some untrained nonpediatric dentists (e.g., general dentists), now unable to administer drugs parenterally, began using oral sedative drugs to achieve more profound levels of CNS depression, with predictable results: death and severe morbidity (e.g., brain damage). Legislation to require permits for oral conscious sedation (OCS) in children appeared in the late 1990s. Enacted in 2000, California's legislation requires a permit for OCS in patients less than 13 years of age.¹⁷ At present, 11 states require advanced education and awarding of a permit for a licensed dentist to administer OCS to a pediatric patient.¹⁵

OCS for adult dental patients had an increase in popularity in the mid-1990s, which continues today. Although many oral drugs are available, one, triazolam, has proven the most popular.^{18,19}

And now, for the first time, state dental boards have acted proactively rather than reactively, as in the past, enacting legislation mandating continuing dental education (CDE) and a permit to administer OCS to the adult dental patient. As of December 2006, 19 states have requirements for CDE and a permit for adult OCS.¹⁵

One route of drug administration has yet to be discussed: inhalation. In contrast to the oral route, the inhalation route represents *the* most controllable technique of drug administration. In dentistry in the United States, the combination of N₂O and O₂ is available and used, with varying frequency, in approximately 35% of dental offices.²⁰ The ADA, in concert with manufacturers of inhalation sedation units, mandated the inclusion of safety features into these machines. The goal of these safety features is to make it close to impossible the administration of levels of O₂ less than 21% (ambient air) to a patient.²¹ Deaths and serious morbidity associated with N₂O–O₂ inhalation sedation in dentistry have not occurred in recent years due primarily to the addition of these safety features and the requirement of the ADA's Commission on Dental Accreditation that all graduating dental students be trained to proficiency in inhalation sedation.²² As of December 2006, only a handful of states require a permit for the use of inhalation sedation.

SEDATION: NONDRUG TECHNIQUES (IATROSEDATION)

Management of a patient's dental fear begins as soon as the patient enters the office. The environment, the ambiance of the office, establishes a mood either of quiet relaxation or of a hurried, frenetic pace. The dental staff should be alert to any tell-tale signs of dental fear and, if noted, report it to the dentist immediately. "Forewarned is forearmed." Relaxation of a patient by the doctor's behavior has been termed *iatrosedation*, a term formulated by Dr. Nathan Friedman, for many years chairman of the Section of Human Behavior at the University of Southern California, School of Dentistry.²³ The word is derived from the Greek prefix *iatro*, "pertaining to the doctor," and *sedation*, "the relief of anxiety."

The concept on which iatrosedation is based is rather basic: that the behavior of the doctor and staff has a profound influence on the behavior of the patient. Other terms applied to this concept include suggestion, chairside/bedside manner, and the laying on of hands. The underlying premise of all these techniques is similar: that one can use nonchemical means to aid in relaxing the patient. For a more in-depth discussion of nondrug techniques of sedation, the reader is referred to *Sedation: a guide to patient management*.²⁴ Examples of iatrosedative techniques include hypnosis, acupuncture, audioanalgesia, and biofeedback.

Iatrosedation forms the building block for all sedation techniques requiring drug administration. Simply put, a patient who remains fearful, perhaps with distrust of the doctor, is less likely to "allow" their CNS-depressant drug to work. Although true for all routes of drug administration, it is especially relevant with the oral and inhalation routes.

Consider the patients' frame of mind in the dental office: afraid that something/everything is going to be painful. Their dentist is telling them, nonverbally, to "trust me." "Allow me, a stranger, to give you a drug that will decrease your level of consciousness so that you are less aware of what is happening around you." "I will take good care of you." The doctor who establishes a bond of trust with their patients will have them sit back in the dental chair and "let the drug work." Conversely, where the doctor-patient relationship is strained or uncomfortable, patients are much less likely to surrender to the clinical effects of the drug, not wanting to "lose control" of the situation. The level defined as minimal sedation is highly unlikely to succeed in this situation. Moderate sedation would have a somewhat greater success rate but still with a significant, perhaps unacceptably high, failure rate (Table 2).

Table 2 Efficacy of Sedation by Routes of Drug Administration

Technique Route	Titrate to Effect	Rapid Reversal	Expected Success Rate(%)
Intravenous	Yes	Yes*	90
Inhalation	Yes	Yes	80
Intramuscular	No	No	67
Intranasal			
Oral (adult)	No	No	50–60
Oral (child)	No	No	Older: 50–60 Younger: 35–40
General anesthesia†	Yes	Yes#	0

*Opioids, benzodiazepines.

†General anesthesia is *not* a sedation technique. It is included for comparative purposes only.

#Dependent on route of administration and drug.

SEDATION: DRUG TECHNIQUES (PHARMACSEDATION)

In dentistry, CNS-depressant drugs are administered by four routes: commonly by oral and inhalation, and less commonly by intravenous (IV) and intramuscular (IM). IN drug administration is a relatively recent addition to this armamentarium, primarily employed to provide moderate sedation in children.²⁵

The following is a brief overview of these routes of CNS-depressant drug administration in dentistry. It is not meant to substitute for a complete course in pharmacology or in the safe and effective technique of drug administration. The doctor wishing to administer drugs by any of these routes should check with their state Board of Dental Examiners for specific education and permit requirements for each technique or level of sedation.

INHALATION SEDATION (N₂O–O₂)

Inhalation sedation with N₂O–O₂ represents the most controllable technique of sedation available. Inhalation sedation possesses a number of compelling clinical properties that serve to increase its success rate and its safety, including (1) rapid onset of action (~20–30 seconds); (2) a level of CNS depression that can rapidly be increased, if necessary; (3) the level of CNS depression that can be rapidly decreased, if needed—a significant factor in increasing the safety of inhalation sedation; (4) complete recovery following the delivery of 100% O₂ at the conclusion of the procedure, permitting almost all N₂O–O₂ patients to be discharged from the dental office unescorted, and with no prohibitions on their postinhalation sedation

activities. No other route of drug administration offers this significant advantage. Because of its rapid onset, inhalation sedation with N_2O-O_2 may be titrated. The ability to titrate increases both the success and safety of the technique.

In order for a drug to be titrated, it must enter into the cardiovascular system rapidly. When possible, titration allows the doctor to individualize the dosage of the drug for each patient, negating the so-called “bell-shaped” or “normal distribution” curve.

The technique of inhalation sedation with N_2O-O_2 possesses very few significant disadvantages. One factor, common to it and several other techniques, is that of patient cooperation. The patient breathes the gasses through a small mask placed on the nose, the nasal hood. Uncooperative patients, usually odontophobic younger children, or any patient who is claustrophobic, might not allow the nasal hood to be placed, condemning the inhalation route to failure. Persons unable to breathe through their nose, for whatever reason, will be unable to receive inhalation sedation in a dental office. A recommended technique of administration of N_2O-O_2 is outlined in Table 3.

Inhalation sedation with N_2O-O_2 may be employed to provide minimum to moderate sedation. It may also be used, in conjunction with drugs administered by other routes, to supplement the CNS depression they provide. N_2O-O_2 when used in combination with sedative agents may produce minimal, moderate, or deep sedation or general anesthesia.¹¹

The use of N_2O-O_2 inhalation sedation in endodontics should become more common given the positive attributes of the technique. A common complaint from endodontists is that the nasal hood is in the way (Figure 1). Once experience is gained in the technique, this ceases to be a concern. Inhalation sedation with N_2O-O_2 has a success rate of approximately 80% in adult patients.

ORAL CONSCIOUS SEDATION

The oral route of drug administration is the least controllable route of drug administration. A number of factors work against an orally administered drug being effective, including a slow onset of action (~1 hour for most drugs); erratic absorption of the drug from the gastrointestinal (GI) tract; and, for some drugs, a significant hepatic first-pass effect. For these reasons, titration of the drug to clinical effect is not possible, eliminating the most important safety factor in drug administration.

Once administered, the level of CNS depression reached by oral drugs is not easily increased (providing deeper sedation) or decreased (lighter sedation).

Table 3 Technique of Administration of Inhalation Sedation with N_2O-O_2

1. Prior to placing nasal hood, start a flow of 5 to 6 LPM (liters per minute) of O_2 .
2. Have patient assist in proper placement and securing of the nasal hood.
3. Determine if patient can “breathe comfortably” with 100% oxygen (“Is the flow volume adequate?”). Increase the flow, if necessary.
4. Start titration of N_2O by increasing its flow to 1 LPM, decreasing the O_2 flow by 1 LPM.
5. After 1 minute determine what, if any, signs and symptoms the patient may be experiencing.
6. If needed, increase N_2O by 0.5 LPM, decreasing O_2 0.5 LPM.
7. Repeat steps 5 and 6 until the patient reaches the desired level of sedation.
8. Administer local anesthesia as would be done if the patient were not receiving N_2O-O_2 .
9. At the conclusion of the procedure, increase the O_2 flow to the level determined in step 3 and return the N_2O to 0 LPM.
10. Permit the patient to breathe 100% O_2 for not less than 3 to 5 minutes before considering removal of the nasal hood.
11. Assess recovery from sedation. If considered recovered, remove nasal hood before terminating the flow of O_2 .
12. Permit the patient to leave dental chair. Have a staff person close to the patient so as to prevent any possible injury when standing, due to postural hypotension.
13. Document treatment in the patient’s chart.

Figure 1 N_2O-O_2 nasal hood.

The duration of CNS depression from orally administered drugs greatly exceeds the typical length of the dental visit so these patients will always require an escort on being discharged from the office. This escort

should be a responsible adult who has a vested interest in the health and safety of the patient.

The only advantages associated with the oral route of drug administration are that it is easier for both the doctor and the patient.

Having just described a technique that seems quite mediocre compared with other routes of administration, it must be stated that there is a legitimate place for orally administered CNS depressants in dentistry.

Odontophobic patients, especially when faced with the fear of root canal treatment, frequently require management with CNS depressants (1) the night prior to the planned appointment, in order for the patient to experience a restful night's sleep, and (2) in the morning, 1 hour prior to the scheduled dental visit, to assist them in overcoming any last minute increase in their anxiety.

In the absence of other sedation techniques in a dental office, the oral route may also be used for intra-operative sedation. However, owing to the lack of control maintained over this technique by the doctor, the goal in administering oral CNS depressants should be limited to minimal to moderate CNS depression.

Many excellent oral preparations are currently available for administration. Table 4 presents some commonly used drugs and their recommended dosages.^{26,27}

When used alone, and in recommended dosages, orally administered drugs will have only an approximately 50 to 60% success rate with adult patients. This success rate is even lower in younger children.

INTRAVENOUS CONSCIOUS SEDATION

CNS-depressant drugs administered intravenously in the dorsum of the hand reach the brain in approximately 20 seconds. With this rapid onset, IV drug administration allows patients to be titrated to a desired level of CNS depression, thereby increasing control over the effect of the administered drug and, ultimately, the safety of the technique. Other advantages of IV drug administration include the ability to rapidly increase the level of sedation, if needed, and the reversibility of many intravenously administered drugs (benzodiazepines and opioids).

Disadvantages associated with intravenously administered CNS depressants include the requirement of

Table 4 Common Orally Administered CNS Depressants

Generic Name	Proprietary Name	Availability (mg)	Usual Dental Dosage
Benzodiazepines			
Alprazolam	Niravam, Xanax	Tab: 0.25, 0.5, 1.0, 2.0	0.25–0.5 (max 4 mg/day)
Diazepam	Valium	Tab: 2, 5, 10	2–10 mg bid-qid
Flurazepam	Dalmane	Cap: 15, 30	15–30 mg at bedtime
Lorazepam	Ativan	0.5, 1.0, 2.0	2–3 mg/day given bid-tid
Midazolam	Versed	Syr: 2 mg/mL	Pediatrics: 0.25–1.0 mg/kg single dose
Oxazepam	Serax	Cap: 10, 15, 30 Tab: 15	Adults (Anxiety): mild to moderate: severe: 15–30 tid-qid
Triazolam	Halcion	Tab: 0.125, 0.25	0.25 qhs, max 0.5
Miscellaneous, non-benzodiazepine anxiolytics, sedatives			
Eszopiclone	Lunesta	Tab: 1.0, 2.0, 3.0	Initial: 2mg qhs

fasting prior to the procedure (NPO status); an inability to quickly lessen the level of CNS depression; an inability to reverse the clinical actions of some drugs (e.g., barbiturates); and prolonged clinical recovery with an attendant need for an adult escort for the patient when discharged from the dental office.

Venipuncture is a learned skill and, though normally quite easy to achieve, represents the most difficult part of the entire IV sedation procedure. Once venous access is obtained, titration to the desired level of CNS depression is normally accomplished easily.

Many CNS-depressant drugs are available for IV administration, but those most often employed are the benzodiazepines, midazolam (Versed), and diazepam (Valium).

State requirements for a permit to employ IV conscious sedation (also termed “parenteral sedation” or “moderate sedation”) most often mandate 60 hours of didactics and either 10 or 20 cases of IV sedation administered by the doctor in a supervised environment.¹⁵ Variation may exist from jurisdiction to jurisdiction, so it is strongly advised that specific state dental board regulations be consulted.

Basic IV sedation techniques have evolved over the past three decades. The combination of pentobarbital (Nembutal), meperidine (Demerol), and scopolamine represented the original IV technique introduced in the 1950s by Dr. Neils Björn Jörgensen at Loma Linda University.²⁸ As described by Jörgensen, the drugs were injected directly into the vein via the syringe that was then removed.²⁹ The Jörgensen technique provided a duration of CNS depression of approximately 2 hours, a function of the barbiturate, a pentobarbital. With the introduction in the early 1960s of the benzodiazepine diazepam, a shorter duration of CNS depression became possible.³⁰ An additional benefit of diazepam was a brief period (approximately 10 minutes) of retrograde amnesia, permitting potentially traumatic procedures to be done with a likelihood of the patient not having any recall. For the patient this meant, in essence, that the fearful event (e.g., local anesthetic injection) never happened.

IV conscious sedation with a benzodiazepine has become the most popular technique in dentistry. IV benzodiazepine sedation meets the needs of contemporary dental practice, that is, sedation for approximately 1 hour. Introduced in the United States in 1986, midazolam (Versed) has now supplanted diazepam (Valium) as the most used IV benzodiazepine in the area of 1-hour IV conscious sedation. Midazolam,

unlike diazepam, is water soluble, thus capable of being administered intramuscularly and intranasally (see following discussions of these techniques). The amnestic properties of midazolam are considerably greater than diazepam’s, providing lack of recall for most, if not all, of the dental appointment. Clinical sedation, however, from the dentist’s perspective, is not quite as good with midazolam compared with diazepam. Both drugs, with one titrating dose, provide the doctor with approximately 1 hour of working time.

Direct injection of a drug into a vein, followed by removal of the syringe at the start of the dental procedure, gave way to the continuous IV infusion, in which venous access is maintained for the duration of the procedure. Initially, winged needles, also known as “scalp vein” and “butterfly needles,” were used (Figure 2). Easy to insert, the winged needle has the disturbing propensity to perforate the vein during the dental procedure, leading to loss of venous access and formation of a hematoma. In recent years, the indwelling catheter has become increasing popular.

Figure 2 IV needles.

Figure 3 Indwelling catheter.

Once inserted and secured in a vein, the 3'' plastic catheter is unlikely to accidentally become dislodged (Figure 3).

Opioids, specifically the short-acting fentanyl, have also been used in IV conscious sedation with increased frequency. When the primary goal of IV drug administration is management of fear, there is usually little or no need for opioid administration. Indeed, in the vast majority of successful IV sedation cases, the only drug(s) administered are either midazolam and/or diazepam. However, in situations in which surgery or other dental procedures that may prove painful are planned, or in which successful pain control may not be easily achieved with local anesthesia alone, opioid administration may be justified.

When administered carefully via titration, success rates of 90% may be achieved with IV sedation. The IV route can be used to achieve moderate and deep sedation, as well as general anesthesia.

INTRAMUSCULAR

IM, like IV, is a parenteral route of administration, in which the drug by-passes the GI tract, being absorbed directly into the systemic (venous) circulation. The hepatic first-pass effect is negated, leading to more reliable absorption and more rapid onset of action (~10–20 minutes) than with enterally administered drugs. However, titration is not possible, as the onset is not rapid enough, thus denying the IM route a

major safety benefit and thereby limiting its indications for use in sedation in dentistry.

Doses of IM drugs are primarily determined on a weight (e.g., mg/kg) basis. Given the appropriate dosage, approximately 70% of patients should be CNS depressed to the desired level of sedation. However, another 15% will likely be undersedated with that same dose, whereas the remaining 15% are CNS depressed to a level beyond that which is being sought. This latter group, hyperresponders to the drug, may be CNS depressed to a level beyond which the doctor is able to safely manage them. For example, an IM drug is administered to a patient to achieve a level of moderate sedation (formerly termed “conscious sedation”). However, the resultant level of CNS depression is deep sedation. At this level, patients are unable to adequately maintain their airway without assistance (e.g., head-tilt, chin-lift). Dental care would, of course, need to be postponed as the doctor is required to “rescue” patients from this unintended level of CNS depression. Airway management and, possibly, ventilatory assistance are continued until the level of CNS depression lightens, a process that could require several hours.

Along with the inability to titrate IM drugs, it is also not possible to rapidly lessen or deepen the level of sedation. Reversal of intramuscularly administered drugs, if possible, by intravenously administered flumazenil or naloxone, would be somewhat successful for a period of time. However, as a reservoir of the IM drug exists within the muscle into which it was injected previously, the drug will continue to be absorbed over several hours leading to the likelihood of a rebound sedation effect occurring as the action of the intravenously administered reversal agent diminishes. IM administration of the reversal agent is generally not recommended as its onset, 10 to 20 minutes, is too slow to provide any immediate relief in the event of oversedation. Additionally, the degree of the intramuscularly administered reversal agent’s effectiveness would be less than that seen following its administration IV.

IM drugs are not as controllable as intravenously administered drugs. Sedation should therefore be limited to a moderate level, with the doctor trained to recognize and manage (e.g., rescue) the patients should they inadvertently enter deep sedation. Patients receiving IM drugs for sedation must also maintain NPO status prior to sedation.

Recovery from IM drugs is prolonged; thus, the patient must have an adult escort when being discharged from the office. This being said, it would seem that IM drugs have few indications in dentistry. However, used judiciously by the doctor trained in parenteral conscious sedation (IV, IM, IN), the technique

can be employed with a likelihood of success of about 67%. Midazolam is the most commonly employed IM CNS-depressant drug in conscious sedation.

INTRANASAL

The IN administration of CNS-depressant drugs is relatively new within medicine and dentistry, though it has been used for many years by drug abusers (e.g., cocaine) and for the administration of nasal decongestants.

Nasal mucosa is highly vascular; therefore, absorption of drugs instilled into the nares is more rapid than for other routes of administration. Lam et al.²⁵ compared the efficacy, in children, of IN midazolam with that of its IM administration, finding the level of sedation to be comparable. IN midazolam has also been adopted in emergency medicine in the management of acute seizures in pediatric patients.³¹ Primosch³² compared nasal drops versus nasal spray as a technique of IN drug administration and found that although the effectiveness of conscious sedation was not influenced by the method of nasal administration, spray administration produced significantly less aversive behavior than administering drops in 2- to 3-year-old dental patients of similar behavioral characteristics.

Most studies and clinical usage of the IN route of drug administration appear in pediatrics, there being few reports of the use of this technique, and of its effectiveness, in adults, thereby limiting its utility in most endodontic cases.

The advantages of IN drug administration include its more rapid onset of action (compared with enteral routes) and the lack of need for injection and the accompanying trauma, both psychological and physical, associated with it.

Disadvantages of IN drug administration are similar to those of IM. IN drugs cannot be titrated. Dosages are based on weight (mg/kg). Along with the inability to titrate IN drugs, it is also not possible to rapidly lessen or deepen the level of the resultant CNS depression. Reversal of intranasally administered drugs, if possible, by intravenously administered flumazenil or naloxone, would be somewhat successful. IM or IN administration of a reversal agent is generally not recommended as its onset, 10 to 20 minutes, is too slow to provide any immediate relief in the event of oversedation. Additionally, the efficacy of an IM or IN reversal agent would be less than that seen with its IV administration.

IN drugs are not as controllable as intravenously administered drugs. The level of CNS depression sought should, therefore, be limited to moderate, with the doctor trained to recognize and manage (e.g., res-

cue) the patients should they enter into deep sedation. Patients receiving IN drugs for sedation must also maintain NPO status prior to sedation.

Recovery from IN drugs is prolonged, thus the requirement for an adult escort for the patient when discharged from the office.

Techniques of conscious sedation will enable the endodontist to manage the dental fears of the overwhelming majority of odontophobic patients. Table 6 illustrates the possible uses of the techniques of conscious sedation in endodontic practice. Unfortunately, not all fears can be successfully managed with conscious sedation techniques. For these few patients, general anesthesia is required.

GENERAL ANESTHESIA

General anesthesia is the controlled loss of consciousness, the final step in our continuum of CNS depression that started with minimal sedation. The success rates of the sedation techniques described above, along with the amnestic properties of some of the drugs employed, specifically the benzodiazepines midazolam and triazolam, has decreased the need for general anesthesia as a method of managing significant numbers of odontophobic patients.

All 50 states regulate the use of general anesthesia in dentistry.¹⁴ A residency in anesthesiology of either 1- or 2-year duration usually represents the educational requirement. As of November 2007, seven residencies in anesthesiology for dentists were accredited by the American Dental Board of Anesthesiology.³³

Doctors who have completed accredited residencies, dentist anesthesiologists, provide anesthesia services for other dentists either (1) by establishing a free-standing outpatient surgical center, in which the endodontist (or any other dentist) brings the odontophobic patient to the surgical center to carry out the scheduled procedures while the patient receives general anesthesia provided by the dentist anesthesiologist, or (2) by traveling to the office of the dentist who will be managing the dental needs of the fearful patient, wherein dentist anesthesiologists bring along all of their anesthesia drugs, equipment, and expertise.

Once general anesthesia has been induced by the dentist anesthesiologist, the dentist can then proceed with the endodontic procedure on a now more nearly "ideal" patient.

SUMMARY

Dental fears exist and are a fact of life, especially in the specialty of endodontics. The primary obstacles to successful endodontic treatment are the presence of dual

Table 5 Comparison of Routes of Drug Administration

Route of Drug Administration	Onset of Action	Titrate Yes–No	Advantages	Disadvantages
Inhalation	Rapid (~20 seconds)	Yes	Patient need not be NPO; rapid onset; titration; rapidly increase or decrease level of CNS depression; full recovery in most patients; no prohibitions of postoperative functions	Patient cooperation required; ineffective if unable to breathe through nose
Oral	Slow (~ 1 hour for maximal clinical effect)	No	Easy for patient; easy for doctor	Patient cooperation needed; slow onset; inability to titrate; erratic absorption from GI tract; significant hepatic 1st-pass effect for some drugs; no control over ultimate level of CNS depression; inability to quickly increase or decrease level of CNS depression; inability to reverse CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office
Parenteral: Intramuscular	Intermediate (10–20 minutes)	No	More reliable absorption than oral; minimal patient cooperation required	Patient must be NPO; potential needle injury; relatively slow onset; inability to titrate; no control over ultimate level of CNS depression; inability to quickly increase or decrease level of CNS depression; inability to reverse CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office
Parenteral: Intravenous	Rapid (~20 seconds)	Yes	Rapid onset; titration; rapidly increase level of CNS depression; most drugs reversible	Venipuncture is learned technique; patient must be NPO; inability to quickly decrease level of CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office
Parenteral: Intranasal	Intermediate (10–20 minutes)	No	More reliable absorption than oral; minimal patient cooperation required	Unpleasant (bitter) taste if liquid enters oral cavity; may irritate nasal mucosa; inability to titrate; no control over ultimate level of CNS depression; inability to quickly increase or decrease level of CNS depression; inability to reverse CNS depression; prolonged recovery; requirement for escort for patient on leaving dental office

Table 6 Techniques of Conscious Sedation—Summary

	Preoperative	Perioperative	Ability to Titrate	CNS Depression Level When Used Alone	CNS Depression Level Used in Combination
	Night prior to treatment	Morning of treatment			
Oral sedation	Yes	Yes	Yes	Min, mod	Min, mod, deep, GA
Inhalation			Yes	Mod	Mod, deep, GA
IV			Yes	Mod, deep, GA	Mod, deep, GA
IM/IN			Yes	Mod, deep, GA	Mod, deep, GA

Min = minimal sedation; Mod = moderate sedation; Deep = deep sedation; GA = general anesthesia.

problems: pain and fear. To ignore fear, in the best of circumstances, will complicate dental treatment unnecessarily, as the patient remains an unwilling participant throughout the procedure. Fear lowers the pain reaction threshold, with odontophobic patients being

unable to sit still during their treatment, adding to the frustration of the treating doctor. Fear increases catecholamine release into the cardiovascular system with a resultant rise in the incidence and severity of medical emergency situations.

The recognition of fear, and its management, removes the primary obstacle to the delivery of health care. Once fear is eliminated, clinically adequate pain control is normally accomplished quite readily. As Peter Milgrom wrote, "Deal with the fear first, then pain will be a minor problem."^{5,34}

CHAPTER 24

THE MEDICALLY COMPLEX ENDODONTIC PATIENT

BRADFORD R. JOHNSON, DENA J. FISCHER, JOEL B. EPSTEIN

One of the challenges faced by dental specialists today is in the assessment and management of patients with increasingly complex medical conditions. Not only has the average life expectancy increased dramatically over the past 50 years, but our geriatric patients are much more likely to be at least partially dentulous and have a complex medical history with multiple medical problems and the use of multiple medications.¹ Approximately 25% of patients aged 65 to 74 and 35% of patients aged 75 and older have a medical condition that would place them in the ASA (American Society of Anesthesiologists' Health Classification System) category III or IV (Figure 1).² An aging population with both the desire and resources to preserve their natural dentition will drive the demand for root canal therapy for patients with complex medical conditions. Even in a typical population of younger and presumably healthier patients, approximately 50% of patients referred to a dental specialty practice can be expected to report at least one positive finding on their health history questionnaire.^{1,3} Since medical complexity is often an indication for referral to a dental specialist,^{4,5} endodontists should be prepared to accurately evaluate medically complex patients and identify situations that require a modification of normal treatment procedures and identify oral and systemic conditions requiring diagnosis and management.

The purpose of this chapter is to serve as a brief overview of common medical conditions that require some modification of the treatment protocol to ensure safe endodontic treatment in an ambulatory dental setting. It is not intended as a substitute for case-specific clinical judgment or consultation with medical experts. For the purposes of this chapter, a medically complex patient will be defined as any patient requiring modification of the usual treatment procedure.

MEDICAL HISTORY AND PATIENT INTERVIEW

“Never Treat a Stranger” (Attributed to Sir William Osler)

The value of a thorough medical history and patient interview cannot be overemphasized. Recognition of a medical condition that requires treatment modification prior to treatment can avert significant treatment complications. Approximately 25 to 30% of patients seeking treatment in a dental office can be expected to report at least one medical condition that has potential relevance to dental treatment, although not all of these conditions will require treatment modification.^{6,7} An adverse outcome, due to failure to recognize a known risk factor and modify treatment accordingly, is a major predictor of a successful liability claim.⁸ Cardiovascular disease, drug allergies, diabetes, and concerns about the safety of vasoconstrictor use are some of the most common medical reasons for referral to a specialist.^{1,9,10} This is consistent with an analysis of the most common medical emergencies in the dental office: angina, hypoglycemia, adverse reaction to local anesthetics, and seizures.¹¹

A standard health history questionnaire should cover all common medical conditions (both treated and untreated), surgeries, hospitalizations, medications, and allergies. Although many standard forms are readily available and are usually convenient and easy to complete, most of these forms do not clearly lead to a specific determination of risk for dental treatment. More useful medical risk assessment models are under development and will be briefly discussed later in this section. The written health history questionnaire should always be supplemented with a patient interview to help decrease

ASA physical classification	Description	Therapy modifications (McCarthy and Malamed, 1979)
ASA 1	A normal healthy patient	None (stress reduction as indicated)
ASA 2	A patient with mild systemic disease	Possible stress reduction and other modifications as needed
ASA 3	A patient with a severe systemic disease that limits activity, but is not incapacitating	Possible strict modifications; stress reduction and medical consultation are priorities
ASA 4	A patient with an incapacitating systemic disease that is a constant threat to life	Minimal emergency care in office (may consist of pharmacologic management only); hospitalize for stressful elective treatment; medical consultation urged
ASA 5	A moribund patient who is not expected to survive without the operation	Treatment in the hospital is limited to life support only; for example, airway and hemorrhage management
ASA 6	A declared brain-dead patient whose organs are being removed for donor purposes	Not applicable

Figure 1 American Society of Anesthesiologists' (ASA) health classification system and suggested treatment modifications. Adapted from Tables 1 and 2, Goodchild J and Glick M.²⁷

false-positive and false-negative findings and to further explore positive findings.¹² The clinician should review any positive findings with the patient and determine the patient's level of compliance with medical treatment recommendations. For example, a compliant patient with well-managed hypertension presents a relatively low risk compared to a patient who refuses to take prescribed medications or does so erratically. Unfortunately, for a variety of reasons, the reliability of self-reported information in the health history may be less than ideal. Patients may simply forget to report important medical information, but it has also been shown that some patients will intentionally omit relevant information due to concerns over privacy or failure to understand how the information could be relevant to dental practice.^{13,14}

MEDICATIONS AND ALLERGIES

The list of medications and allergies should be consistent with the disclosed medical conditions and can

alert the clinician to unlisted medical conditions as well as potential drug interactions. Relevant medical conditions and severity of systemic disease can often be determined by a careful analysis of the patient's list of medications.¹⁵ Allergies to materials used in endodontic treatment are covered later in this chapter and drug interactions are covered in Chapter 25, "Drug Interactions and Laboratory Tests."

Herbs, dietary supplements, vitamins, and other over the counter medications can contribute to complications in the dental setting, although patients often fail to report the use of these substances in the initial evaluation.¹⁶ In a recent survey of surgical patients, approximately one-third reported the use of a nonprescription medication that could potentially inhibit coagulation or interact with anesthetics.¹⁷ In particular, *Ginkgo biloba*, ginger, garlic, ginseng, feverfew, and vitamin E all inhibit platelet aggregation and can increase the risk of bleeding.¹⁸ Ingredients in over-the-counter (OTC) weight loss

products can potentiate the effect of epinephrine and increase cardiac stress, although the most obvious example of this phenomenon, ephedra, has been removed from the US market by FDA order.

PREVIOUS DENTAL TREATMENT

A standard screening question for all patients should enquire about any problems with previous dental treatment. This line of questioning serves several important functions. First, it allows the patient to discuss any previous negative dental experiences as well as express possible anxiety related to the proposed treatment. A report of difficulty in achieving profound local anesthesia is a common finding, especially for root canal therapy. This provides an opportunity to demonstrate concern for your patient and discuss how you plan to avoid a repeat of the previous experience. Second, potential adverse reactions to dental materials or drugs may emerge in response to this question. Finally, since this question is designed at least in part to help develop rapport with your patient, it can serve as a good lead into other important but potentially more sensitive questions (e.g., use of oral contraceptives, history of human immunodeficiency virus (HIV))

PHYSICAL EXAM: VITAL SIGNS

In addition to the mandatory health history questionnaire and patient interview, vital signs (blood pressure, heart rate, respiratory rate, temperature, height, and weight) should be recorded prior to dental treatment whenever possible. In particular, blood pressure, heart rate, and respiratory rate provide the essential risk assessment baseline information for all patients. Temperature may be routinely recorded but is specifically indicated in the presence of infection or signs of generalized malaise or toxicity. Height and weight can usually be obtained from the patient or the guardian, and this information is particularly important in determining appropriate drug dosages in pediatric and geriatric patients and in assessing unexplained changes in weight.

RELATIVE STRESS OF THE PLANNED PROCEDURE AND BEHAVIORAL CONSIDERATIONS

A patient's ability to tolerate the stress of dental treatment depends on the procedure planned, time required to complete the procedure, physical health status, and psychological factors. Anticipation of a stressful dental procedure can increase the heart rate

and endogenous secretion of epinephrine in otherwise healthy adults.^{19,20} In fact, even anticipation of a routine dental checkup can result in increased blood pressure in some patients.²¹ Most changes in heart rate and blood pressure are within the normal physiological range, although more significant changes have been observed before administration of local anesthetic, during subgingival scaling and during extractions.²² Since there are no specific guidelines for assigning stress levels to various dental procedures, clinical judgment is essential in determining whether or not stress-reducing treatment modifications should be employed. Dental specialists, by virtue of additional training and experience, should be expected to provide treatment in a shorter time period and should be better prepared to manage perioperative complications than a general practitioner.

Endodontic treatment in general is often considered a high-stress dental visit, especially among patients with no prior endodontic treatment experience or patients who have had a previous negative experience with endodontic treatment. For many, the perception of the treatment often differs from the reality that most current endodontic treatment is minimally invasive, relatively comfortable, efficient and very well tolerated by the majority of patients when skillfully performed. In a study that measured salivary cortisol levels in patients undergoing a variety of dental procedures, root canal treatment was no different than a routine dental exam, prophylaxis, or restorative treatment, and only tooth extraction resulted in a significant increase in salivary cortisol.²³ Surgical root canal procedures, the presence of acute pain, self-reported dental anxiety, or difficulty with previous treatment, and lengthy procedures would all be expected to increase the level of stress.^{22,24} If any of these conditions are present in addition to significant systemic disease, treatment modification including a stress reduction protocol should be considered (see Chapter 23, "Anxiety and Fear in Endodontics").

PHYSICAL HEALTH STATUS

The American Society of Anesthesiologists' (ASA) Health Classification System is the most widely used system for assessing physical health status and helps to determine the potential need for medical consultation and treatment modifications prior to dental and medical procedures (see Figure 1). In general, ASA I status represents a healthy patient who does not require any treatment modification. An ASA II patient presents with well-controlled systemic

disease and usually will not require significant treatment modification, although stress reduction may be indicated. Patients in the ASA III category or above will almost always require medical consultation and possible treatment modifications. However, the ASA classification system has several significant limitations and should be used only as a general guide for determining peri- and postoperative risk. Even experienced anesthesiologists exhibit differences of opinion in the classification of cases.^{25,26} In addition, when used alone, the ASA system is not a good predictor of operative risk.²⁷ Various authors have proposed a medical risk assessment process that focuses more clearly on medical conditions specifically relevant to dental practice.^{2,6,27,28} Clinicians may want to consider health history questionnaires and verbal questions that focus primarily on medical conditions that would, when present, elevate the patient to ASA II status or above. That is, any positive response to one of the health history questions would automatically classify the patient as at least ASA II and further exploration would be necessary to determine the extent of systemic disease. de Jong et al.^{12,28,29} have developed and validated a patient questionnaire consisting of approximately 30 questions for use in assessing the risk for dental treatment.

MEDICAL CONSULTATIONS

Approximately one-third of patients referred for a medical consultation result in recommendations for some modification of treatment procedures.⁹ A request for consultation may occur by phone or letter and each approach has certain advantages and disadvantages. A phone conversation is immediate and may allow for the discovery of additional useful information. However, the lack of a written letter from the physician increases the risk for potential misunderstanding and provides a lower level of documentation from a medicolegal standpoint. The substance of all medical consultation conversations should be documented in the patient's record and, whenever possible, a letter detailing the physician's recommendations should be requested. A letter provides more formal documentation of the communication between health care providers.

When requesting a medical consultation, the clinician should be specific and concise. The medical condition in question should be identified and the nature of dental procedure planned should be described (e.g., a brief description of the procedure, the type of anesthetic planned, the potential for bleeding, the expected length of procedure). The clinician should specifically ask the physician if the patient's medical condition

requires any modification in the usual treatment protocol and, if so, what modifications are recommended. Since the ultimate responsibility for providing safe treatment rests with the dentist, any concerns about recommended treatment modifications should be resolved with the physician prior to treatment.

Assessing the Need for Treatment Modifications

MULTIDIMENSIONAL RISK ASSESSMENT MODEL (MD-RAM)

Systemic disease can result in the loss of reserve capacity to handle stress.¹⁵ A patient's ability to handle stress decreases in direct relation to the extent of systemic disease. The three primary components of risk assessment for dental treatment are physical health status (reserve capacity), emotional or psychological status, and type of dental procedure planned.³⁰ Lapointe et al.¹⁵ proposed a two-dimensional risk assessment model that correlated the severity of disease and procedural stress. However, this model presented only two specific medical conditions as examples (ischemic heart disease and chronic obstructive pulmonary disease (COPD)) and did not explicitly consider patient anxiety as a variable. Dental anxiety can increase sympathetic activity and for some patients can potentially precipitate a medical emergency.³¹

We propose a new model, the Multidimensional Risk Assessment Model (MD-RAM; Figures 2 and 3), that incorporates the three primary aspects of risk assessment into a unified approach for evaluating perioperative risk related to treatment for the ambulatory dental patient. In this model, the dental patient is assigned a score ranging from 1 to 4 in each of the three domains: physical health status (using the ASA classification system); procedural stress (type of procedure, length of time to complete the procedure, and clinician expertise—Figure 4); and psychological status (self-reported dental anxiety—Figure 5). As with any model, the output is only as good as the information input.

This model may provide a general guide for patient assessment and is not intended to be all inclusive or a substitute for case-specific clinical judgment. The primary purpose of this model is to assist clinicians in determining if treatment modification, often a stress reduction protocol, may be indicated prior to dental treatment. Disease-specific recommendations will be discussed later in the chapter.

MULTIDIMENSIONAL RISK ASSESSMENT MODULE (MD-RAM)

Figure 2 Multidimensional Risk Assessment Model (MD-RAM).

MD-RAM score	Interpretation
3-5	No treatment modification usually indicated
6-7	Possible medical consultation and treatment modification
8-9	Medical consultation often indicated and probable treatment modification
10-12	Medical consultation strongly advised; may require treatment in a hospital or specially equipped out-patient facility

Figure 3 Interpretation of MD-RAM score.

Procedural stress scale	Examples*
1	Denture adjustment; non-invasive oral exam; radiographs
2	Procedures requiring local anesthesia; prophylaxis with sub-gingival scaling; simple restorative procedures; uncomplicated non-surgical root canal treatment
3	Patients with acute pain and/or significant infection; extractions; surgical root canal; periodontal surgery
4	Bony impactions; trauma surgery

* = The clinician should consider possible upgrading if procedure is lengthy and move either up or down depending on clinician's experience.

Figure 4 Estimating procedural stress. Adapted in part from Lapointe HJ et al.¹⁵

Dental anxiety scale	Verbal descriptor
1	No anxiety
2	Mild anxiety
3	Moderate anxiety
4	Severe anxiety

Figure 5 Behavioral scale—patient's self-reported dental anxiety.

Cardiovascular Disease

HYPERTENSION

Hypertension is one of the most common medical conditions likely to be encountered in a dental office. Hypertensive patients are defined as those receiving treatment for hypertension or those with a mean systolic blood pressure (SBP) of 140 mg Hg or greater and/or a mean diastolic blood pressure (DBP) of 90 mg Hg or greater. By this definition, approximately 24% of the adult population of the United States is hypertensive with about half of this group untreated and only one-

quarter receiving successful treatment for hypertension.³² The goal for patients with diabetes or renal disease is to maintain blood pressure below SBP of 130 and DBP of 80. Since hypertension is typically asymptomatic, approximately one-third of patients with high blood pressure are unaware of their condition.³³ Even patients with normal blood pressure at the age of 55 to 65 years have an almost 90% risk of developing hypertension by the age of 80 to 85 years.³⁴ Patients with untreated or inadequately treated hypertension are at significantly increased risk for acute complications such as myocardial infarction (MI) and stroke and chronic complications of hypertension.

Classification	Systolic Blood Pressure (SBP) in mm Hg	Diastolic Blood Pressure (DBP) in mm Hg
Normal	< 120	and < 80
Prehypertension	120-139	or 80-89
Stage 1 Hypertension*	140-159	or 90-99
Stage 2 Hypertension	≥ 160	or ≤ 100

* For patients with diabetes or renal disease, the goal is to maintain blood pressure less than 130/80 mm Hg.

Figure 6 Blood pressure classification for adult patients. Adapted from Herman WW et al.³⁶

The clinical significance to the dental practitioner is clear—since at least 15% of all adult dental patients have either untreated or inadequately treated hypertension, initial blood pressure measurement is an essential screening tool prior to dental treatment. In addition, it is appropriate to measure blood pressure at least annually during recall visits for all patients and at every visit for patients when an invasive dental procedure is planned.

Guidelines for the classification of blood pressure were recently revised in the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7, 2003) (Figure 6). The JNC 7 report added a new category, prehypertension, for patients with SBP of 120 to 139 and/or DBP of 80 to 89 in recognition of the fact that this group was at greater risk for developing hypertension and should receive lifestyle modification advice and subsequent monitoring. The report also combined the previous Stage 2 and Stage 3 categories into a new Stage 2 category for patients with SBP greater than or equal to 160 and/or DBP greater than or equal to 100. From a practical standpoint, patients with well-controlled hypertension or SBP below 160 and DBP below 100 should tolerate all routine dental procedures,³⁵ although referral for evaluation by the patient's physician is appropriate due to the well-documented benefits of maintaining blood pressure in the normal range. Patients with SBP between 160 and 180 or DBP between 100 and 110 should also be able to tolerate most dental procedures without significantly increased risk of perioperative cardiovascular complications; however, complexity and stress of the planned treatment should be carefully considered with attention given to stress reduc-

tion strategies prior to treatment.³⁶ Although clear guidelines for establishing a cutoff point for dental treatment (emergency or routine) are lacking, it is generally accepted that patients with SBP greater than 180 and/or DBP greater than 110 should be referred for medical consultation and treatment prior to dental treatment and only emergency management of pain or acute infection should be considered.³⁶ Patients with SBP above 210 and/or DBP above 120 should be referred for emergent medical evaluation.

VASOCONSTRICTOR USE IN PATIENTS WITH CARDIOVASCULAR DISEASE

Vasoconstrictors are used routinely in endodontic therapy as a component of local anesthetics and often as a hemostatic agent during periapical surgery. Local anesthetic with a vasoconstrictor, most commonly lidocaine with 1:100,000 epinephrine, is the usual anesthetic of choice for root canal therapy, although many nonsurgical procedures can be performed using local anesthetics without vasoconstrictor.³⁷ When a vasoconstrictor is indicated, epinephrine is preferred over norepinephrine or levonordefrin due to a decreased potential for alpha-1 receptor stimulation. Surgical procedures typically require greater quantities of local anesthetic with a vasoconstrictor than nonsurgical root canal treatment. In particular, patients with advanced cardiovascular disease, geriatric patients, and patients taking certain medications (e.g., MAO inhibitors and nonselective beta blockers) may have a reduced tolerance for vasoconstrictor-containing local anesthetics. Since local anesthetics with vasoconstrictors are very helpful in obtaining

adequate hemostasis and visibility during periapical surgery, it may be difficult to perform the procedure using anesthetics without vasoconstrictors.³⁸

The use of local anesthetics with vasoconstrictors in patients with cardiovascular disease has been somewhat controversial and was addressed by the JNC 7 report. While the general goal should be to minimize the use of vasoconstrictors in patients with cardiovascular disease, the benefit of greater depth and duration of anesthesia when local anesthetics with a vasoconstrictor are used is a significant argument in favor of their use. Adequate pain control is an essential component of endodontic therapy since pain-related stress could stimulate the release of significant quantities of endogenous catecholamines. Different kinds of stress can increase the release of endogenous epinephrine by as much as 20 to 40 times over baseline values.³⁹ Pooled results from six studies of patients undergoing extraction or other minor oral surgery procedure demonstrated an average increase in SBP and DBP of 11.7 and 3.3 mm Hg, respectively, as well as an increase in heart rate of 4.7 beats per minute (bpm). The use of local anesthetics containing epinephrine for these procedures resulted in an additional relatively minor increase in SBP of 4 mm Hg and 6 bpm.³² Careful aspiration and use of adequate gauge needle to facilitate aspiration during injection is required to minimize the chance of intravascular injection. Most authors feel that 0.036 to 0.054 mg of epinephrine (approximately two to three cartridges of local anesthetic with 1:100,000 epinephrine) should be safe for all patients except those with severe cardiovascular disease or other specific risk factors, and those with SBP requiring urgent medical attention.^{36,40,41} Local anesthetics with vasoconstrictors should be avoided or used with extreme caution in patients with the following cardiovascular conditions: severe or poorly controlled hypertension, arrhythmias that are refractory to treatment, MI within the past month, stroke within the past 6 months, coronary artery bypass graft within the past 3 months, and uncontrolled congestive heart failure (CHF).³⁰

An important exception to this general rule regarding vasoconstrictors is the choice of local anesthetic for intraosseous (IO) injections in patients with cardiovascular disease. IO injections are most commonly used as a supplemental anesthetic technique for teeth that are otherwise difficult to anesthetize. A transient increase in heart rate can be expected in about two-thirds of patients receiving an IO injection using lidocaine with 1:100,000 epinephrine, although heart rate returns to near baseline within 4 minutes after injection.⁴² No increase in heart rate was found

in patients receiving an IO injection with a 3% mepivacaine solution. Although in this study no significant change in blood pressure was found in either group, the authors recommended 3% mepivacaine without vasoconstrictor for patients with any medical condition that could reduce their tolerance for epinephrine.

Although most experts agree that the use of gingival retraction cord containing epinephrine should be avoided in patients with significant cardiovascular disease,^{36,40} some uncertainty exists over the use of racemic epinephrine-impregnated pellets as recently advocated for improved hemostasis during periapical surgery.^{38,43} In two clinical studies, no significant changes were observed in blood pressure or heart rate when epinephrine pellets (either cotton or collagen) were placed in the bony crypt to improve hemostasis during periapical surgery.^{44,45} It is unlikely that a patient healthy enough to tolerate two or three cartridges of local anesthetic with 1:100,000 epinephrine would experience any untoward effects from the proper use of epinephrine-impregnated pellets during periapical surgery. Regardless, other alternative topical hemostatic agents are available and should be considered for patients with significant cardiovascular disease.

ISCHEMIC HEART DISEASE

When coronary atherosclerotic heart disease becomes sufficiently advanced to produce symptoms, it is referred to as ischemic heart disease. Ischemic heart disease is relatively common in the general population, especially with increasing age, and typically presents as angina or heart failure.⁴⁶ In most cases, diminished blood perfusion of the myocardium due to coronary artery disease (atherosclerosis) is the underlying cause with hypertension as a common contributing factor in heart failure. CHF and enlargement of the heart result from weakening of the damaged heart muscle.

Chest pain secondary to ischemic heart disease results when the oxygen demand of the myocardium exceeds the oxygen supply. Transient pain is referred to as angina pectoris and is often described as an aching, squeezing sensation or tightness in the middle of the chest. Angina is often precipitated by physical activity or stress and may radiate to the arm or jaw and may present as facial or dental pain. Fear and anxiety associated with dental treatment may be a precipitating factor for angina in some patients.⁴⁶ Sublingual or other forms of nitrates are the standard treatment for angina and should result in rapid reversal of symptoms. Patients should always be instructed to bring their usual

antianginal medicine with them for dental appointments. If symptoms are not relieved with oral nitrates and suspension of stress-inducing activity, then MI should be suspected and immediate emergency treatment should be initiated. Since angina is usually a transient event, patients with progressive pain or pain at rest are considered to have unstable angina and present a significant perioperative risk for MI.³⁰ These patients are usually categorized as ASA IV. Chest pain that is manageable with rest or medication and relatively unchanged in duration, frequency, or severity over time is termed stable angina and represents a better prognosis and somewhat lower risk level than unstable angina. Typically, patients with stable angina would be classified as ASA II or ASA III.

Compared to other surgical procedures, most dental and oral surgery procedures are considered relatively low risk.^{47,48} However, a history of significant cardiac disease can be a major predictor of perioperative risk, even for procedures with relatively low procedural stress. Recent MI (less than 1 month), unstable angina, past MI with significant residual damage, decompensated CHF, significant arrhythmias, and severe valvular disease are all considered major predictors of increased perioperative cardiovascular risk, and these patients would usually be classified as ASA IV. Patients with stable angina, past history of MI (greater than 1 month) with minimal residual myocardial damage, compensated CHF, or diabetes mellitus (DM) should be considered at intermediate risk and would usually be classified as ASA II or ASA III.^{30,47} The presence of multiple risk factors creates an additive increase in the overall perioperative risk.⁴⁹ Even patients with a history of recent MI or unstable angina should be able to tolerate routine dental procedures with local anesthesia, although medical consultation is required and conscious sedation with monitoring is often recommended.^{48,50}

Treatment modification considerations for patients with ischemic heart disease should include morning appointments, short appointments, oral premedication with an anxiolytic drug and/or nitrous oxide/oxygen sedation, limited use of vasoconstrictors (as previously discussed), adequate pain management (during and after the dental appointment), and possible cardiac monitoring.³⁰ Sedation with a short act-

ing oral benzodiazepine (e.g., triazolam or ativan) and/or nitrous oxide can reduce the stress of a dental procedure and increase the effectiveness of local anesthesia.³¹ Clinicians must be aware of the medical need and legal requirements that include special training, permits, and monitoring when anxiolysis crosses over into conscious sedation. If conscious sedation is required, it is best performed by a trained provider of anesthesia/sedation and with another operator providing the dental care.

HEART MURMURS AND VALVULAR DISEASE

Patients with valvular disease present two primary considerations for dental treatment: potential risk for infective endocarditis and risk of excessive bleeding in patients on anticoagulant therapy.⁴⁶ Management considerations for patients on anticoagulant therapy are discussed later in this chapter. Most heart valve abnormalities affect either the aortic or the mitral valve and represent partial obstruction of blood flow (stenosis) or valve incompetence (regurgitation). Heart murmurs are common and may be benign or signify major underlying diseases such as degenerative valve disorders (e.g., aortic stenosis), rheumatic heart disease, congenital valve lesions, prosthetic valves, atrial fibrillation, or CHF.⁵¹ Two other conditions that place patients at increased risk for infective endocarditis are systemic lupus erythematosus and certain medications used for weight reduction (dexfenfluramine and fenfluramine-phentermine).^{51,52} Dental management requires evaluation of the type of heart condition and the risk of bacteremia from the planned dental procedure. New guidelines for the prevention of infective endocarditis were published in 2007 and represent a significant change from previous American Heart Association guidelines.⁵³ For example, antibiotic prophylaxis is no longer recommended for patients with a history of mitral valve prolapse (with or without regurgitation), rheumatic heart disease, bicuspid valve disease, aortic stenosis, and certain congenital heart conditions. Antibiotic prophylaxis is now recommended only for patients with valvular disease associated with the highest risk of adverse outcomes from infective endocarditis. For patients in the highest risk category, antibiotic

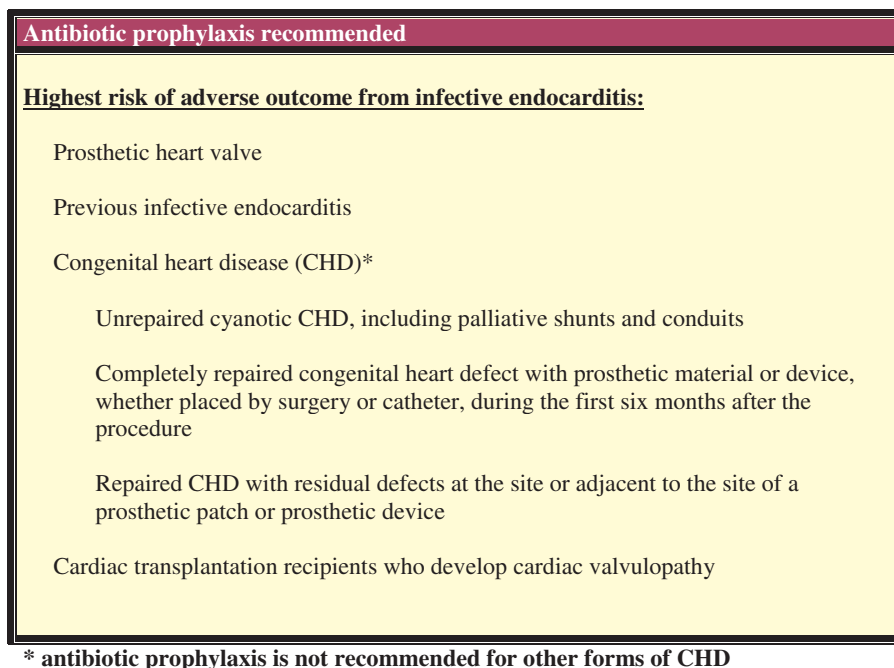

Figure 7 Recommendations for antibiotic prophylaxis based on risk stratification for infective endocarditis. Adapted from Wilson W et al.⁵³

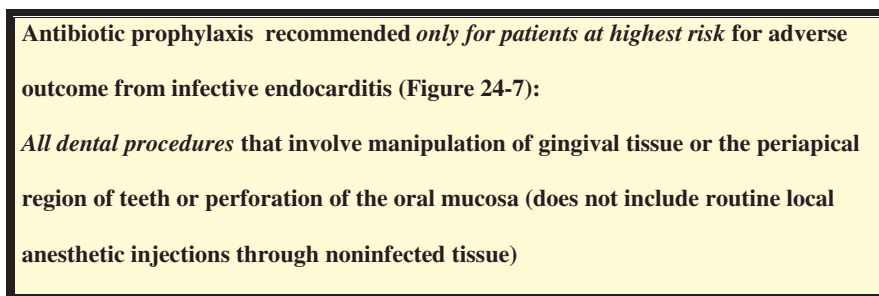

Figure 8 Risk of dental procedures. Adapted from Wilson W et al.⁵³

prophylaxis is recommended for dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa. For all other patients with valvular disease, the risks associated with routine antibiotic prophylaxis are greater than potential benefits.⁵³ Figures 7 and 8 list the specific heart valve abnormalities and dental procedures that are considered highest risk for infective endocarditis. In general, procedures associated with nonsurgical root canal treatment such as local anesthetic injection, placement of the rubber dam, and instrumentation when contained within the canal system do not place the patient at significant

risk for infective endocarditis.⁵⁴ The incidence and magnitude of bacteremia when canal instrumentation does not extend into the periapical tissues is very low, and almost all bacteria are eliminated from the blood within 10 minutes.^{55,56} Canal instrumentation beyond the apex, intraligamentary and IO injections, and periapical surgery can all be expected to result in a higher risk for transient bacteremia. In these situations, antibiotic premedication is recommended for patients in the highest risk disease categories. Infective endocarditis is only rarely directly linked to dental procedures and the efficacy of the recommended antibiotic regimen is

Standard oral regimen	Adults: 2.0g Amoxicillin Children: 50mg/kg
Alternative oral regimen for patients allergic to penicillin or patients who are currently taking a penicillin class antibiotic	Adults: 2.0g Cephalexin or other 1 st or 2 nd generation cephalosporin in equivalent dosage* OR 600mg Clindamycin OR 500mg Azithromycin or clarithromycin Children: 50mg/kg Cephalexin or other 1 st or 2 nd generation cephalosporin in equivalent dosage* OR 20mg/kg Clindamycin OR 15mg/kg Azithromycin or clarithromycin
Patients unable to take oral medications	Adults: 2.0g IM or IV Ampicillin OR 1.0g IM or IV Cefazolin or ceftriaxone* Children: 50mg/kg IM or IV Ampicillin OR 50mg/kg IM or IV Cefazolin or ceftriaxone*
Alternative IM/IV regimen for patients allergic to penicillin and unable to take oral medications	Adults: 1.0g IM or IV Cefazolin or ceftriaxone* OR 600mg IM or IV Clindamycin Children: 50mg/kg IM or IV Cefazolin or ceftriaxone* OR 20mg/kg IM or IV Clindamycin within 30 minutes before the procedure

* = Cephalosporins should be used with caution in patients reporting an allergy to penicillin since approximately 5%–15% of patients who are allergic to penicillin will demonstrate cross reactivity with cephalosporins, especially first and second generation cephalosporins.

Figure 9 Antibiotic prophylaxis for dental procedures—all regimens are a single dose given 30 to 60 minutes before the procedure. Adapted from Wilson W et al.⁵³

questionable.^{53,57–61} The current regimen and drugs of choice for antibiotic prophylaxis are presented in Figure 9.

According to Lessard et al., some patients with significant heart murmurs may have dyspnea, fatigue and difficulty in breathing when reclined in the dental chair⁵¹ and therefore the dental procedure may need

to be performed with the chair in a more upright position. They also suggest that the use of a rubber dam may be contraindicated for some of these patients due to restriction of air flow; however, this may be overcome with careful application of the rubber dam. Failure to use the rubber dam is considered below the

standard of care for root canal therapy and extraction may be the only option for these patients if a rubber dam cannot be used.

ANTICOAGULANT THERAPY AND BLEEDING DISORDERS

Management of patients on anticoagulant therapy depends on the type of anticoagulant, the reason for anticoagulant therapy, and the type of procedure planned. Warfarin (Coumadin—DuPont Pharmaceuticals, Wilmington, DE) anticoagulants are commonly prescribed for the treatment or the prevention of thromboembolic events. This category of anticoagulant works by blocking the formation of prothrombin and other clotting factors. The international normalized ratio (INR) value is the accepted standard for measuring prothrombin time (PT). The desired therapeutic range for INR is usually between 2 and 3.5, depending on the underlying medical indication for anticoagulant therapy.

Limited oral surgery procedures, defined as simple forceps extraction of one to three teeth, may be safely performed on patients with INR values within the normal therapeutic range.^{62–64} Nonsurgical root canal treatment does not usually require modification of anticoagulant therapy, although it is important to ascertain that the patient's INR is within the therapeutic range, especially if a nerve block injection is required. Periapical surgery may present a greater challenge for hemostasis even for patients well maintained within the therapeutic range. The clear field visibility normally required for proper surgical management of the root end may not be possible in patients on anticoagulant therapy. Consultation with the patient's physician is required to assist in developing an appropriate treatment plan. Some patients may be able to tolerate discontinuation of warfarin therapy 2 days prior to a planned surgical procedure to allow for the INR to "drift" downward. In a prospective cohort study, Russo et al.⁶⁵ report that suspension of warfarin 2 days prior to a surgical procedure resulted in no bleeding problems and no thromboembolic events. They found that the average time spent at an INR less than 2.0 (critical value) was 28 hours and that 90% of the patients returned to the desired therapeutic INR value within 7 days. However, this strategy may place certain patients at greater risk for a thromboembolic event and in these cases discontinuation of anticoagulant therapy would not be recommended.

In general, patients on warfarin anticoagulant therapy should present minimal risk for significant bleeding during or after oral surgery and local measures to

control bleeding should be adequate.^{66,67} Jeske and Suchko,⁶⁸ in a review prepared for the American Dental Association Council on Scientific Affairs and Division of Science, recommend against routine discontinuation of anticoagulant therapy prior to dental procedures, including surgical procedures. Regardless of the management approach selected, consultation with the patient's physician and an INR test on the day of surgery are strongly recommended. Hospitalization and conversion to heparin therapy may be considered in special cases, but the patient, physician, and surgeon must carefully weigh the potential risks against the expected outcome and benefits. A new category of heparin anticoagulant, low molecular weight heparins (LMWHs), allows for patient self-administration and may present a viable alternative for some patients who need to remain at a high level of anticoagulation but wish to reduce the cost and time associated with traditional heparin conversion therapy.

Low-dose aspirin therapy is known to increase bleeding time by irreversibly inhibiting platelet aggregation. No treatment modifications should be necessary for nonsurgical root canal procedures. However, surgical procedures require evaluation of the reason for and the necessity of aspirin therapy. It has been a common practice to advise patients to discontinue aspirin therapy for 7 to 10 days prior to an oral surgical procedure.⁶⁹ At low-dose therapeutic levels (<100 mg/day), aspirin may increase bleeding time and potentially complicate surgical procedures. However, Ardekanian et al.⁶⁹ concluded that low-dose aspirin therapy (<100 mg/day) should *not* be discontinued prior to oral surgery procedures and that bleeding could be controlled by local measures. Higher dose therapy may present a greater risk for bleeding either during or after surgery. Even though a patient on aspirin therapy may not be at high risk for significant intra- or postoperative bleeding, a concern for periapical surgery is the visibility problems created by oozing blood. Consultation with the patient's physician is advised to determine the medical reason for aspirin therapy and to weigh the risks and benefits of discontinuing aspirin prior to the proposed surgery. It should be possible to perform periapical surgery without discontinuing aspirin therapy if necessary, but the visibility during the procedure may be compromised and the prognosis may decrease accordingly.³⁸

Nonsteroidal anti-inflammatory drugs (NSAIDs) also have an antiplatelet effect but, unlike aspirin, the effect is reversible when discontinued and platelet activity should be expected to return to normal within approximately three half-lives of the drug. Other

commonly prescribed antiplatelet drugs include dipyridamole, ticlopidine, clopidogrel, abciximab, integrilin, tyrafiban, and lamifiban. Heavy alcohol consumption, liver disease, and certain medications can increase the risk of perioperative bleeding in patients taking antiplatelet medications. Medical consultation is advised prior to surgical procedures and lab tests to determine platelet count and function (PFA-100 and Ivy BT) may be indicated. Some herbs and dietary supplements may also affect bleeding risk.

Patients with inherited or acquired bleeding disorders are also at risk for excessive bleeding during and after periapical surgery procedures and may be at risk from local anesthetic injections particularly when using nerve block injections. Impaired liver function secondary to past or current alcohol or drug abuse may also predispose a patient to excessive bleeding during surgery. A medical consultation, usually with a hematologist, is required prior to dental treatment for patients with serious bleeding disorders such as thrombocytopenia, hemophilia, and von Willebrand's disease. Replacement of deficient coagulation factors or platelet transfusion may be required prior to dental treatment,⁷⁰ particularly if an inferior alveolar nerve block is required or a surgical treatment is planned. If non-surgical root canal treatment can be performed with only infiltration local anesthesia, replacement may not be necessary.⁷¹ However, this decision must be reached in consultation with the patient's hematologist.

ARRHYTHMIAS AND CARDIAC PACEMAKERS

Cardiac arrhythmias are a heterogeneous group of conditions defined as any disturbance in the normal rate or rhythm of the heartbeat. Arrhythmias are the result of abnormal impulse generation, impulse conduction, or both and can range from harmless to life threatening.⁴⁶ The overall prevalence of cardiac arrhythmias in the general dental patient population is 15% to 17% with approximately 2 to 4% representing serious, potentially life-threatening arrhythmias.³⁰ Although arrhythmias are not uncommon in normal, healthy adults, the possibility of underlying cardiovascular disease, systemic disease, or medication-induced arrhythmia should be carefully evaluated prior to dental treatment. Anxiety associated with dental treatment may induce arrhythmias in susceptible patients. In addition, patients with cardiovascular disease are more prone to arrhythmias during oral surgery procedures with local anesthesia.⁷² Patients taking digoxin for atrial fibrillation or CHF are especially at risk for arrhythmias during oral surgery procedures.⁷³

Medications are usually the first line of treatment for cardiac arrhythmias, although many of these have a narrow therapeutic safety range (e.g., digoxin) and must be carefully monitored. Surgery, cardioversion, and pacemakers are also used to treat arrhythmias. It is common for patients with atrial fibrillation to be treated with an anticoagulant (typically warfarin sodium—management considerations discussed previously in this chapter). A history of cardiac arrhythmia is often disclosed in the medical history. In addition to the medical history, patients with an irregular pulse, unusually rapid or slow pulse, reports of syncope, palpitations, dizziness, angina, or dyspnea should be referred to a physician for evaluation prior to dental treatment. Once the nature of arrhythmia and the stability of the condition have been determined, most dental treatment can be safely performed using the same stress reduction treatment modifications listed in the discussion of ischemic heart disease. As always, the clinician and staff should be prepared to manage a medical emergency if necessary.

Electrical interference from certain dental devices is a potential concern for patients with implanted cardiac pacemakers or cardioverter/defibrillators. In particular, electronic apex locators (EAL) and electric pulp testers (EPT) are commonly used in root canal therapy. Manufacturers of EAL and EPT devices warn against the use of these devices in patients with cardiac pacemakers. However, current cardiac pacemakers are very well shielded from external electrical fields and the possibility for electrical interference seems to be very low. A recent clinical study supports previous *in vitro* research and a case report in concluding that EAL and EPT devices should be safe to use in patients with cardiac pacemakers and cardioverter/defibrillators.⁷⁴⁻⁷⁶ One caveat from this study is that a mucosal lip clip was used to complete the circuit with the EPT device instead of the common clinical practice of having the patient hold the EPT wand in their hand. This lip clip technique is recommended if one elects to use an EPT device on a patient with a cardiac pacemaker, since the practice of using the patient's hand to complete the circuit may allow for electrical current to pass through an area of the body in closer proximity to the pacemaker. The safety of this variation of the EPT technique has not yet been tested.

CONGESTIVE HEART FAILURE

CHF is the fourth most common medical diagnosis in all age groups and represents the end-stage of other common cardiovascular diseases such as coronary

New York Heart Association CHF classification	Signs and symptoms	Dental management considerations
Class I	No limitations on physical activity; no dyspnea, fatigue, or palpitations with ordinary physical activity	Should be able to tolerate routine dental treatment; stress reduction protocol as needed
Class II	Slight limitation on physical activity; comfortable at rest but may experience fatigue, palpitations, and dyspnea with ordinary physical activity	Should be able to tolerate routine dental treatment; stress reduction protocol as needed; possible medical consultation
Class III	Significant limitation of activity; comfortable at rest but even minor activity results in symptoms	Medical consultation; consider treatment in hospital dental clinic or similar facility; avoid vasoconstrictors
Class IV	Symptoms present at rest; symptoms exacerbated by any physical activity	Medical consultation; conservative treatment only; treatment in hospital dental clinic; avoid vasoconstrictors

Figure 10 New York Heart Association's classification system for patients with congestive heart failure (CHF) and dental management considerations. Adapted from Little JW et al.³⁰

artery disease, hypertension, cardiomyopathy, and valvular heart disease.³⁰ CHF results in an inability of the heart to efficiently pump blood that can involve one or both ventricles. Patients with CHF typically present with significantly diminished reserve capacity for handling stress (including dental treatment) and are often taking multiple medications with the potential for drug interactions.

Patients with well-managed CHF should tolerate routine dental treatment with possible minor treatment modifications, similar to those recommended for patients with ischemic heart disease. In addition, the underlying causes (coronary artery disease, hypertension, valve disease, etc.) and medications should be considered and managed appropriately. Patients with moderate to advanced CHF may require a more upright chair position due to the presence of pulmonary edema. The clinician should be alert for orthostatic hypotension when making adjustments in chair position. Uncompensated, advanced CHF requires medical consultation prior to dental treatment and vasoconstrictors should be avoided. These patients may require

treatment in special care facilities or hospital-based clinics. The New York Heart Association (NYHA) has developed a classification system for CHF that can be adapted to assist in assessing risk for dental treatment (Figure 10).

Diabetes

Diabetes mellitus (DM) is a complex metabolic disorder characterized by abnormalities in carbohydrate, fat, and protein metabolism resulting either from a deficiency of insulin (type 1) or from target tissue resistance to its cellular metabolic effects (type 2). Hyperglycemia is the most clinically important metabolic aberration in DM and the basis for its diagnosis. Chronic hyperglycemia is associated with ophthalmic, renal, cardiovascular, cerebrovascular, and peripheral neurological complications. DM is defined as a fasting blood glucose level greater than 125 mg/dL and the normal fasting blood glucose level is considered to be less than 110 mg/dL. Patients with fasting plasma

glucose levels greater than 110 mg/dL but less than 126 mg/dL represent a transitional condition between normal and DM and are considered to have impaired glucose tolerance.⁷⁷ Identification of patients at this stage can allow for earlier preventive interventions and possibly delay or prevent progression to DM. There are 20.8 million children and adults in the United States, or 7% of the population, who have DM. While an estimated 14.6 million have been diagnosed with DM, 6.2 million people (or nearly one-third) are unaware that they have the disease.⁷⁸ The epidemic of obesity in the United States is anticipated to result in an increase in the prevalence of diabetes.

When reviewing medical histories, the clinician should be aware of cardinal symptoms of DM, such as polydipsia, polyuria, polyphagia, weight loss, and weakness, and should be referred to a physician for diagnosis and treatment.³⁰ In diabetic patients, the clinician should ascertain how well controlled the condition may be. Dental appointment scheduling should take into account the importance of nutritional consistency and the avoidance of appointments that will overlap with or prevent scheduled meals. Symptoms of hypoglycemia may range from mild, such as anxiety, sweating, tachycardia, to severe, such as mental status changes, seizure, and coma. Severe hypoglycemic episodes are a medical emergency and should promptly be treated with 15 g of oral carbohydrate, such as 6 oz orange juice, three to four teaspoons of table sugar, five Life Savers, or three glucose or dextrose tablets. If a patient is unable to cooperate or swallow, 1 mg glucagon may be administered by subcutaneous or intramuscular injection. Side effects of glucagon include nausea, vomiting, and headache.

It has been well established that hyposalivation, gingivitis, periodontitis, and periodontal bone loss are associated with DM, especially when poorly controlled.^{79,80} The well-controlled diabetic is at no greater risk of postoperative infection than is the nondiabetic.⁸¹ Therefore, surgical procedures in well-controlled diabetics do not require prophylactic antibiotics. However, when surgery is necessary in the poorly controlled diabetic, prophylactic antibiotics should be considered due to the altered function of neutrophils in diabetics. Surgery may also increase insulin resistance such that a diabetic may become hyperglycemic in the postoperative period. Preoperative antibiotics should be administered in these instances.⁸² Furthermore, delayed alveolar healing following dentoalveolar surgery should raise the suspicion of osteomyelitis, for which prompt surgical consultation should be arranged. Finally, patients with DM may present with systemic complications, each of

which should be taken into account prior to dental procedures.

Pulmonary Disorders: Asthma, COPD, and Tuberculosis

Asthma is a chronic inflammatory respiratory disease with recurrent episodes of chest tightness, coughing, dyspnea, and wheezing resulting from hyperresponsiveness and inflammation of bronchiole tissue. Overt attacks may be provoked by allergens, upper respiratory tract infections, genetic and environmental factors, certain medications, and highly emotional states such as anxiety, stress, and nervousness.

The endodontist should obtain a good history to determine the severity and stability of disease. Patients should be instructed to bring their inhalers (bronchodilators) to each appointment and inform the endodontist of the earliest sign or symptom of an asthma attack. During dental treatment, the most likely times for an acute exacerbation of asthma are during and immediately after local anesthetic administration and with stimulating procedures such as pulp extirpation.⁸³ Because stress is implicated as a precipitating factor in asthma attacks, sedation may be beneficial. While nitrous oxide may be used in patients with mild-to-moderate asthma, its use is contraindicated in patients with severe asthma due to its potential to cause airway irritation.⁸⁴ Alternatively, oral premedication may be accomplished with small doses of a short-acting benzodiazepine. In patients taking theophylline, macrolide antibiotics should be avoided, as they have the potential to develop toxic levels of theophylline. In addition, it is important to note that aspirin and other NSAIDs may trigger asthma attacks in a proportion of patients.⁸⁵

COPD is a term for pulmonary disorders characterized by chronic irreversible obstruction of airflow from the lungs and represents the fourth most common cause of death in the United States.⁸⁶ The three most common forms of COPD are chronic bronchitis, emphysema, and bronchial asthma. Patients with pulmonary diseases typically present with one or more of the following symptoms: cough, dyspnea, sputum, hemoptysis, wheezing, or chest pain.⁸⁷ Patients should be placed in a semisupine position. Since the use of a rubber dam may induce a feeling of airway constriction, careful application of the rubber dam and administration of humidified low-flow oxygen, generally between 2 and 3 L/min, may be considered. Nitrous oxide should not be used in patients with severe COPD.

Tuberculosis (TB) is an infectious disease that is spread by way of bacilli-containing airborne droplets, typically by coughing, sneezing, or talking. The signature lesion of TB is the tubercle, a granuloma formed by the continuing ingress of macrophages and lymphocytes to the site of infection.⁸⁸ In the lung, tuberculous granulomas are frequently associated with regions of tissue necrosis, termed *caseous necrosis* due to its gross appearance. After the infection is established, symptomatic individuals will show pulmonary manifestations of the disease, often limited to the periphery of the middle and lower regions of the lung,⁸⁸ though reactivated disease is most commonly found in the lung apices.⁸⁹ Oral tubercular infections are rare, occurring in 0.05 to 5% of patients with TB, though when lesions are present, they typically consist of ulcers, fissures, or swellings on the dorsum of the tongue.⁹⁰ Despite the declining incidence of TB in the United States, health care workers including endodontists and their staff remain at high risk for contracting the disease. It is imperative for the endodontist to educate office staff about TB prevention and recognition of symptoms and oral manifestations of the disease to protect the staff and other patients from becoming infected. A thorough medical history should be obtained, and any elective dental procedures on a patient with established or suspected active TB should be delayed until the individual can be treated and subsequently proved noninfectious. Routine dental treatment is appropriate after it has been established that the patient has been adequately treated and there are no signs or symptoms of active disease. The clinician should be aware of potential drug interactions when managing dental patients undergoing antitubercular treatment. In patients taking medications such as rifampin and isoniazid, acetaminophen should be avoided due to the potential for liver damage. The use of aspirin and muscle relaxants is discouraged in those individuals taking streptomycin due to a heightened risk of ototoxicity and respiratory paralysis, respectively.⁹¹ Streptomycin is also known to cause facial paresthesia and pancytopenia.

Central Nervous System: Stroke, Seizure Disorders, and Hydrocephalic Shunts

Cerebrovascular accident or stroke is defined as the acute onset of neurologic deficits persisting for at least 24 hours. Strokes are subclassified into ischemic insults, occurring secondary to thrombosis or embolization, or hemorrhagic, which usually indicate an arterial process. The lack of blood flow leads to deprivation of oxygen

and glucose in a localized area of the brain. The endodontist should be aware of how to identify the patient having a stroke in his/her office. Regardless of the procedure, a patient's blood pressure should be checked before treatment to identify a patient whose blood pressure is elevated and who might be at risk for a stroke if subjected to stress. Slurred speech, loss of motor control over a portion of the body, unilateral facial droop, unilateral visual changes, and unilateral severe headache are all potential signs of a stroke or a transient ischemic attack. Should any of these events occur, the patient should have his/her vital signs checked, be placed in a supine position, have vital signs monitored, and be transported to an emergency facility immediately, as treatment must be activated in a timely manner. Patients with a history of stroke may be at risk for aspiration due to swallowing abnormalities, so they should be positioned in a semisupine position, and rubber dams should be carefully applied and should always be used. Poststroke patients may be on oral anticoagulants; so if surgical intervention is planned, the endodontist should contact the physician to determine whether or not the risk of a thromboembolic event outweighs the benefits of postoperative hemostasis (please refer to section "Anticoagulant therapy and bleeding disorders"). The endodontist should also be aware that the poststroke patient may experience emotional problems, including depression and behavior inappropriate to the situation.

Seizures are one of the most commonly encountered neurological disorders and can manifest as an isolated incident with unknown etiology or as a symptom of a condition that requires long-term treatment. A seizure is a temporary involuntary disturbance of brain function that results in synchronous, excessive, abnormal electrical discharges of the neurons in the central nervous system.⁹² This manifestation can take the form of motor disturbances, altered feelings, or changes in the patient's level of consciousness. The two main categories of seizure classification are partial and generalized. Most people who have seizures have good control and are capable of receiving routine dental care. The endodontist should be aware of the patient's seizure medications, since many antibiotics are contraindicated. Should a seizure occur in the dental office, the procedure should be stopped immediately and all instruments should be removed from the oral cavity. The patient should be placed in a supine position and low to the ground. Basic life support should begin immediately, including opening the airway, obtaining vital signs such as heart rate and blood pressure, and contacting emergency medical services.

The risk of shunt infection following invasive dental treatment for patients with hydrocephalic shunts (ventriculoperitoneal and ventriculoatrial) is believed to be about 3.0 to 5.0% and because of this there is a lack of consensus regarding the need for antibiotic prophylaxis.⁹³ The authors of this study found that pediatric dentists were more likely to be concerned about streptococcal microorganisms and neurosurgeons were more concerned about staphylococcal microorganisms in shunt infection. The majority of both groups recommended penicillin prophylaxis, although there are more appropriate antibiotics if staphylococcal microorganisms are presumed to be responsible for most shunt infections (please refer to the discussion in section “Prosthetic joints and other prosthetic devices”). Consultation with the patient’s neurosurgeon is advised and close attention to any changes in prophylaxis guidelines is important.

Renal Disease and Dialysis

Chronic renal failure is a slowly progressive condition characterized by an irreversible reduction in the glomerular filtration rate. The progression of this disease begins with an asymptomatic decrease in the kidney function and eventually results in end-stage renal disease (ESRD). Throughout the decline in function, multiple systems are affected, directly related to the kidney dysfunction. ESRD is potentially fatal unless the patient undergoes dialysis or kidney transplantation (please see section “Solid Organ Transplantation” regarding kidney transplantation). Dialysis may take the form of hemodialysis, which represents 90% of dialysis treatment,⁹⁴ or peritoneal dialysis. This treatment removes fluid and wastes and equilibrates electrolytes and acid–bases via diffusion and osmosis across a semipermeable membrane.

The clinician should be aware of the ESRD patient’s type and days of dialysis treatment as well as comorbid conditions such as hypertension and/or diabetes. Mechanical trauma to platelets and anticoagulants such as heparin used during hemodialysis may increase the renal patient’s tendency for bleeding. While it is recommended that dental procedures be performed on nondialysis days, typically the day after dialysis,⁹⁵ the endodontist should be aware that abnormal platelet function may cause a greater risk of bleeding during surgical procedures. In addition, patients with ESRD require aggressive treatment of odontogenic infections. Antibiotic premedication has also been recommended for hemodialysis patients with shunts who undergo invasive dental proce-

dures,^{96–98} and other authors have recommended antibiotic prophylaxis for all hemodialysis patients undergoing procedures that cause mucosal bleeding to prevent vascular access infections, bacteremia, and infective endocarditis.⁹⁷ Renal osteodystrophy and secondary hyperparathyroidism may occur in late-stage disease due to disorders in calcium, phosphorous, and abnormal vitamin D metabolism. Such a manifestation may predispose renal patients to jaw fracture during surgical procedures.

Because many drugs are metabolized via the kidney, renal dosing should account for the drug’s extended half-life by lengthening the interval between medication doses. In particular, antibiotic medications should be adjusted for renal dosing. NSAIDs should be avoided in patients with renal insufficiency due to their nephrotoxic effects, but no longer need to be avoided when the patient has ESRD.

Cancer Chemotherapy and Radiation Therapy

Oropharyngeal cancer encompasses a variety of malignant diseases. More than 90% of oral cancers are squamous cell cancers, 9% are salivary gland tumors, sarcomas and lymphomas, and the remaining 1% are metastatic cancers originating in other parts of the body.⁹⁹ In the year 2006, the American Cancer Society reported 31,000 people with newly diagnosed oropharyngeal cancers and 7800 deaths from this disease.¹⁰⁰ Numerous risk factors have been implicated in the etiology of oropharyngeal cancer, including tobacco, excessive alcohol, ultraviolet light exposure, immunosuppression, and viruses. Oral cancer has a variable appearance, including white or red patches, an exophytic mass, an ulceration, a granular raised lesion, a submucosal mass, or a combination thereof. Treatment of oropharyngeal cancer is composed of surgical intervention, radiation treatment, and chemotherapy and for systemic cancers possibly hematopoietic stem cell transplantation (HSCT). Multimodality therapy is now more commonly used for oropharyngeal cancer in order to obtain increased survival rates.

Cancers that are amenable to surgery and do not affect the oral cavity require few treatment plan modifications. However, oropharyngeal cancer treatments and complications may cause significant changes in the oral cavity. Preceding cancer treatment, all sources of inflammation and potential infection should be eliminated. Whenever possible, nonrestorable teeth and teeth with a poor long-term periodontal

prognosis (i.e., not expected to be retained for the patient's lifetime) within the field of high-dose radiation should be extracted more than 2 weeks prior to radiation therapy. Symptomatic nonvital teeth can be endodontically treated at least 1 week before initiation of head and neck radiation or chemotherapy although dental treatment of asymptomatic teeth even with periapical involvement can be delayed, particularly if treatment can be limited to intracanal therapy. Many cancer patients have indwelling catheters that may be susceptible to infection and, while controversial, the American Heart Association (AHA) regimen for antibiotic prophylaxis (see Figure 9) has been recommended before invasive dental procedures.¹⁰¹ If an individual is receiving chemotherapy, the endodontist should be familiar with the patient's white blood count (WBC) count and platelet status. Endodontic procedures can be performed if the neutrophil count is greater than 2000 cells per cubic millimeter and platelets are greater than 50,000 cells per cubic millimeter. Postradiation osteonecrosis (PRON) results from radiation-induced changes in the jaws, may arise in bones exposed to high-dose radiation, and is characterized by asymptomatic or painful bone exposure. Protocols to reduce the risk of osteonecrosis include selection of endodontic therapy over extraction, expert atraumatic surgical procedures, considering the use of nonlidocaine local anesthetics that contain no or low concentration of epinephrine, and prophylactic antibiotics plus antibiotics during the week of healing.¹⁰²

BISPHOSPHONATE-ASSOCIATED OSTEONECROSIS OF THE JAWS

Bisphosphonates are bone resorption inhibitor medications that are commonly used in conjunction with cancer chemotherapy and the prevention or treatment of osteoporosis. Recent reports have suggested that bisphosphonates (e.g., pamidronate, zoledronic acid) may cause osteonecrosis of the maxillary and mandibular bones, either spontaneously or following dental surgical procedures or oral trauma.¹⁰³⁻¹⁰⁷ Although the mechanism of action is unknown, it is suggested that a decrease in bone cellularity and antiangiogenic effects and decreased blood flow resulting from bisphosphonate therapy could lead to a generalized impairment in bone remodeling.¹⁰⁵ There appears to be a dose-response relationship in that patients taking IV formulations appear to be at greater risk for bisphosphonate-associated osteonecrosis (BON).¹⁰⁸ There are currently no scientific data to support any specific treatment protocol for the management of patients with

BON, though minimally invasive procedures have been recommended.¹⁰⁶ Before initiation of bisphosphonate therapy, aggressive preventive treatment should be performed including oral hygiene, caries control, and extraction of teeth with a poor long-term prognosis. For patients who have been taking bisphosphonate medication, preventive care for high-risk patients is important to reduce the risk of developing BON. Nonsurgical endodontic treatment of teeth that would otherwise be extracted should be considered. Teeth with extensive carious lesions might be treated by nonsurgical endodontic therapy possibly followed by crown resection and restoration similar to preparing an overdenture abutment.¹⁰⁹ For patients at higher risk of developing BON, surgical procedures including surgical endodontic procedures should be avoided if possible. Informed consent for endodontic procedures should involve a discussion of risks, benefits, and alternative treatments with the patient.

Bone Marrow and Solid Organ Transplantation

HEMATOPOIETIC STEM CELL TRANSPLANTATION

HSCT may be indicated in patients with hematological malignancy, nonhematological malignancy, and some nonmalignant disorders. Patients may undergo an autologous (self) or an allogeneic (nonself) transplantation, each of which has its own pros and cons. The goal is to treat bone marrow disease or to intensify therapy that would destroy the bone marrow, following which the patient is "rescued" by the infusion of previously stored autologous hematopoietic stem cells or hematopoietic stem cells from a matched donor. Prior to transplantation, patients should undergo a thorough dental examination and treatment to permit adequate healing before the HSCT. Pretreatment endodontic therapy should be completed at least 10 days prior to initiation of cancer therapy. Teeth with poor prognoses should be extracted, utilizing the 10-day window as a guide. The current AHA protocol for antibiotic prophylaxis prior to invasive oral procedures may be warranted in patients who have indwelling catheters (e.g., Hickman catheter). Prophylactic antibiotics are also recommended in patients who are neutropenic (<1,000 neutrophils per cubic millimeter).

During and following high-dose chemotherapy/HSCT, aggressive oral hygiene measures should be

instituted. Numerous oral complications may develop, including mucositis, graft-versus-host disease, infection, taste changes, and bleeding. Patients should not resume routine dental treatment, including dental scaling and polishing, until adequate immunological reconstitution has taken place; this typically occurs no less than 1 year posttransplant. The aerosolization of debris and bacteria during the use of high-speed rotary cutting instruments can put the patient at risk for aspiration pneumonia; additionally, bacteremias occur as a result of dental treatment and can cause serious outcomes. Should treatment be deemed necessary within 1 year posttransplant, the endodontist must consult with the oncologist to determine appropriate treatment.

SOLID ORGAN TRANSPLANTATION

It is important to reduce the risk of infection in the immunosuppressed recipient of a transplant.¹¹⁰ Pretransplant patients should undergo eradication of dental disease, including endodontic procedures as warranted to remove any potential sources of infection, and deferral of any elective treatments. Of course, the endodontist should take into account the underlying condition for which the transplant is required. In the immediate posttransplant period, emergency dental procedures may be necessary. At this stage, patients are highly immunosuppressed to prevent organ rejection, so the AHA regimen of antibiotic prophylaxis with possible postoperative

antibiotics may be recommended for invasive procedures. Further, patients may have indwelling catheters that may lead to a recommendation for antibiotic prophylaxis. Should a patient experiences transplant rejection, dental care provided should be limited to emergency care only until stabilization is again achieved. After the posttransplantation patient has stabilized, indicated dental procedures may be performed after consultation with the patient's transplant team. Postoperative guidelines regarding prophylactic antibiotics have not been established but, if recommended, AHA guidelines may be used.¹¹⁰ Finally, the endodontist should be aware that posttransplant recipients will likely be on immunosuppressant therapy, regardless of the length of time posttransplant.

Prosthetic Joints and Other Prosthetic Devices

Patients with prosthetic joints may be at increased risk for developing a hematogenous joint infection following dental procedures. Since the necessity of prophylactic antibiotics in this group of patients is controversial, consultation with the patient's orthopedic surgeon is advised. Current recommendations include antibiotic coverage with higher risk dental procedures (see Figure 8) within 2 years following prosthetic joint surgery, for those who have had previous hematogenous prosthetic joint infections and for those with some medical conditions (Figure 11).¹¹¹

All patients during first two years following total joint replacement
Immunocompromised/immunosuppressed patients
Inflammatory arthropathies such as rheumatoid arthritis, systemic lupus erythematosus
Drug- or radiation-induced immunosuppression
Patients with medical comorbidities
Previous prosthetic joint infections
Malnourishment
Hemophilia
HIV infection
Type 1 diabetes
Malignancy

Figure 11 Patients at potential increased risk of experiencing hematogenous total joint infection. Adapted from ADA, AAOS Advisory statement.¹¹¹

Patient Type	Suggested Drug	Regimen
Patients not allergic to penicillin	Cephalexin, cephadrine or amoxicillin	2 grams orally 1 hour prior to dental procedure
Patients not allergic to penicillin and unable to take oral medications	Cefazolin or ampicillin	Cefazolin 1g or ampicillin 2g intramuscularly or intravenously 1 hour prior to the dental procedure
Patients allergic to penicillin	Clindamycin	Clindamycin 600 mg orally 1 hour prior to the dental procedure
Patients allergic to penicillin and unable to take oral medications	Clindamycin	600mg intravenously 1 hour prior to the dental procedure

Figure 12 Suggested antibiotic prophylaxis regimens for patients with total joint replacement. Adapted from ADA, AAOS Advisory statement.¹¹¹

The selection of antibiotic and dosage regimen differs slightly from the commonly accepted regimen for prevention of bacterial endocarditis since different microorganisms are more commonly associated with late joint infections (Figure 12). These guidelines suggest prophylaxis for recently placed large joint prostheses even though there is little evidence that oral flora account for many infections in joint prostheses. These guidelines will be continually reviewed and current guidelines must be followed for medicolegal purpose.

Antibiotic prophylaxis is not indicated for dental patients with pins, plates, screws, and penile or breast implants, nor is it routinely indicated for dental patients 2 years after total joint replacements. A patient with a total joint replacement or other surgically placed prosthesis with acute orofacial infection should be aggressively treated as any other patient to eliminate the source of infection, and appropriate antibiotics should be administered as warranted.

Pregnancy

Few procedures are contraindicated during pregnancy. There is no contraindication to using necessary diagnostic procedures, such as appropriate radiographs, as long as normal safety precautions are followed. If dental caries is the source of pain or infection, invasive care such as endodontic therapy should be provided regard-

less of the patient's phase of pregnancy.¹¹² Elective dental procedures may often be performed in the second trimester, when the pregnancy is mostly devoted to maturation. While some medications may be harmful to the fetus, safe alternatives are often available. Lidocaine and prilocaine local anesthetics have an FDA category B rating and consequently should be first-line choices for use with pregnant women. A common misconception is concern over the use of local anesthetics containing epinephrine. Local anesthetics containing epinephrine should be relatively safe for use during pregnancy¹¹³ and allow for greater depth and duration of anesthesia as well as reduction of any potential systemic effect of lidocaine. In addition, the only commonly available alternative to local anesthetics with a vasoconstrictor is 3% mepivacaine, an FDA category C drug. If antibiotics are warranted, many first-line choices are rated by the FDA as category B for pregnancy risk. Pregnant women may be more susceptible to infection,¹¹⁴ which may be partly due to physiological changes as well as alterations in pharmacokinetics.

Human Immunodeficiency Virus

HIV is a blood-borne retrovirus infection transmitted primarily by blood and bodily fluids by intimate sexual contact and parenteral means. Upon infection, a viral enzyme reverse transcriptase allows the virus to integrate its own DNA into the genome of an infected cell

and replicate using the infected cell's ribosomes and protein synthesis. Initially, immune seroconversion with antiviral antibody production occurs followed by a significant decrease in CD4⁺ lymphocytes over a period of up to years. The most effective management in the progression of HIV infection and AIDS is a combination of antiviral agents known as highly active antiretroviral therapies (HAART), which has significantly increased the lifespan and the quality of life of individuals infected with HIV. Upon initial assessment of an HIV-infected individual, the patient's physician should be contacted to determine CD4⁺ counts as well as baseline kidney and liver function. It is safe and desirable to assure that comprehensive dental care is available to HIV-positive patients. No modification of irreversible procedures or surgical treatment is recommended unless patients have reduced platelet count (<50,000 cells per milliliter) or neutrophil counts <1,000 cells per milliliter, at which time a patient may require antibiotic prophylaxis. Routine antibiotic use is contraindicated. The prognosis for successful healing of necrotic teeth with chronic apical periodontitis following root canal treatment is essentially the same for HIV-positive patients as for noninfected patients.^{115,116} The endodontist should examine oral tissues, as oral conditions associated with HIV may identify a person who is unknowingly infected with HIV, may be used in staging and classification, and/or may denote progression to AIDS. Surgically treated teeth do not show delayed healing. Antibiotics are used only if warranted by the clinical infection, and in a neutropenic patient.

Sickle Cell Anemia

Sickle cell anemia (SCA) affects approximately 1 in 400 African-Americans and as much as 30% of the population of some Central and West African countries. Clinical concerns in endodontic practice include the propensity for painful vasoocclusive episodes and bacterial infections.¹¹⁷ Since patients with SCA may be considered immunocompromised and infections can trigger a sickle cell crisis, these patients usually require aggressive treatment of infections, including the use of systemic antibiotics.¹¹⁷ The vasoocclusive aspects of the disease can result in tissue and bone necrosis and pulpal necrosis in an otherwise intact and healthy tooth.¹¹⁸ Since teeth with asymptomatic necrotic pulps can become infected, patients with SCA require careful pulpal evaluation. Nonsurgical root canal treatment of asymptomatic necrotic teeth prior to the development of acute symptoms and infection is indicated. There is a lack of consensus regarding the value of prophylactic

antibiotics for patients with SCA, although the majority of pediatric dentistry program directors and pediatric hematologists recommend antibiotic coverage for invasive procedures such as extraction or other surgical procedures.¹¹⁹ The use of a local anesthetic with no vasoconstrictor (or minimal vasoconstrictor) may be advisable for nonsurgical procedures since the microvasculature is often already compromised by SCA. Osteomyelitis is much more common in patients with SCA¹¹⁷ and the risk/benefit ratio for surgical endodontic procedures should be carefully considered for patients with SCA.

Liver Disease

End-stage chronic liver disease (cirrhosis) is the result of hepatocellular injury and necrosis that leads to fibrosis and nodular regeneration. Cirrhosis may be asymptomatic for long periods of time and may be undiagnosed until systemic signs are apparent. Ultimately, chronic liver disease affects multiple body systems. For more information on the preliver transplant patient, please see section "Solid organ transplantation" earlier in this chapter.

Performing any surgery in the preliver transplant patient involves the risk of severe hemorrhage due to thrombocytopenia or reduced hepatic synthesis of coagulation factors. Preoperative evaluation should include a complete blood count with platelet count, PT or INR, and partial thromboplastin time to ensure an intact coagulation system. Patients with cirrhosis have an increased susceptibility to infection. Odontogenic infections should be treated aggressively with appropriate antibiotic treatment. Antibiotic prophylaxis prior to dental procedures is recommended only if the patient has a history of spontaneous bacterial peritonitis (SBP), ascites (accumulation of excess fluid in the abdomen), another medical indication for antibiotic prophylaxis, or whose medical condition would drastically deteriorate should SBP develop. When antibiotic prophylaxis is indicated in the patient with end-stage liver disease, a recommended oral regimen is 2.0 g of amoxicillin plus 500 mg of metronidazole 1 hour before the dental procedure, or patients may be given 2.0 g of ampicillin plus 500 mg of metronidazole intravenously 1 hour before the procedure.¹²⁰ Finally, the pharmacokinetics of drugs commonly used in dentistry can be altered in patients with end-stage liver disease. Alteration of medication dosage based upon hepatic compromise, additional medications, and site of metabolism of the medication may require consultation with the patient's physician.

Adrenal Suppression and Long-Term Steroid Use

The adrenal cortex produces mineralocorticoids, such as aldosterone, and glucocorticoids, such as cortisol, which are important in maintaining fluid volume. Adrenocortical insufficiency may result primarily from Addison's disease, an autoimmune condition, or secondarily from hypothalamic or pituitary disease or from the administration of exogenous corticosteroids (30 mg per day or more of cortisol equivalent [about 5 mg prednisone]). Supplemental steroids are often recommended before and possibly following surgery to prevent adrenal crisis in patients who receive chronic daily steroid therapy.¹²¹ In these patients, for minor surgical procedures such as routine endodontic surgeries, the glucocorticoid target is about 25 mg of hydrocortisone equivalent (5 mg of prednisone) on the day of surgery. If a moderate risk surgery is to be performed, the glucocorticoid target is about 50 to 75 mg per day of hydrocortisone equivalent on the day of surgery and for one postoperative day. Nonsurgical dental procedures, including nonsurgical root canal treatment, generally require no supplementation; however, this should be reviewed on a case-by-case basis and consideration given to the anticipated procedural stress and patient tolerance for dental treatment.¹²¹ As a rule of thumb, a patient who recently discontinued the use of exogenous corticosteroids should wait 2 weeks before undergoing surgical procedures. Patients on alternate day steroids do not likely require steroid supplementation. Efforts to control pain and infection can decrease the risk of an adrenal crisis.

Allergy to Materials Used in Endodontic Therapy

The prevalence of allergies and allergy-related diseases has increased significantly in recent years.¹²² Approximately 15 to 20% of dental patients report some form of allergy on their medical history questionnaire and approximately 5% report allergy to one or more drugs.¹²³ In fact, allergy is the single most common positive finding on the medical history questionnaire.² Fortunately, with the exceptions of latex and certain antibiotics, the majority of reported allergies are to substances not typically used in dental treatment. Even so, many materials used in root canal therapy have the potential for eliciting an allergic reaction. The medical history questionnaire serves as the first stage in screening for allergies but should always be supplemented

with direct patient questioning about the history of allergic reactions to any drugs or substances. True allergic reactions are characterized by one or more of the following signs and symptoms: skin rash, swelling, urticaria, chest tightness, shortness of breath, rhinorrhea, and conjunctivitis.¹²³

Type I (immediate or anaphylactic, IgE-mediated) and Type IV (delayed, cell-mediated) are the two types of allergic reactions most likely to be encountered as a result of exposure to a substance used in endodontic treatment. Type I hypersensitivity requires previous exposure to the antigen and can occur after a single prior exposure or multiple prior exposures to the allergen. The reaction occurs shortly after exposure and can rapidly progress to life-threatening anaphylaxis. Type IV hypersensitivity typically appears 48 to 72 hours after exposure and is mediated by T lymphocytes in contrast to the humoral immune system (antibody)-mediated Type I reaction. Contact dermatitis is a classic Type IV reaction. When materials used in endodontic treatment come in contact with the periapical tissues (either intentionally or inadvertently), there is the potential for a delayed Type IV hypersensitivity reaction. The allergic potential of various materials commonly used in endodontic treatment is summarized in Figure 13.

LOCAL ANESTHETICS

True Type I allergy to an amide local anesthetic is extremely rare. Nevertheless, patients reporting a history of allergic reaction to a local anesthetic require thorough evaluation prior to proceeding with treatment (assuming that a local anesthetic is needed for root canal treatment) since true allergic reactions have been reported.¹²⁴⁻¹³³ Perhaps the most common response elicited upon exploration of the presumed allergic reaction is a report of tachycardia, syncope or general uneasiness following local anesthetic injection. Such a response almost certainly represents a psychogenic reaction rather than true allergy.^{132,134} Careful aspiration during injection can help prevent an inadvertent intravascular injection and subsequent increased toxicity and potential for adverse reaction.

In a recent prospective study of 5,018 dental patients who received a local anesthetic, 25 (0.5%) adverse reactions were recorded.¹²⁴ Twenty-two of the reactions were mild, quickly reversible, and considered to be psychogenic in nature. Only two of the reactions were initially viewed as possible allergic reactions and both of these were excluded as true allergic reactions after provocative challenge tests. In another study of 236 patients who experienced an adverse reaction after injection of local anesthetic, all tested negative following

Category	Material	Allergic potential
Barriers	Natural rubber latex	+
	Vinyl (polyvinyl chloride)	–*
	Nitrile (acrylonitrile and butadiene)	–*
	Polychloroprene (Neoprene)	–*
Irrigating solutions and disinfectants	Sodium hypochlorite (0.5%–6%)	+
	Hydrogen peroxide (3%–30%)	–
	Chlorhexidine (0.2%–2%)	+
	Iodine Potassium iodide (2%–5%)	+
	Ethylenediamine tetraacetic acid (EDTA) (10%–17%)	–
	Citric acid (10%–50%)	–
	MTAD (mixture of tetracycline, citric acid and detergent)	?
Intracanal medications	Phenols	+
	Aldehydes	+
	Calcium hydroxide	–
	Iodine containing pastes	+
Sealers and filling materials	ZnOE materials (various sealers and temporary filling materials)	+
	Epoxy resins	+
	Glass ionomers	–
	Composite resins	?
	Mineral trioxide aggregate (MTA)	–
	Calcium chelate/polyvinyl resin	–
	Gutta percha (trans 1,4-isoprene polymer)	?

* = Type I allergic reactions are generally not seen with use of these synthetic materials; however, chemicals used in processing and powders in gloves may still cause Type IV reactions in sensitive individuals
 ? = allergic potential is uncertain or unknown but probably low; allergy to one of the components is possible.

Figure 13 Allergic potential of materials commonly used in endodontic treatment. Adapted in part from Hensten A and Jacobsen N,¹⁵⁸ and Zehnder M.¹⁵¹

intra-dermal injection of local anesthetic containing epinephrine and preservative.¹³⁵

Both sulfite preservatives used in local anesthetics containing epinephrine and latex allergen released into the anesthetic solution from the vial stopper are poten-

tial causes of allergic reactions. Although reaction to the sulfite preservative is also believed to be rare,¹³⁵ allergic reactions to preservatives used in local anesthetics have been reported.^{136–138} Since preservatives are used only in local anesthetics containing a vasoconstrictor, the risk

of allergic reaction from this potential source can be eliminated by using an anesthetic without vasoconstrictor and preservative (e.g., 3% mepivacaine). Local anesthetic cartridges contain two potential sources of latex allergen that could possibly leach into the anesthetic solution—the rubber stopper and the diaphragm. A recent review of the literature found no case reports or controlled studies demonstrating that the latex present in a dental local anesthetic cartridge could cause an allergic reaction.¹³⁹ However, the same review found several case reports of allergic reactions attributed to trace amounts of latex found in other medication vial stoppers and intravenous tubing. Even though there is no strong evidence to support the avoidance of local anesthetic cartridges in patients with a known latex allergy, experts in the area have recommended using local anesthetic from glass-enclosed vials to avoid any potential risk of exposure to latex allergens.^{140,141} If it can be determined that the local anesthetic cartridge contains non-latex materials for the diaphragm and stopper, then there is no need for concern.

It should also be noted that a documented allergy to one type of amide local anesthetic does not necessarily imply allergy to all amide local anesthetics and often a readily available alternative can be found after testing.^{128,132} As a practical matter, patients referred for allergy testing should be given sample cartridges of at least two different local anesthetics so that the allergist can test with the same solution that will be used for dental treatment. Options for patients with a documented allergy to all commonly used local anesthetics include sedation, general anesthesia, electronic anesthesia,^{132,142} and injectable diphenhydramine. A solution of 1% diphenhydramine with 1:100,000 epinephrine can be compounded by a local pharmacist and used for infiltration or mandibular block injections. The dosage should be limited to a maximum of 50 mg at each appointment.¹²³

LATEX

Of the many materials used in the dental office with the potential for initiating an allergic reaction, natural rubber latex (NRL) is the most common.¹⁴³ Reports of allergic reactions to NRL began in 1987 coincident with the widespread adoption of universal precautions, including the use of latex gloves for practically all medical and dental procedures.^{144,145} Type IV sensitivity is the most common type and is related to the various chemicals used in processing NRL. The potentially much more serious Type I sensitivity to NRL is a reaction to proteins found in NRL. Approximately 6% of the general population is believed to have Type I sensitivity to

NRL and this number increases to as much as 17% for health care workers.¹⁴⁶ Urticaria is the most common initial finding in Type I sensitivity reaction to NRL.¹⁴⁴ Patients with a history of multiple surgeries (especially spina bifida) or atopy (multiple allergies) and health care workers all have an increased risk of sensitivity to NRL. Some food allergies (e.g., avocado and banana) are associated with an increased risk of latex allergy. Considering the multiple potential sources of exposure to NRL in the dental office (e.g., rubber dam material, gloves, local anesthetic cartridges, rubber mouth props, rubber tubing, and even some blood pressure cuffs), history of allergy to NRL requires special treatment modifications. In addition, clinicians who treat patients with known or suspected sensitivity to NRL should be prepared to provide initial management of an acute allergic reaction if necessary.

Consultation with the patient's primary care physician or allergist is advised to help assess the degree of risk, previous reactions and treatment, and possible premedication with a corticosteroid. All potential sources of NRL exposure in the dental office should be considered. Non-latex gloves and rubber dam materials are now readily available from commercial sources, and these items may be easily substituted for NRL-containing products. Since latex allergens can be transferred by contact with powder from latex gloves and other sources, it may be prudent to schedule the patient as the first of the day to decrease the chance of contact with residual latex allergens on environmental surfaces, clothing, and room air.¹⁴⁷ The potential for cross-reaction with gutta-percha in NRL-sensitive patients has not been demonstrated although caution should be exercised to avoid extrusion of any filling material beyond the confines of the root canal space (for more on this subject, please refer to section "Intracanal medications, cements, and filling materials"). Also, as previously discussed, the potential for reaction to latex allergens present in the local anesthetic cartridge stopper or diaphragm should be considered.

ANTIBIOTICS AND ANALGESICS

Allergy to penicillin is one of the most common drug allergies and affects approximately 2.5 million people in the United States.¹²³ Although many reported allergic reactions cannot be confirmed unless the patient is willing to undergo testing to rule out allergy to penicillin, it is safest to assume the allergy is real and select an alternative antibiotic. In the case of allergy to penicillin, it should be presumed that the patient is also allergic to the synthetic penicillins. In addition, cephalosporins show cross-reactivity in approximately 5% to 10% of penicillin allergic

patients.¹²³ Clindamycin is an appropriate alternative to penicillin for treatment of endodontic infections and bacterial endocarditis prophylaxis.^{54,148} Clarithromycin is another medication that can be considered. More information about antibiotic selection and dosage is found in Chapter 21, “Treatment of Endodontic Infections, Cysts, and Flare-Ups.”

NSAIDs are the usual drugs of first choice for management of endodontic-related pain and are tolerated well by most patients. However, caution should be used in prescribing NSAIDs in patients with asthma and/or known allergy or sensitivity to aspirin. Reports of allergy to codeine are most commonly related to gastrointestinal side effects rather than true allergy, although allergy to opioid analgesics does occur. If the patient’s history suggests an adverse reaction related to gastrointestinal distress (including nausea, emesis, or constipation), an alternative synthetic narcotic or a combination pain medicine may be considered. Analgesics are discussed in more detail in Chapter 22, “Management of Endodontic Pain.”

IRRIGATING SOLUTIONS

Sodium hypochlorite, in concentrations varying from 0.5% to 6%, is currently the most commonly used canal disinfectant and irrigating solution in endodontics.^{149–151} Sodium hypochlorite not only possesses excellent tissue solvent and antimicrobial properties but also demonstrates concentration-related tissue toxicity. Although an allergic reaction and/or hypersensitivity to sodium hypochlorite when used as an endodontic irrigating solution is rare, several cases have been reported.^{150,152,153} It has been suggested that some patients may be sensitized by exposure to household bleaching products.¹⁵⁰ Alternatives to sodium hypochlorite include sterile saline or water, chlorhexidine (0.2% to 2%), iodine potassium iodide (2% to 5%), hydrogen peroxide (3%), ethylenediamine tetraacetic acid (EDTA, 10% to 17%), citric acid (10%), and a recently introduced material, MTAD.^{151,154–157} Of these alternatives, iodine potassium iodide and chlorhexidine possess the potential for stimulating an allergic reaction. A recent review article provides an excellent overview of the relative advantages and disadvantages of these selected irrigating solutions.¹⁵¹

INTRACANAL MEDICATIONS, CEMENTS, AND FILLING MATERIALS

Intracanal medications such as formocresol, formaldehyde, eugenol, camphorated phenols, and cresatin are all known to be potential allergens.^{158,159} Fortunately, these canal medications are not frequently

used in current endodontic therapy. Calcium hydroxide paste, a commonly used intra-appointment medication, is not allergenic. Temporary filling materials containing zinc oxide and eugenol (ZnOE) have the potential for allergic reactions and, unlike materials contained exclusively within the confines of the root canal space, are likely to have contact with mucosal tissues.¹⁶⁰

Zinc oxide and eugenol, a potential allergen, is a common component of many root canal sealers and two common root-end filling materials (IRM and Super EBA). Sealers containing formaldehyde or paraformaldehyde (such as N2 paste and Endometazone), especially when extruded beyond the apex, have been demonstrated to stimulate often severe allergic reactions.^{161–164} Resin-based sealers such as AH26 and AHPlus also have the potential to stimulate an allergic response,¹⁵⁸ although this is believed to be rare. Calcium hydroxide-based sealers such as Sealapex or glass ionomer sealers such as Ketac-Endo could be reasonable alternatives for patients with known allergy to any of the components of ZnOE or resin-based sealers. As always, one should carefully read the list of ingredients since at least one sealer marketed as a calcium hydroxide-based sealer contains a significant ZnOE component.

Dentin-bonded resin-type root-end filling materials have demonstrated excellent biocompatibility in long-term clinical studies with no evidence of allergic reactions in treatment failures.^{165–167} However, the choice of resin filling material is important since some resins are known to release formaldehyde when setting. Mineral trioxide aggregate (MTA), a relatively new material used for root-end fillings, apexification, perforation repair, and pulp capping, has demonstrated excellent biocompatibility and no suspected allergic potential.^{168–170}

Although there have been case reports of suspected allergic reactions to gutta-percha in patients who were allergic to NRL,^{171,172} the possibility that the reactions were due to another material used in root canal treatment could not be ruled out. In fact, cross-reactivity between commercially available gutta-percha and NRL has not been demonstrated.^{173,174} In addition, gutta-percha is normally well contained within the confines of the root canal space and therefore should not have the potential to elicit an immune response. Gutta-percha manufactured for root canal treatment contains other ingredients such as barium sulfate, zinc oxide, waxes, and coloring agents; so potential allergy to any of these materials should be considered, especially if there is a potential for extrusion of filling material. Newer non-gutta-percha filling materials (e.g., Resilon) show promise but could be expected to contain many of the same added ingredients as commercially available gutta-percha. In patients

with multiple allergies (atopy) and suspected allergy to any of the components of gutta-percha, consultation with the patient's physician is advised. If safe use of the standard obturating material cannot be confirmed, one alternative is to fill the root canal space with MTA. This technique presents some technical challenges, especially in smaller canals, but should be manageable by an experienced clinician. MTA has a relatively long setting time (about 4 hours) but once final hardening has occurred, removal of the filling material through an orthograde approach is extremely difficult and is possible only in large, straight canals.

CHAPTER 25

DRUG INTERACTIONS AND LABORATORY TESTS

PAUL D. ELEAZER

Drug Interactions

Drug interaction discussions are often exhaustive, but may not be directed to probabilities of interactions clinicians are more likely to experience. Drug–drug interactions as well as some food–drug and herbal medicine–drug interactions that are likely to occur will be considered in this chapter. While dentists are not obliged to treat every patient, they cannot deny treatment based on a patient’s disability, such as a medical condition. Therefore, it is important to be prepared to treat patients taking multiple drugs by becoming aware of dangerous drug interactions.

The drug interaction information in this chapter is derived from the work of a panel of pharmacologists who factor likelihood of an interaction with severity of the possible reaction to arrive at a level of clinical significance.¹ Some less likely reactions with serious potential adverse results are also included. Certainly new reactions, some serious, will be discovered as more knowledge accumulates. On-line resources are available for updated information.^{2,3}

Principles of pharmacology and history taking can help the clinician determine probable risk for individual patients. Drug interactions can be classed as pharmacokinetic or pharmacodynamic. Pharmacokinetic reactions include changes of rate or extent of absorption, distribution, metabolism, or excretion. Pharmacodynamic drug interactions involve a change in the patient’s response without a change in drug plasma level.

An example of a pharmacokinetic absorption is the anti-diarrheal Kao-Pectate (kaolin and pectin) which decreases absorption of tetracycline antibiotics. An example of pharmacokinetic drug interac-

tion of distribution is epinephrine and β -blocker drugs competing for the same binding site on albumin. Metabolism-type pharmacokinetic interactions include the macrolide family of antimicrobials competing for the breakdown liver enzyme pathway with drugs such as Tagamet (cimetidine). Elimination drug reactions include the competition of methotrexate and nonsteroidal anti-inflammatory drugs (NSAIDs) for removal by the kidney.

An example of pharmacodynamic reaction is ethanol and a benzodiazepine combining to increase central nervous system (CNS) sedation without a detectable difference in plasma levels in either of the drugs from their levels if administered alone.

Interviewing the patient may provide valuable clues about possible drug reactions or interactions. When drug action is plotted against response in a large patient population, the graph is almost always a bell-shaped curve, meaning that a few patients develop an exaggerated response and some show very little effect. Most people have the expected response. If a patient has a history of over- or under-response to a drug, the clinician should be alert to a similar response. Drug interactions for members of the same drug class are likely to be analogous, but there are exceptions. A second major consideration in history taking is the possibility of inaccurate reporting by the patient. Such may be the case with a patient who denies a medical problem based on a sense of bravado or one who vainly wants to postpone admission of the encroachment of age. Furthermore, patients may simply forget important details of their drugs or dosages. Also, many lay persons who are not well versed in medical conditions may not grasp

the importance of reporting all their specific conditions or chronic medications.

Some authors have suggested that generic medications may not be as effective as brand name drugs, especially for certain categories of drugs. An example of this is illustrated by the discovery of imperfections with enteric coatings that would not protect the medication from adverse effects of acidic stomach contents.⁴

The prudent practitioner should observe drug interaction reports for newly introduced drugs and be cautious about prescribing these drugs until sufficient time has elapsed to elucidate all reactions. Often, drug interactions are discovered after a drug is introduced to the market, even though many lab tests, animal tests, and human trials were performed before release of the drug for sale. An example of such a situation is the drug ketorolac (Toradol). It was found very effective in controlling postoperative dental pain and was widely prescribed before being associated with stomach and kidney problems that eventually lead to withdrawal of the oral form from the market, except for brief follow-up to parenteral use.⁵

Dentists are fortunate in that they seldom need to prescribe drugs for chronic use. Brief exposure limits drug interactions and side effects compared to long-term use. Even so, some important drug interactions occur rapidly.

For many drug interactions, the net result is simply a change in reaction to one or both drugs. The change can be an increased response or a decreased effect. Sometimes, a combination of drugs results in an unexpected interaction. An example of a surprising increased drug effect occurs when administering benzodiazepine drugs to patients taking the calcium channel blocker diltiazem (Cardizem). The combination causes little change to diltiazem action, but results in a rapid increase in benzodiazepine sedation, apparently because the calcium channel blocker decreases metabolic breakdown of the benzodiazepine. In one study, the area under the curve of drug concentration over time for a benzodiazepine was nearly tripled.⁶

Individual variation plays an important role in much of what we know about drug interactions. Generally, those affected more are the elderly, whose metabolic systems are less robust. Often, those with chronic systemic disease, and those taking multiple medicines, are more likely to have drug interactions, perhaps because unknown reactions may be at work. Patients taking herbal med-

icines and those on atypical diets also may be more likely to have an unexpected drug reaction.

Some patients may not be greatly affected by a drug interaction and might not report it to their prescribing doctor. Even among observant patients, the number of dramatic drug interactions that affect every patient every time is probably very low. This inconsistency of effect may allow the practitioner to gain confidence in prescribing drugs if they see their patients having no problems. Even for a specific individual, past experience with combining drugs is no guarantee of safety.

The most serious reactions of concern to dentists are listed in Tables 1–12. With theophylline, the margin between therapeutic dose and toxic level is narrow. With international travel now commonplace, drugs removed from the market in one country may be brought in from another, making the need to know overseas trade names as well as the generic labels. Such is the case with non-sedating antihistamines astemizole (Hismanal) and terfenadine (Seldane), which can cause life-threatening *torsades de pointes* cardiac arrhythmias if combined with macrolide antibiotics.

Systemic epinephrine can adversely affect a patient without drug interaction by increasing anxiety and causing frightening tachycardia. Keeping the local anesthetic in the local area minimizes the possibility of drug interaction. However, Lipp et al.⁷ experimented with labeled epinephrine and found a 22% incidence of intravascular injection without positive aspiration, meaning that the clinician should not derive a false sense of security from a lack of aspiration of blood during an anesthetic injection. Avoidance of systemic interaction can best be assured by slow injection with observation of the patient for signs of systemic injection of epinephrine, such as pallor, tachycardia, and anxiety.

The concept of decreased drug effect of oral contraceptives by orally administered antibiotics has received attention in the lay press. Careful research has led to the belief that antibacterial drugs commonly used by dentists are very unlikely to cause a failure in oral contraception. Research suggests that the antifungal drug ketoconazole and the anti-tuberculosis drug rifampin may have an effect on oral contraceptives. It is prudent for clinicians to suggest alternative methods of contraception to female patients of childbearing age because birth control pills are not 100% effective and because of the misinformation in the lay press.

Over-the-counter drugs can cause drug interactions of concern to the dentist. Herbals can also cause drug interaction problems. One problem with herbals is that many patients consider them to be dietary supplements and fail to report that they are taking an herbal. Recent study has elucidated many drug interactions with herbals.

Dentists commonly use antimicrobial drugs, pain relievers, and local anesthetics. Antimicrobial drugs have eliminated many risks of life. The first true antibiotic, penicillin, came into common use among dentists following World War II. Because so many patients have taken antibiotics, it is a little wonder that many drug interactions have been identified.

Tetracyclines were developed after penicillin. As they were gaining in popular usage, penicillin drugs were undergoing structural changes to offer different forms to counter antimicrobial resistance. Erythromycin, the original macrolide antibiotic, was introduced after tetracyclines. For a time, erythromycin was widely popular among dentists, who chose it because there was no risk of anaphylactic reaction and because antibiotic resistance to this drug originally seemed to be a limited problem. While severe allergic problems have not arisen, bacterial resistance and serious drug interactions have limited use of erythromycin and its congeners, clarithromycin (Biaxin) and azithromycin (Zithromax). The many drugs now known to interact with macrolides do so because of shared metabolic pathways that delay metabolism. Higher levels of one or both drugs commonly result in severe cardiac rhythm problems, some life-threatening. Surprisingly, even anti-arrhythmic drugs may cause such arrhythmias when administered with macrolides. One should note that combinations do not always cause a predictable reaction, meaning that prescribing a certain dose for a particular individual without untoward reaction does not guarantee a similar result for subsequent prescriptions.

Severe muscle wasting serious reactions may occur with macrolides when combined with "statin" drugs, very commonly used for lowering cholesterol. These drugs inhibit HMG-CoA reductase, a key enzyme in the production pathway of the "bad" or low density cholesterol. Muscle aches are among the first symptoms that can occur with the drug alone, but occur much more often when the macrolide antibiotic effectively increases its concentration by impeding metabolism through their common liver pathway. The symptoms may

take a few days to appear. Damaged muscle leads to increased creatine phosphokinase enzyme levels, which are typically used to confirm a clinician's suspicion of this potentially very serious drug interaction. Early reports question whether rosuvastatin (Crestor) is subject to this interaction.⁸

Ergot derivatives, which mitigate vascular headaches, may interact with macrolide antibiotics, inducing peripheral ischemia secondary to vasospasm. Not all patients respond to reversal therapy for this drug interaction, making this a very serious potential problem.

Yet another category of classic interaction with drugs slowing metabolic pathways occurs with macrolides. To reach therapeutic levels, theophylline is often administered in doses close to the toxic threshold. When paired with erythromycin, the decreased elimination may push the concentration of the bronchodilator into the danger zone. Obviously, the higher the patient's therapeutic dose, the greater the risk. Early studies indicate azithromycin probably acts similarly, while clarithromycin may not.^{9,10}

Table 1 contains more serious and more probable reactions of drugs with macrolide antibiotics. Dentists who prescribe macrolides should maintain vigilance for signs of any interaction.

Table 2 ranks potential reactions to metronidazole (Flagyl), a drug many dentists prescribe. This drug's antibacterial spectrum is for obligate anaerobes, but some obligate anaerobes are resistant. Clinicians often use this DNA impeding agent with a penicillin or cephalosporin bactericidal drug. Research has shown that most endodontic infections contain multiple organisms, characteristically with many facultative microbes.¹¹ Outcome analysis of microbial susceptibilities of cultures from endodontic infections shows that metronidazole alone is not effective for these infections.¹²

Metronidazole shares the adverse interaction of anticoagulant drugs with all antibiotics. By killing normal gut flora, the production of vitamin K decreases, thus altering the balance between the normal clotting enhancing vitamin and the clot-preventing anticoagulant. The result is that a clinical bleeding problem is more likely. Metronidazole has an additional interaction of importance to the clotting balance. It further increases bleeding proclivity by a direct inhibition of metabolism of warfarin (Coumadin).¹³

Also of note, metronidazole shows interaction with ethanol, just like with disulfiram (Antabuse),

Table 1 Potential Reactions between Macrolide* Antibiotics and All Drugs

Rapid Reactions	Delayed Reactions
Very significant Established reaction ▲ Carbamazepine (Tegretol) (→ toxicity) (76b)	Established reactions ▲ Cisapride (Propulcid) (→ arrhythmia) (192) ▲ Digoxin (→ toxicity) (285a)

resulting in nausea and vomiting in many patients. The clinician should caution patients to avoid ethanol while taking metronidazole and for 1 full day thereafter to ensure no untoward drug interaction. Another drug interaction of metronidazole is, when combined with Antabuse, patients taking metronidazole have experienced acute psychotic reactions.

Table 2 Metronidazole* (Flagyl) and All Drugs

Rapid Reactions	Delayed Reactions

It also may cause nausea if combined with ethanol or disulfiram (Antabuse), but reaction is inconsistent. ▼ Drug action is probably diminished. ▲ Drug action is probably increased.	

Except for potentially fatal allergic reactions (anaphylaxis), the penicillin family of antibiotics, and the cephalosporins, have remained relatively free of serious drug interactions (Table 3). The penicillins are very effective against common endodontic pathogens.¹² Most cephalosporins are not

Table 3 Penicillins/Cephalosporins and All Drugs

Delayed Reactions

effective against the strict anaerobes found in endodontic infections. There may be cross-allergenicity between penicillins and cephalosporins.

Methotrexate, a powerful anti-metabolite for some types of cancer and for refractory arthritis patients, combined with penicillin has caused severe toxicity, including renal failure, myelosuppression, neutropenia, thrombocytopenia, and skin ulcers. Cephalosporins have not been reported to cause this drug interaction.

Quinolone antibiotics have potential to cause severe interactions with several drugs (Table 4). As with macrolides, quinolones cause serious cardiac rhythm problems in the presence of many other drugs. The macrolide–quinolone combination is one of the drug interactions that can cause fatal arrhythmias. Macrolides or quinolones plus

cisapride (Propulcid) may interrupt normal nerve impulse conduction within the heart that may threaten life. Yet another problem that quinolones have is the drug interaction with theophylline. The shared metabolic pathway similarly causes theophylline concentrations to increase to toxic levels. These similarities occur even though the molecular structures of the two drug classes are quite different.

Coumadin plus a quinolone may produce a cardiac rhythm problem.¹⁴ All antibiotics can cause bleeding problems for patients taking anticoagulants because the antibiotic kills gut flora that produce vitamin K, a natural substance that enhances clotting. Lack of this balance means patient takes longer to clot. When healthy patients take an antibiotic, the reduction in vitamin K causes no clinically apparent change in clotting parameters. The well-informed dentist should be able to evaluate blood clotting tests such as bleeding time and International Normalized Ratio (INR) with the patient's physician.

Tetracyclines have seen resurgence in popularity among dentists because of their actions against collagenase and their effectiveness against periodontal pathogens, many shared with endodontic diseases. Both of these advantages carry over into endodontics. While there is a long list of drugs that interact with tetracyclines, the reactions tend to be inconsistent and are rarely life-threatening (Table 5). The digoxin–tetracycline interaction arguably has the most serious potential. In a small portion of the population, the gut flora metabolizes a significant percentage of their digoxin dose, meaning that they need a fairly high dose to achieve the proper steady-state digoxin level.

▼ Drug action is probably diminished.
▲ Drug action is probably increased.

Tetracyclines can induce significant microflora changes, such that greater digoxin absorption leads to toxic levels. As noted above, macrolides interact with digoxin in a different way, inhibiting renal excretion of digoxin, also reaching potentially toxic levels, and this change can last for many days after macrolide is stopped.

While it may be nice to contemplate treating endodontic patients without antibiotics, such is an unrealistic dream. No antibiotic is without potential interaction with other drugs. The rapid discovery of new interactions mandates that those who treat infected patients keep abreast of contemporary information.

Pain control drugs fall into a similar situation. Certainly, modern endodontic techniques and better appreciation of the value of “not” harming tissues adjacent to root canals have helped reduce the need for pain-relieving drugs. Yet, postoperative pain will remain a factor in treating some endodontic maladies. Clinical experience of many dentists reinforces the experimental observations that NSAIDs are effective pain relievers. Most practitioners find NSAIDs as effective as codeine or hydrocodone for most patients. Chronic NSAID use has revealed stomach and kidney problems, especially among the elderly, but only a few problems have been associated with short-term use.

Serious drug interactions with NSAIDs are relatively rare (Table 6). The effect of Coumadin is potentiated by NSAIDs. The prescription of NSAIDs for only a few doses limits the clinical appearance of this interaction. But a very serious

NSAID reaction is with methotrexate, resulting in kidney failure. This reaction is more likely with high-dose methotrexate, typically used for anti-neoplastic therapy, as opposed to the lower doses used for rheumatoid arthritis refractory to less powerful drugs.

Patients taking β -blockers may experience hypertension breakthrough when taking NSAIDs. Sulindac (Clinoril) apparently does not have the propensity to cause this reaction.¹⁵

Lithium toxicity induced by adding NSAIDs has occurred. The decrease of lithium metabolism has not resulted in clinical problems in healthy patients.¹⁶

NSAIDs and the very popular antidepressants that work by selective serotonin re-uptake inhibition (SSRI) drugs within brain synapses can interact adversely. Increased gastrointestinal (GI) bleeding has been reported, although the problem has also occurred when an SSRI drug was used alone.¹⁷

Narcotic pain relievers will continue to play a useful role for dentists, albeit less necessary because of improved understanding and better instruments and techniques. Demerol (meperidine) is the most troublesome for potential interactions. The most serious, sometimes resulting in death, is less likely now because oxidase inhibitors are rarely prescribed. Other reactions are listed in Table 7.

Control of intra-operative pain is a standard by which patients judge their endodontic caregiver. Pilots are judged by how smoothly they can land a plane even though this is a small part of a pilot's skill. Similarly, patients judge us by our skill at giving an “easy shot.”

There are two separate drug interaction considerations with local anesthetics, the anesthetic itself

Note that death has been reported from giving Demerol to Manomine oxidase (MAO) inhibitor patients.

*Most reactions are due to additive central nervous system effects.

and the vasoconstrictor. Epinephrine is very rapidly metabolized, so any drug interaction is rapidly apparent (Table 8). Tolerance of the vasoconstrictor in one dose means that an additional dose after about 5 minutes can be given with similar result, given that neither is injected systemically.

Hypertensive events have been documented in patients taking β -blockers, Furazolidone (Furoxone) tricyclic antidepressants, methyl dopa, and the anti-hypertensive drugs guanethedine (Ismelin) and Rauwolfia alkaloids. Beta-blocker interactions are potentially the most serious. It is advisable to take a preoperative blood pressure reading to establish a baseline for that patient. Furthermore, intravascular injection occurs without a positive aspiration of blood.⁷

The anesthetic itself does not cause any known very serious drug interactions (Table 9). The problem with the anesthetic is that repeated injections build to overdose levels because, unlike the very rapidly metabolized vasoconstrictor, the anesthetic agent is metabolized over hours. This is especially important for pediatric patients whose body mass cannot tolerate as much anesthetic as an adult.

Beta-blockers may interact with lidocaine, lowering the number of doses to reach the toxic range. This drug interaction is believed to be via inhibition of hepatic metabolic enzymes.¹⁸

Cimetidine (Tagamet) increases lidocaine levels too, probably by the same general effect on liver

enzymes. Yet, the reaction does not occur every time the drugs are combined.¹⁹ Research on other histamine H2 antagonists failed to show this interaction.

Benzodiazepine reactions are typically one of the increased drug effects and can be accounted for by beginning with a lower dose, perhaps a half pill, until the patient's own reaction is defined. The protease inhibitor reactions however have been reported to induce severe sedation and respiratory depression. As noted in Table 10, no drug interactions with benzodiazepines have been ranked in the very significant category.

Table 11 lists drugs that may be used by dentists that interact with Coumadin (warfarin). This extensive list calls for careful consideration by the

Table 10 Benzodiazepine* and All Drugs

Rapid Reaction Delayed Reaction

Somewhat less significant	
Established reactions	Suspected reactions
Ethanol (325)	Carbamazepine (Tegretol) (123a)
Azole antifungals (122b)	Hydantoin (Dilantin) (375)
	Modafinil (Provigil) (131b)
	Non-nucleoside reverse transcriptase (131d)
	Inhibitors
	Protease inhibitors (133)
	St. John's Wort (136a)
	Macrolide antibiotics (131a)
	Rifampin (136)
Probable reactions	
Diltiazem (Cardizem) (128)	
Food (129b)	

Numbers in brackets indicate page number in *Facts and Comparisons Drug Interactions*.¹

*In most reactions, benzodiazepine effect is increased, but decreased with Rifampin. Generally, titration of dosage is indicated.

Table 11 Drugs Prescribed by Dentists That May Interact with Warfarin Anticoagulant**Delayed Reactions**

Very significant

Established reactions

- Sulfonamides, bleed (98)
- Metronidazole, bleed (82)
- Vitamin E, bleed *(197a)
- Aspirin (ASA), bleed (94)

Probable reaction

- NSAIDs/(86a) CoX₂ inhibitors (86b) = bleed
- Quinolones = bleed (92)
- Macrolides = bleed (79)

Somewhat less significant

Established reaction

Suspected reactions

- Acetaminophen = ▲ vitamin K, thus ▼ bleed (39)
- Carbamazepine (Tegretol), ▼ bleed (50)
- Vitamin K = ▼ bleed (109)
- Most antibiotics kill vitamin K bacteria = bleed (51, 89, 92, 47, 82, 93, 98)

NSAIDs, nonsteroidal anti-inflammatory drugs. Numbers in brackets indicate page number in *Facts and Comparisons Drug Interactions*.¹ Most drug interactions result in increased bleeding. Tylenol, Tegretol, rifampin, and vitamin K increase bleeding. The Tylenol reaction is apparently not consistent and, if reported, exceeded six doses/week. Vitamin K reverses the action of warfarin. However, there is currently no antidote for Plavix. ▼ Drug action is probably diminished. ▲ Drug action is probably increased.

dentist and alerting the patient to watch for signs of bleeding. Notably, the rapid reaction category is empty, indicating that short-term use carries less harmful potential.

Drug Interactions with Food and Herbals

Many patients are now taking herbal medicines, yet consider them as harmless food supplements. Table 12 lists more serious interactions with prescription drugs that should be reviewed (the table is derived from the panel of experts described in the beginning of this chapter). Facts and comparisons herbal supplements and food publication ranks potential interactions into only three categories, of which the more serious two are included.²⁰ However, many new drug interactions with herbals and food are currently under study and the fact that more people are now taking herbals means that more interactions will be elucidated.

Grapefruit–drug absorption interactions account for many newly discovered drug level changes.

Table 12 Drugs Prescribed by Dentist That May Interact with Herbal Medicines**Significance levels**

1	Amoxicillin + Khat → ▼ amoxicillin (85, 86)
1	ASA or NSAIDs + Ginkgo biloba → bleed by platelet aggregation) (19, 20)
1	Benzodiazepines + Kava → ▲ benzo levels (sedation) (84)
	Benzodiazepine + St. John's Wort → ▼ Benzodiazepine (sedation)
2	Corticosteroids + Licorice → ▲ corticosteroid (87)
1	Ciprofloxacin + Calcium-supplemented orange juice → ▲ Cipro (95a) ↓ antibiotic absorption
1	Cipro + Zinc → ▲ Cipro (154ba) ↓ antibiotic absorption
1	Acetaminophen + Ethyl Alcohol → Hepatotoxic Metabolite (14e)
1	Macrolide antibiotics + Grapefruit → ▲ absorption of macrolide (toxicity) (44a)
2	Tetracycline + Zinc → ▲ tetracycline ↓ antibiotic absorption
1	Tetracycline + dairy products → ↓ Tetracycline due to chelation (12a–12d)
	Levofloxacin + orange juice (plain or with ca ⁺⁺) → ↓ Levoflox (95f)

Numbers in brackets indicate page number in *Facts and Comparisons Drug Interactions*.¹

Significance level 1 = herbal drug should not be combined. Significance level 2 = herbal drug may be continuously allowed.

▼ Drug action is probably diminished.

▲ Drug action is probably increased.

Apparently, this citrus fruit speeds absorption far more than other similar fruits. The result can be damagingly high levels of drug, even in the absence of other drugs. This action contradicts the typical finding that food binds with drugs to decrease absorption, or at least slows drug absorption.

Khat is a stimulant plant from East Africa that is usually chewed. It has been imported into the United States and other counties as a recreational euphoric agent. It sometimes is smoked to achieve higher concentrations, which may induce hallucinations. Khat has been shown to decrease absorption of amoxicillin and its close congener, ampicillin. This may lead to persistence of an infection. A small study demonstrated the maximum decrease to occur 2 hours after chewing khat.²¹ Other potential drug interactions with khat have not been investigated thoroughly.

Ginkgo biloba, which is commonly used as a memory enhancer, interacts with salicylates and NSAIDs to increase bleeding. The apparent mechanism is by lowered platelet aggregation.

Kava, an herbal drug from the South Pacific plant of the same name, is drunk as a tea or now available in pill form to relieve stress and produce a sense of well-being. A single, but serious drug interaction-induced coma has been reported. While the reaction occurred when combined with alprazolam (Xanax), experts anticipate that the danger likely extends to the entire benzodiazepam family.²²

Another herbal anxiolytic–benzodiazepine interaction has been anticipated, but not yet reported, between a benzodiazepine and the weed-derived St. John's Wort. Experimental evidence demonstrated that the combination of the herbal and clonazepam (Klonopin) decreased the benzodiazepine levels.²³

Licorice has been shown to alter levels of corticosteroids, either increasing or decreasing the drug.²⁴ The interaction would be more serious in patients on high-dose steroid. No evidence exists yet as to exact mechanism of the interaction or about any potential problems with natural steroid drugs or overall action on inflammation or healing.

Orange juice, particularly when calcium-fortified, lowers the levels of the fluoroquinolones Cipro (ciprofloxacin) and Levaquin (levofloxacin). While the exact mechanism is unknown, the suspicion is that the orange juice and the drug compete for transportation across the intestinal membrane.²⁵

Cipro absorption is also diminished in the presence of zinc, as are tetracycline concentrations. This essential heavy metal additive is common in multivitamin preparations. The net result of the interactions is lowering of antibiotic levels in the 25 to 40% range.^{26,27}

Tetracycline absorption is also hindered by dairy products, which all contain the heavy metal ion calcium. Doxycycline is the least affected of the tetracycline family to bind with heavy metal ions, a process called chelation.²⁸

Ethyl alcohol is discussed in "Drug Interactions", but there is a brief review in here.²⁰ Perhaps, because it is so often used or abused among patients, alcohol is sometimes considered a food. Generally, its interactions are to increase action of drugs that act on the CNS. It delays gastric emptying, so can delay absorption of almost any drug taken by mouth. It specifically interacts with metronidazole in a disulfiram class reaction, inducing nausea and vomiting. All the above reactions are dose related, so the astute clinician should caution patients accordingly. The interaction with Tylenol (acetaminophen) is different and potentially lethal. Chronic use of ethyl alcohol increases the enzyme that metabolizes acetamino-

phen, resulting in the rapid metabolism of acetaminophen with consequent high levels of a toxic acetaminophen metabolite, known as NAPQI, N-acetyl-p-benzoquinone.

Lab Tests of Potential Importance in Endodontics

Dentists may be uncomfortable in ordering laboratory tests. Referral to a physician is always appropriate, but there is no reason for a dentist to be intimidated by the process. Dentists are often the first healthcare provider to identify systemic disease. Frequently, this is the case because oral tissues are the first to be affected. Also, many patients do not regularly visit their physician, or many receive only cursory information on subtleties of oral changes from disease. Leukemia, bacterial endocarditis-induced oral petechiae, bleeding disorders, various cancers, and many other diseases are first suspected in the dental office. Ordering a laboratory test to confirm or rule-out suspicions is perfectly appropriate for any dentist. Culture and sensitivity testing for identification of the cause of an infection and the most likely effective antimicrobial should be in every dentist's armamentarium.

Laboratory tests are commonly helpful to dentists. The list of lab tests commonly helpful to dentists is not exhaustive, and dentists should not be limited to those tests listed below. Disorders of inflammation, perhaps related to a chronic dental infection, may cause an increased erythrocyte sedimentation rate. Blood tests can be helpful in identifying blood dyscrasias from cellular imbalances to inflammatory system evaluation and to clotting factors. Most classic hemophiliacs are diagnosed early in life and can provide the dentist with important information by history. Every dentist should be aware of the risks associated with altered blood clotting profiles of their patients. Newly identified risk assessment studies have shown the mortality and morbidity of decreasing anti-clotting parameters. The dentist should be comfortable in interpreting these tests to determine if a patient is a candidate for a surgical procedure.

The prothrombin time test has been largely replaced by the INR, which uses a standardized control and expresses the result in a percent of normal clotting time. This test evaluates the extrinsic clotting mechanism. With an INR of 1 being the

normal level, minor dental-alveolar surgery can be carried out to an INR level <3.5 with local methods of hemostasis sufficing. For other than minor surgery, consultation should be obtained with consideration for modification of the anticoagulation or hospitalization.

The partial thromboplastin time test remains valuable to determine the intrinsic clotting pathway, which is the clotting factors in blood plasma.

Bleeding time, the number of minutes required for a standard wound to clot, may help diagnose later onset problems of importance to the dentist such as von Willebrand's disease, where the intrinsic factor VIII is diminished by this hereditary defect. Also, bleeding time identifies disorders of the platelet system, including those induced by salicylates or NSAIDs.

Complete blood counts enumerate platelets, different white blood cells, and red blood cells and can confirm or rule out many suspicious findings. An increased number of red cells, polycythemia vera, can reveal itself as darker gingival, because of the engorgement of the vascular system. Bleeding gingival can be seen in many forms of leukemia. Petechiae due to sickle cell anemia can be diagnosed by the occasional characteristic shaped red blood cells.

While it is easier to direct patients and staff who are accidentally exposed to blood-borne pathogens to someone trained in counseling for such risks, tests for such infectious agents may be ordered by the dentist who suspects a disease.

Patients with unexplained radiolucencies of their jaws may need testing for certain disorders. For example, a multiple myeloma patient will have the abnormal Bence Jones protein in their urine. A patient with hyperparathyroidism-caused bone radiolucencies will have elevated blood calcium and decreased blood phosphorus. Urine levels of calcium may be lower, with increased urine phosphorus. Serum alkaline phosphatase is elevated in hyperparathyroidism, although not as markedly as with Paget's disease.

Diabetes mellitus has broad implications in healing. Blood or urine glucose elevations can be the impetus needed to send a patient for medical care.

Allergies can make life unpleasant for many. They may stem from food allergies which can cause nutritional imbalances which may be suggested by changes in oral tissues. They may include dental materials, such as nickel or eugenol, making the patient less likely to have a favorable treatment

outcome. The dentist who suspects such a problem will probably refer the patient to an allergist for skin or other tests and then help manage the dental aspects of the patient's care.

Summary

There is a limited understanding of drug interaction incidence because of under-reporting. Also, animal studies may not transfer directly to the human. Animals cannot express mood changes effectively and there are some metabolic differences between animals and man.

The astute clinician should explain possible adverse or undesirable reactions with patients so that they may watch for an adverse outcome. This chapter emphasizes drug reactions that are potentially very serious and/or very likely to occur. Some practitioners will see interactions of drugs beyond those covered here. It is important to report suspected drug interactions to the Food and Drug Administration (FDA) for evaluation. The FDA periodically sends information about newly discovered serious drug interactions to practitioners registered by state license to practice dentistry. Furthermore, the reader should remember that information about drug interactions is constantly changing, mostly with newly discovered interaction reports.

CHAPTER 26

ENDODONTICS INSTRUMENTS AND ARMAMENTARIUM

A. DENTAL DAM AND ITS APPLICATION

WILLIAM G. SCHINDLER

It may be difficult, if not impossible, to achieve a sterile field in endodontics; however, every effort should be made to work as much as possible in a bacteria-free field. That being said, *the use of dental dam is absolutely essential during nonsurgical endodontic therapy.* For root canal treatment, rapid, simple, and effective methods of dam applications have been developed. In all but the most unusual circumstances, the dental dam can be placed on the tooth being treated in less than a minute. Its routine use will enhance every aspect of endodontic therapy.

Although the modern nonsurgical endodontic approach to the use of dental dam has changed, the importance and purposes of the dam remain the same:

1. It provides a dry, clean, and disinfected operating field removed from saliva and blood.
2. It protects the patient from possible aspiration or swallowing of tooth debris, restorative materials, bacteria, necrotic pulp tissue, and instruments¹⁻³ (Figure 1).
3. It protects the adjacent soft tissues (tongue, lips, cheek) by retracting them out of the way.
4. It protects the patient's soft tissues from irritating irrigating solutions and drugs that may be used during treatment.
5. Visibility and efficiency are improved.
6. Its routine use protects the clinician from litigation related to instrument aspiration or swallowing. Even swallowing diluted sodium hypochlorite can be dangerous in addition to it having an unpleasant taste.⁴ *Use of dental dam for nonsurgical endodontics is the standard of care.*⁵

The clinician should be aware that there may be rare instances when coronal access to root canals might be

made prior to the placement of the dental dam. Examples of this situation may include severe tipping of teeth, extreme calcification of the canal system, and orientation difficulties related to coronal restoration. However, once the chamber or canals have been located and before instruments or irrigating solutions have been used, the dental dam must be placed.

Equipment

DAM MATERIAL

Dental dam is available in a variety of thicknesses, colors, sizes, and material. The medium-weight thickness is highly recommended for general all-around use. It has the advantage of nicely adapting to the cervical area of the tooth, providing a fluid seal without the use of floss or ligature ties around each tooth. Also, it does not tear easily and provides more protection from injury to the adjacent soft tissues and increased visibility than does the thinner material. There are, however, some advantages in the use of thin-weight dam material on mandibular anterior teeth and partially erupted posterior teeth. These teeth have very little bulk of contour and the thinner material will exert less dislodging force on the clamp. The disadvantage is that it is easily torn.

Dam materials may be purchased in precut 5" × 5" (127 mm × 127 mm) or 6" × 6" (152 mm × 152 mm) sheets. The choice of light- or dark-colored material is largely up to the practitioner. Darker material provides a contrasting color as a background for the light-colored tooth.

Figure 1 **A**, Swallowed endodontic file ended up in the appendix resulting in acute appendicitis. **B**, Specimen shows file in the appendix removed by appendectomy. Use of dental dam would have prevented this complication. **C**, Dental burs can sometimes disengage from hand pieces and be swallowed, as shown here. This is also preventable with dental dam. (**A** and **B**, Reproduced with permission from Thomsen LC, Appleton SS, Engstrom HI. Appendicitis induced by an endodontic file. *Gen Dent* 1989;37:50.)

Dental dam is available in latex or non-latex material. With the apparent increasing incidence of patients allergic to latex, non-latex dental dam must be available in all offices.^{6,7} Latex-free dams are available (Coltene Whaledent, Inc., Cuyahoga Falls, OH) and supplied in a powder-free, 6" × 6", medium thickness. In an emergency, non-latex glove material can also be used (Figure 2).

PUNCH

Any dental dam punch that is convenient for the operator and creates a sharp, clean hole in the dam material is satisfactory. All too often the punch has

not been correctly centered over the hole, and a "nick" on the cutting margin results, producing an incomplete jagged cut in the dam material. This results in a poor seal at the time of placement and may make the dam susceptible to tearing.

FRAMES

In addition to supporting the dam, frames should be radiolucent to prevent obstruction of an important area on radiographs that are taken during treatment. There are a variety of dental dam frames that meet this requirement. The U-shaped Young's frame is made of radiolucent plastic for endodontic

Figure 2 Latex-free barrier dams must be used for patients sensitive to latex; in this case a latex-free glove was cut up and used as a barrier.

Figure 3 The U-shaped Young's dental dam frame is an example of commonly used frames.

applications. It is easily manipulated and is used widely (Figure 3). The Nygaard-Østby (N-Ø) dental dam frame (Coltene Whaledent, Inc.) is shield-shaped to

fit the face, is made of radiolucent nylon, and may be in place while a tooth is subjected to X-rays without interfering with the radiographic image.

An articulated frame developed to facilitate endodontic radiography (Figure 4) is also curved to fit the face. It is hinged in the middle to fold back, allowing easier access for film and sensor placement. Derma-Frame (Ultradent Products, Inc., South Jordan, UT) is a soft metal frame that may be formed to fit the

patient's face. The frame retains its configuration but may then be reshaped after use.

Recently, several dental companies have introduced disposable, single-use, pre-framed dental dams. The HandiDam (Figure 5) and the InstaDam (Zirc Co., Buffalo, NY) allow the clinician to quickly apply the

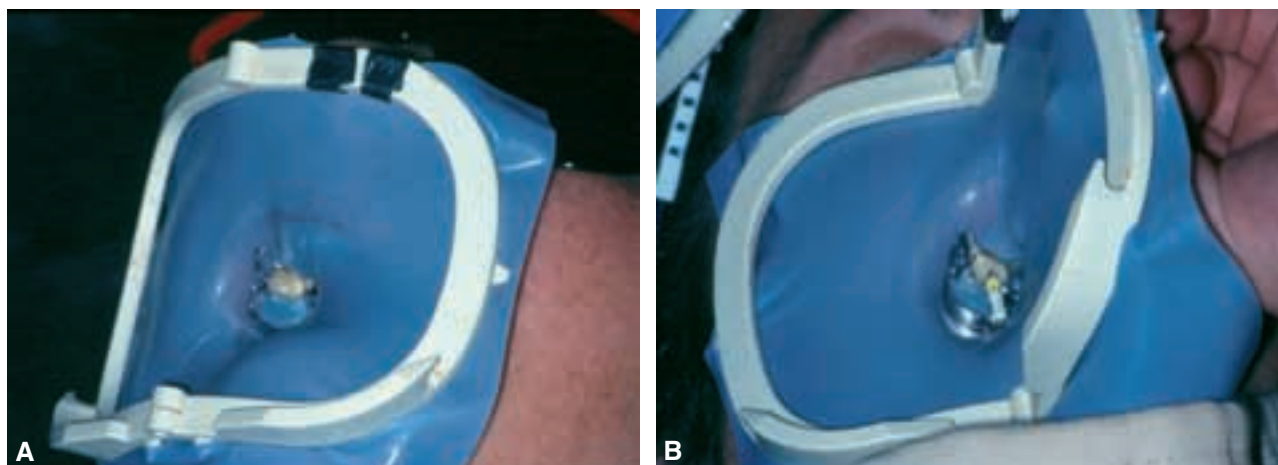

Figure 4 Hinged dental dam frame. **A**, In closed position, frame is curved to fit face. **B**, Open position, from either side, allows passage of radiographic film holder.

Figure 5 Frame and dam combinations such as the HandiDam (Asepticco, Inc., Woodinville, WA) allow convenient placement of a dental dam barrier for single teeth; the material is available both in latex and latex-free.

Figure 6 There are a variety of clamps available for all situations, including plastic clamps.

dam without the addition of a conventional frame. Both of these innovative devices are available in latex and latex-free versions.

CLAMPS

The dental dam clamp secures the dam to the tooth and helps in soft-tissue retraction. Although the selection of five to seven clamps will permit the clinician to isolate the majority of teeth treated, the experienced operator will expand that number. Teeth that are rotated, partially erupted, fractured, unusual in crown form, or with severe carious involvement all present problems requiring special clamps or clamping techniques. There are a variety of clamps available to meet any clinical situation that may arise (Figure 6). Table 1 lists a suggested assortment of metal clamps for various teeth.

For endodontic treatment particularly, the use of clamps with wings allows a more rapid, efficient means of applying the dental dam. The wings allow the dentist to place the clamp, dam, and frame in one operation (Figure 7). In addition, the wings cause a broader buccal–lingual deflection of the dam from the isolated tooth, thus allowing increased access. One disadvantage of the use of winged clamps is that the wings may occasionally interfere with radiographic interpretation of file or master cone positioning.

Plastic clamps (Moyco/Union Broach, York, PA) are also available in two sizes, large and small, and are used in selected cases. When metal clamp obstruction is a problem, radiolucent plastic clamps allow for an unobstructed film-view of the tooth.

FORCEPS

Either the Ash- or Ivory-style clamp forceps is acceptable. One advantage of the Ivory forceps, however, is

Table 1 Dental Dam Clamp Selection

	Clamps
Maxillary teeth

Premolars	0, 2, 2A, W2A
Molars	3, W3, W8A, 14, 14A
Mandibular teeth	
Incisors	6, 9, 210, 212
Canine	6, 9, 210
Premolars	0, 00, 2, W2A
Molars	3, W3, W8A, 14, 14A

Figure 7 Winged clamp, dental dam, and frame ready for placement on tooth. Bow of clamp is oriented to the distal.

the projections from the engaging beaks. These allow the clinician the opportunity to exert a gingivally directed force, which is often necessary to direct the clamp beyond the bulk of contour and into proximal undercuts. The Ash-style forceps beaks, however, afford a fulcrum point for posterior or anterior rotation of the clamp.

ADJUNCTS TO DENTAL DAM PLACEMENT

In addition to the previously mentioned materials, several other items will be of benefit for the efficient application of the dental dam.

A plastic or cement instrument can be used to shed the dental dam off the wings of the clamp once the clamp has been positioned. It is also used, along with a stream of air, to invert or “tuck” the edges of the dam into the gingival sulcus, thus ensuring a fluid-proof seal. This is particularly necessary in multi-tooth applications.

Dental floss is an essential adjunct to dam placement, even for endodontic therapy. Floss can be used for testing of contacts prior to dam application and for passing the dam material through the contacts after placement. It is recommended that the operator release the lingual grasp of the floss after passing it through the contact and pulling it out to the buccal, rather than back through the contact. Another product that may help with the stabilization of the interproximal dam is the Wedjets stabilizing cord (Coltene Whaledent, Inc.) (Figure 8). Small strips of the cord

Figure 8 Wedjets cord (Coltene Whaledent, Inc.) can help stabilize the interproximal area of the dental dam.

can be wedged into the interproximal space over the dam to fix the dam in place.

Even with proper techniques of placement of the dental dam, there will still be clinical situations in which some small amount of leakage of fluids can be anticipated. Adjustments can be made including repositioning of the clamp and closer attention to inversion of the dam material around the tooth. When those techniques are ineffective, leakage can usually be effectively controlled by the placement of a “patching” material at the interface of the tooth and the dam material. Orabase, rubber base adhesive, Cavit, a mixture of Super Poly-Grip Denture Adhesive with zinc oxide powder, and periodontal packing have been used in the past with limited success.⁸ Currently, the application of OraSeal Caulking (Ultradent Products, Inc.) seems to provide a quick, easy-to-apply solution to the problem of seepage of fluids around the dental dam (Figure 9).

Techniques of Application

ROUTINE TECHNIQUES

Two techniques of dental dam application that can be used routinely are next described, followed by examples of special situations that may complicate the process.

Prior to application of the dental dam, it is suggested that the patient should rinse for 30 seconds with an effective antibacterial agent. A mouth rinse of

Figure 9 A, Partially erupted first molar clamped with a W8A with leakage toward the lingual and distal. **B**, Leakage controlled with Oraseal (Ultradent Products, Inc.).

0.12% chlorhexidine gluconate, such as Peridex (Proctor & Gamble, Cincinnati, OH), will reduce the number of microorganisms in the mouth prior to dam placement.⁹

SINGLE MOTION TECHNIQUE

This is the most efficient endodontic dam application technique through the use of winged clamps resulting in the dam, clamp, and frame being taken to the tooth to be isolated in a single motion (see Figure 7).

1. Select the clamp to be used.
2. Punch one appropriate-sized hole just off center of a 6" × 6" piece of dam material.
3. Stretch the dam over the frame and fit the clamp through the punched hole so that the wings retain the clamp.
4. Place the clamp over the tooth with the accompanying frame and dam attached so the clamp is seated over the bulk of contour of the tooth.
5. Use a plastic or cementing instrument to flick the dam off of the wings of the clamp. The dam material should be positioned on the tooth below the clamp.
6. Use floss to aid in passing the dam through contacts.

DOUBLE MOTION TECHNIQUE

This technique is still very efficient, requires the use of a winged or wingless clamp, and involves a seven-steps procedure.

1. Select the clamp to be used.
2. Punch one appropriate-sized hole just off center of a 6" × 6" piece of dam material.
3. Loosely attach the dam material to the four corners of the frame.
4. Place the clamp over the bulk of contour of the tooth to be isolated and ensure the clamp is secure.
5. Stretch the dam over the clamp so the dam material is seated under the clamp and hugging the cervical area of the tooth.
6. Completely stretch the dental dam onto all prongs of the frame.
7. Use floss to aid in passing the dam through contacts.

Regardless of the technique used, the surface of the tooth and dental dam should be disinfected with an appropriate disinfectant (i.e., 2.5% sodium hypochlorite, 10% iodine tincture, 2% chlorhexidine) prior to access of the root canal system.¹⁰

REMOVAL OF DAM

1. For single-tooth applications, simply remove the clamp with the forceps and remove the dam.
2. For multiple-tooth applications, first remove the clamp, then place a finger under the dam in the vestibule, and stretch the dam to the facial, away from the teeth. Cut the stretched interproximal dam with scissors and then remove the dam. After removal, it is essential that the dam be

inspected to ensure that no interproximal dam has been left between the teeth.

Techniques for Special Situations

MULTIPLE ADJACENT TEETH REQUIRING TREATMENT OR EXTREME MOBILITY OF THE TOOTH BEING TREATED

The posterior tooth is clamped normally whereas a second clamp is reversed (with the bow pointing mesially) on the most anterior tooth (Figure 10). Or, the most posterior tooth is clamped normally, whereas the anterior portion of the dam is retained without a clamp. A strip of dental dam, a piece of floss, or a Wedjets cord can be placed interproximally to hold the anterior portion of the dam in place.

INSUFFICIENT TOOTH STRUCTURE OR PORCELAIN CROWNS OF VENEERS WHERE AN INTACT POSTERIOR TOOTH IS IN PLACE

The split-dam technique can be effectively used utilizing a clamped tooth posterior to the tooth to be treated (Figure 11). Two holes can be punched, one

Figure 10 The posterior tooth is clamped normally whereas a second clamp is reversed (with the bow pointing mesially) on the more anterior tooth.

for the clamped tooth and one for the tooth anterior to the tooth to be treated. The dam between the two holes can be cut with iris scissors. Once the clamp is placed on the posterior tooth, the dam can be placed on the clamped tooth and stretched mesially to anterior tooth and held in place with a Wedjets cord, floss, or a cut piece of dental dam. A cotton role can be

Figure 11 The split-dam technique can be effectively used by clamping a tooth posterior to the one to be treated and stretching over a tooth anteriorly.

placed under the lip or cheek in the mucobuccal fold over the tooth to be treated.

BRIDGE ABUTMENTS, SPLINTS, AND ORTHODONTICS WITH WIRES

Punch a larger-than-normal hole in the dam. Place OraSeal around the punched hole on the underside of the dam. Clamp the tooth in the normal manner. If leakage is a problem, add more Oraseal around the abutment at the site of leakage.

TOOTH WITH CALCIFIED PULP CHAMBER AND CANAL(S)

Use the three-tooth dental dam isolation technique previously described in the multiple adjacent teeth requiring treatment technique. The involved tooth is without a clamp, allowing the clinician to better visualize the Cemento Enamel Junction (CEJ) region of the tooth. A periodontal probe can be traced along the root surface to orientate oneself to the crown–root angulations during difficult access cavity preparations.

TERMINAL TOOTH WITH INSUFFICIENT TOOTH STRUCTURE

If insufficient tooth structure is present to allow a clamp from being placed on the tooth and the tooth is the terminal tooth in an arch, the clinician must first determine whether the tooth is sufficiently periodontally sound and restorable. If the tooth is determined to be retainable, perhaps a clamp with prongs extending apically can be used to effectively engage and hold on the tooth, followed by dam placement. If that is unsuccessful, the tooth may require coronal build-up restoration with pin-retained restorative materials so the retainer can be properly placed. Additionally, the terminally positioned tooth can undergo periodontal crown lengthening to expose more tooth structure to allow for clamp placement¹¹ (see Chapter 18, “Endodontic–Periodontic Differentiation”).

Summary

Clinicians will find endodontic procedures more rewarding and less frustrating as their mastery of dental dam applications increases. The use of simplified techniques, improved materials, and organized procedures, as well as patience and practice, will hasten this mastery. Endodontists have long recognized that the use of dental dam is imperative in the practice of endodontics.

B. INTRODUCTION OF NICKEL–TITANIUM ALLOY TO ENDODONTICS

WILLIAM A. BRANTLEY

Prior to the prescient review article by Civjan et al.¹ on the potential uses of nickel–titanium alloys for dentistry, pioneering feasibility studies for orthodontics were performed by George Andreasen et al.^{2,3} This work led to the commercial development of the first NiTi alloy for orthodontics (Nitinol) by the Unitek Corporation (now 3M Unitek, Monrovia, CA). The mechanical properties of this alloy, along with its notable clinical applications, were presented in a classic article by Andreasen and Morrow.⁴ Particularly important were the very low elastic modulus and very wide elastic working range of the NiTi alloy, compared with stainless steel, which was the major orthodontic wire alloy for clinical use at that time.

Subsequently, Harmeet Walia thought that this nickel–titanium (NiTi; see next section) alloy might have enormous potential for endodontic files, because its very low elastic modulus would permit the negotiation of curved root canals with much greater facility than stainless steel instruments available at the time. Using special large-diameter orthodontic wires contributed by the Unitek Corporation, Quality Dental Products (Johnson City, TN) fabricated the first prototype NiTi hand files by machining rather than the conventional manner of twisting the tapered stainless steel wire blanks. The properties of these first NiTi files in bending and torsion were compared with those for stainless steel hand files of the same size manufactured by a similar machining process. The highly promising initial results of these pioneering laboratory studies were first presented by Walia et al.⁵ at the annual meeting of the International Association for Dental Research in 1987, and a more complete description of this work was published the next year in a seminal article in the *Journal of Endodontics*.⁶ Subsequently, more information about

torsional ductility, which was superior to that for machined stainless steel instruments,^{5,6} and cutting ability of the NiTi hand files, was reported by Walia et al.⁷ at the 1989 annual meeting of the American Association for Endodontists.

Based on these promising research results, innovative dental manufacturers began to market NiTi endodontic instruments in the 1990s. A major impetus was the merger of Quality Dental Products with Tulsa Dental Products (now Dentsply Tulsa Dental, Tulsa, OK), and this latter company introduced Pro-File NiTi rotary files in 1993. Subsequently, many other manufacturers introduced NiTi rotary instruments for endodontics, and studies of the properties and performance of these instruments became an intensive area for endodontics research. In January 2007, PubMed listed over 350 articles dealing with various aspects of the NiTi endodontic instruments since their inception.

Mechanical Behavior and NiTi Phases for Nickel–Titanium Alloys

The NiTi alloy used in orthodontics and endodontics was developed by Buehler and associates. This alloy was termed “Nitinol” from *nickel*, *titanium*, and the Naval Ordnance Laboratory, the site of this development work that is described in a classic review article by Buehler and Wang.⁸ The alloy is based on the NiTi intermetallic compound and can exhibit superelastic behavior (termed “pseudoelastic” in materials science) and shape memory with appropriate processing conditions.⁹ Because of the difference in atomic weights of nickel and titanium, the equiatomic NiTi alloy composition is 55 wt% Ni and 45 wt% Ti.

When a superelastic NiTi wire is loaded in tension, normal elastic behavior initially occurs. With further tensile loading, the elastic stress reaches a certain level at which there is an extended horizontal region of elastic strain (upper superelastic plateau). Up to about 10% elastic strain can occur in a superelastic NiTi orthodontic wire at this constant stress.¹⁰ During subsequent tensile unloading, the alloy will exhibit a horizontal region of elastic strain at a lower stress (lower superelastic plateau) on the stress-strain plot. With further unloading, the strain reaches the end of the lower superelastic plateau, and the final portion on the stress-strain plot again corresponds to the linear elastic unloading.

Khier et al.¹¹ compared the bending properties of superelastic and nonsuperelastic NiTi orthodontic wires. For elastic bending of superelastic NiTi orthodontic wires having clinically relevant test spans, the upper and lower superelastic plateaus are less well defined (Figure 1), because stress varies linearly over the cross-section. The regions on the bending plots that correspond to these plateaus have greater slopes for nonsuperelastic NiTi wires, such as the original 3M Unitek Nitinol orthodontic wire (Figure 2). If the

superelastic alloy is loaded in tension to a value of strain beyond the upper plateau region, there will be some permanent strain after unloading. This permanent strain will be greater for a nonsuperelastic NiTi wire having the same dimensions and loaded to the same overall strain as the superelastic wire. By contrast, a NiTi wire alloy that exhibits shape memory behavior in the oral environment will have no residual permanent strain after unloading from beyond the upper plateau region; the wire will completely return to its initial dimensions before loading.⁹

The mechanical behavior of the superelastic, non-superelastic, and shape memory NiTi alloys arises from the nature and proportions of their microstructural phases, which has been discussed by Brantley¹² for orthodontic NiTi wires. There are three NiTi phases in these alloys.⁹ Austenitic NiTi (austenite) has a complex body-centered cubic structure, and exists at higher temperatures and lower stresses.

Martensitic NiTi (martensite) has a complex structure described as monoclinic, and exists at lower temperatures and higher stresses. Transformation between austenite and martensite occurs by a twinning process at the atomic level, and the reversibility of this twinning is the origin of shape memory.^{9,12} During tensile loading, the upper superelastic plateau corresponds to the stress-induced transformation from the initial austenitic structure to martensite, and the lower superelastic plateau corresponds to reverse transformation from martensite to austenite.

The R-phase is an intermediate phase with a rhombohedral structure that can form during forward transformation from martensite to austenite on heating and reverse transformation from austenite to martensite on cooling.⁹ Formation of R-phase is favored by the presence of dislocations and precipitates in the NiTi alloy.¹³ A substantial density of dislocations is expected in NiTi orthodontic wires and endodontic instruments, because the alloy experiences considerable permanent deformation during the manufacturing processes. Because of the relatively narrow range of the equiatomic NiTi phase field in the nickel–titanium phase diagram at low temperatures, Ti₂Ni and Ni₃Ti precipitates are expected in Ti-rich and Ni-rich alloys, respectively.¹⁴ Oxide particles also form during processing of the NiTi alloy by manufacturers.⁹ Such nickel–titanium oxide precipitates have been observed by Alapati et al.¹⁵ on the cutting tip of a rotary instrument (Figure 3) and were presumably elongated during the manufacturing process for the starting wire blank.

Figure 3 SEM photograph of the cutting tip for a LightSpeed instrument after one simulated clinical use, showing elongated nickel-titanium oxide precipitates and flattening of the rollover. Scale bar length is 5 μ m. Reprinted from Alapati et al.¹⁵ with permission from the American Association of Endodontists.

Several phase transformation temperatures are important: A_s , the starting temperature for transformation to austenite; A_f , the temperature at which transformation to austenite is finished; M_s , the starting temperature for transformation to martensite; and M_f , the temperature at which transformation to martensite is finished. The R_s and R_f temperatures for transformations involving the R-phase are defined in a similar manner.

If a NiTi orthodontic wire or endodontic instrument is cooled to a sufficiently low temperature (shown in later differential scanning calorimetry [DSC] plots), it will consist entirely of martensite. Upon heating, martensite will start transforming to R-phase at the R_s temperature, and this transformation will be finished at the R_f temperature. With further heating, R-phase starts transforming to austenite at the A_s temperature, and transformation is finished at the A_f temperature. Alternatively, if the NiTi orthodontic wire or endodontic instrument is heated above the A_f temperature, it will be converted entirely to austenite. Then, upon cooling to sufficiently lower temperature, the alloy starts transforming from austenite to R-phase at the R_s temperature, and this transformation will be finished at the R_f temperature. With further cooling, R-phase starts transforming to martensite at the M_s temperature, and transformation is finished at the M_f temperature. These transformation processes are summarized in Figure 4.

Use of Differential Scanning Calorimetry to Study Nickel–Titanium Alloys

DSC can be used to easily determine the transformation temperature ranges (TTRs) for NiTi phases and

Forward transformation sequence

M → R → A (Heating)

Reverse transformation sequence

A → R → M (Cooling)

Figure 4 Structural transformations in NiTi alloys for orthodontic wires and endodontic instruments: M, martensite; R, R-phase; A, austenite. Beginning with martensite at low temperatures, starting temperatures are R_s and A_s for forward transformations on heating, which are finished at R_f and A_f temperatures. Beginning with austenite at high temperatures, starting temperatures are R_s and M_s for reverse transformations on cooling, which are finished at R_f and M_f temperatures. Starting and finishing temperatures for the same transformation can be different for heating and cooling.

enthalpy changes in NiTi alloys.^{16,17} A test sample is heated or cooled at the same rate (typically 10°C/min) as an inert control material. The difference in thermal energy to heat both materials at this rate is plotted as heat flow per unit sample weight (W/g) as a function of temperature. Bradley et al.¹⁸ used DSC to compare superelastic, nonsuperelastic, and shape memory NiTi orthodontic wires.

In their first published article on the use of DSC to investigate NiTi rotary instruments, Brantley et al.¹⁹ compared ProFile (Dentsply Tulsa Dental) and Light-Speed (LightSpeed Technology, San Antonio, TX) instruments in the as-received condition. Figure 5 presents heating and cooling DSC plots for a test sample consisting of several segments from an as-received ProFile instrument. The temperature range from -75°C to 75°C is shown. The lower curve is for the initial heating cycle and the upper curve is for the subsequent cooling cycle. Exothermic reactions are represented by peaks in the upward direction. The two endothermic peaks on the heating curve correspond to initial transformation from martensite to R-phase (M → R), followed by transformation from R-phase to austenite (R → A). This latter transformation is completed at an A_f temperature of approximately 25°C, so the as-received instrument will be in the superelastic condition at 37°C, which Thompson reported to be desired by man-

ufacturers.²⁰ (Some investigators determine the A_f temperature from the intersection of a tangent line to the right side of the peak with an extension of the adjacent baseline, which gives a lower value.) A single exothermic peak is observed on the cooling curve, because the peaks associated with the reverse transformations of A → R followed by R → M could not be resolved.

Figure 6 presents DSC plots for the tip segment from another as-received ProFile instrument (Dentsply Tulsa Dental) in a subsequent study by Brantley et al.,²¹ investigating instruments subjected to simulated clinical use. This test sample was also in the superelastic condition, but the A_f temperature on the heating curve was less than 0°C. The endothermic peak on the heating curve corresponds to the M → R transformation, followed by R → A, which could not be resolved as two separate peaks. The weaker broad exothermic peak over the same temperature range on the cooling curve corresponds to the reverse transformations of A → R, followed by R → M. The broad low-temperature peak has been reported by Brantley et al.²² to arise from twinning within martensite, and similar low-temperature peaks have been observed by Brantley et al.^{23,24} in NiTi orthodontic wires, using temperature-modulated DSC.

Figure 7 presents DSC plots for the tip segment of a ProFile instrument, from the same batch as the

instrument for Figure 6, which had been subjected to one simulated clinical use.²¹ Similar DSC plots were obtained for tip segments from other ProFile instruments in this batch, which had been subjected to three and five simulated clinical uses. After one, three, and five simulated clinical uses, the tip segments still remained in the superelastic condition, with the A_f temperature on the heating curve less than 0°C. Thus, DSC was unable to detect effects from up to five simulated clinical uses on the tip segments of these instruments.

Figure 8 shows DSC plots for the tip segment from a LightSpeed NiTi rotary instrument that had been subjected to one simulated clinical use.²¹ This tip segment is also in the superelastic condition, because the A_f temperature on the heating DSC curve is less than 25°C. There were minimal differences compared with Figure 8 for the DSC plots from tip segments of other LightSpeed instruments from the same batch that were subjected to three and five simulated clinical uses, as well as with DSC plots from the tip segment of an as-received LightSpeed instrument.²¹ Interestingly, the DSC plots for a test sample consisting of several segments for a LightSpeed instrument from a different batch were similar to Figure 5 for an as-received ProFile instrument.¹⁹

These two DSC studies by Brantley et al.^{19,21} showed that there are substantial differences in the character of the NiTi phases for segments taken from different portions of the same rotary NiTi instrument. Moreover, evident batch effects were observed in the DSC plots for instruments from the same manufacturer. The DSC results also indicated that the stresses experienced by a rotary instrument during manufacturing vary with position along its axis and that there may be differences in the manufacturing procedure and starting NiTi alloy. Nevertheless, regardless of the considerably different character of the various DSC plots,^{19,21} test samples from the ProFile and LightSpeed instruments, in either the as-received condition or after simulated clinical use, always displayed superelastic behavior at 37°C, although there were relatively large differences in the A_f values for test samples.

From these DSC studies,^{19,21} it is tempting to assume that the optimum microstructure for superelastic NiTi rotary instruments would have the maximum amount of austenite that could reversibly transform to martensite, with a large enthalpy change (peak area). When there is substantial stable work-hardened martensite in the microstructure, the enthalpy change for reversible transformation to austenite is

much smaller.^{18,23} However, further research is needed to test this hypothesis and its relevance to the clinical performance of NiTi instruments.

In a contemporary DSC study, Kuhn and Jordan²⁵ analyzed ProFile (Dentsply Maillefer, Baillagues, Switzerland) and Hero NiTi rotary instruments having different ISO (International Organization for Standardization) sizes and tapers. Both as-received and clinically used instruments were selected, and test samples were obtained from portions of the instruments that would be active or inactive during cutting. Their observations were in good agreement with the results by Brantley et al.^{19,21}. The DSC plots for as-received Hero instruments with different tapers were similar to Figure 5, and plots for active and inactive portions of the same instrument were different. The A_f temperature of 20°C on heating for Hero instruments was lower than the A_f temperature of 35°C for ProFile instruments. Transformation temperatures were decreased after clinical use of the instruments.

Kuhn and Jordan²⁵ also studied the effects of heat treatments at six temperatures from 350° to 700°C. Whereas only single peaks were observed on the heating and cooling DSC plots for as-received instruments (interpreted as direct transformations of M → A and A → M, respectively), the DSC plots were altered for annealed test samples. Heat treatments below 510°C resulted in two DSC peaks during heating (M → R followed by R → A) and two peaks during cooling (A → R followed by R → M). After heat treatments above 510°C, one peak was observed during heating (interpreted as M → A) and one peak during cooling (interpreted as A → M). Heat treatment shifted the martensite transformation to lower temperatures. When heat treatment was performed at 600°C, recrystallization of the NiTi microstructure occurred in the instruments, as previously found for NiTi orthodontic wires.¹² Kuhn and Jordan²⁵ observed that heat treatments below 600°C caused test samples to have increased bending flexibility, whereas flexibility was decreased by heat treatments above 600°C. They recommended that heat treatment at 400°C, corresponding to the recovery annealing stage before recrystallization,¹² be utilized by manufacturers prior to machining the NiTi instruments to decrease the work hardening of the alloy.

Alapati et al.²⁶ have recently reported the first use of temperature-modulated DSC to investigate heat-treated NiTi rotary instruments. This technique provides much greater resolution about the complex structural transformations in the NiTi orthodontic wires than is possible with conventional DSC,^{23,24}

and it should be extensively employed for future investigations on NiTi instruments. Future research should also include the use of X-ray diffraction and transmission electron microscopy, along with scanning electron microscopy and measurements of mechanical properties, to determine the NiTi phases and their characteristics in as-received, heat-treated, and clinically-used instruments.

X-ray diffraction provides information about the NiTi phases in a test sample, and Iijima et al.²⁷ have reported the use of a new micro-X-ray diffraction technique to determine the NiTi phases at different locations on a NiTi instrument. Although preparation of the very thin foil specimens is challenging, transmission electron microscopy can be used to obtain insight at the nanometer to submicron level into causes of fatigue behavior and provide information about the NiTi phases and dislocation configurations due to manufacturer processing or clinical use of the instruments.^{28–30} Scanning electron microscopic (SEM) observations of polished and etched test samples can show whether the rotary instrument has a conventional wrought microstructure or provide evidence of heat treatment that caused recrystallization to yield equiaxed grains.¹² Vickers hardness measurements can be used to verify whether the NiTi instrument is in the superelastic condition and to investigate the extent of work hardening.^{12,31}

As another example of combining experimental techniques, Miyai et al.³² recently investigated torsional and bending properties of EndoWave, Hero 642, K3, ProFile .06, and ProTaper instruments and found that their functional properties (particularly flexible bending load level) were related to phase transformation behavior determined by DSC. Transformation temperatures for Hero and K3 instruments were significantly lower than for EndoWave, ProFile, and ProTaper instruments. However, the clinical significance and predictability from such DSC results for performance of the NiTi instruments remain to be established in future research.

Effects of Heat Sterilization on Properties of Nickel–Titanium Instruments

There have been numerous laboratory studies of NiTi instruments subjected to multiple heat sterilization cycles. Repeated sterilization has been found by Silvaggio and Hicks³³ and Canalda-Sahli et al.³⁴ to cause changes in torsion and bending properties, and

by Rapisarda et al.³⁵ and Schäfer³⁶ to affect cutting efficiency. However, Hilt et al.³⁷ found no effects on the torsional properties, hardness, and microstructure of NiTi files from the number of sterilization cycles and the type of autoclave sterilization.

Whereas Mize et al.³⁸ found that repeated heat sterilization did not affect the number of cycles for fatigue failure, Chaves Craveiro de Melo et al.³⁹ and Viana et al.⁴⁰ reported that repeated heat sterilization caused substantial increases in the number of cycles for failure. These observations indicate the necessity of having a standard technique for evaluation of the fatigue behavior of NiTi instruments.

Recent DSC studies by Alexandrou et al.⁴¹ have shown that after 11 sterilization cycles, ProFile and Flexmaster instruments had the completely austenitic structure needed for superelastic behavior in the oral environment. Alexandrou et al.⁴² also found that after 11 sterilization cycles, the Mani NRT instruments were either austenite or a mixture of austenite and R-phase at 37°C and concluded that these instruments are also capable of superelastic behavior under clinical conditions.

In future studies, it would be worthwhile to compare etched microstructures of the NiTi alloy for instruments subjected to multiple heat sterilization cycles with etched microstructures for as-received instruments to determine whether changes occurred in the original wrought structure due to the sterilization cycles. Comparison of the X-ray diffraction patterns and Vickers hardness for sterilized and as-received instruments would reveal^{12,27,31} whether sterilization caused relief of the residual stresses present in the as-received instruments from the manufacturing process. Such residual stresses may contribute to the clinical failure of the NiTi instruments.

Failure of Nickel–Titanium Instruments and Failure Mechanisms

The manufacturing process of machining the NiTi rotary instruments from starting wire blanks²⁰ results in rollover at the edges of the flutes⁶ and a variety of surface defects.^{6,43–45} Machining grooves, microcracks, and surface debris are evident when as-received instruments are examined with a scanning electron microscope, and instrument fracture generally occurs at surface defects.

Recent extensive clinical studies by Knowles et al.⁴⁶ for LightSpeed instruments and by Di Fiore et al.⁴⁷ for ProFile, ProTaper, ProFile GT, and K3 Endo instruments reported separation (fracture) rates of less than 1.5% and much less than 1%, respectively. No statistically significant difference in incidence of fracture was found for the ProFile, ProTaper, ProFile GT, and K3 Endo instruments.⁴⁷ Although these rates are very low and justify the widespread use of rotary NiTi instruments, clinical failures are sources of anguish for both the patient and endodontist. Accordingly, there have been substantial research efforts to characterize the instrument failures and determine their origins and to develop new instruments that would minimize the occurrence of failures.

One contributing mechanism for clinical failure of NiTi instruments, reported by Alapati et al.,⁴⁸ may be the widening of surface machining grooves by tenacious dentin debris deposits. The SEM photograph in Figure 9 shows an example of this phenomenon for a clinically fractured ProTaper instrument. The potential role of dentin debris for failure of rotary NiTi instruments requires further study.

Alapati et al.⁴⁹ have also performed an extensive SEM study of clinically failed NiTi rotary instruments to characterize the major aspects of their fracture processes. Instruments generally appeared to exhibit

Figure 9 SEM photograph of a clinically fractured ProTaper instrument showing a widened machining groove containing dentin debris that was close to the area in which the fracture occurred. Scale bar length is 22 μm . Reprinted from Alapati et al.⁴⁸ with permission from the American Association of Endodontists.

Figure 10 Secondary electron image of the fracture surface of a ProTaper rotary instrument that failed during clinical use, showing elongated dimples indicative of ductile fracture and secondary phase particles that may be nickel-titanium oxides. Scale bar length is 6 μm . Reprinted from Alapati et al.⁴⁹ with permission from the American Association of Endodontists.

ductile fracture, rather than brittle fracture, as shown in Figure 10 of a clinically fractured ProTaper instrument,⁴⁹ where the surface has the characteristic dimpled appearance for ductile fracture.^{50,51} SEM observations at high magnification show that these dimples are nucleated at secondary phase particles in the microstructure, such as nickel–titanium oxides.⁹ The volume fraction of such particles may indicate the quality of the starting NiTi wire alloy used for manufacturing the instruments.

An example of a more complex fracture surface is shown for a clinically failed ProFile GT instrument in Figure 11.⁴⁹ Transgranular fracture occurred across the fine grains in this microstructure, as well as intergranular fracture along some grain boundaries. Voids or regions of separation between some grains can also be seen in Figure 11 and suggest the loss of small grains, subgrains, or secondary phase particles during the fracture process.⁴⁹ Although this rotary instrument may have experienced overall ductile fracture during clinical failure, the features in Figure 11 do not resemble those for ductile fracture in Figure 10.

Two other major failure processes, excessive torsional deformation without separation and axial fracture, were observed by Alapati et al.⁴⁹ for these clinically retrieved NiTi rotary instruments. Permanent

Figure 11 SEM photograph of the fracture surface of a ProFile GT instrument that failed during clinical use, showing transgranular (cleavage) fracture and intergranular fracture along grain boundaries. Scale bar length is 3 μm . Reprinted from Alapati et al.⁴⁹ with permission from the American Association of Endodontists.

torsional deformation, giving an “unfluted appearance,” and permanent bending deformation without instrument separation, as well as instruments that fractured in these modes, under clinical conditions, have been observed by other investigators.^{44,52–56} The axial fracture mode for clinically retrieved instruments⁴⁹ involved crack propagation in a direction approximately parallel to the flutes that connected pitted regions on the surface. These pits may have been former sites of secondary phase particles.

Alapati et al.⁴⁹ did not observe the characteristic striations^{50,51} for cyclic fatigue on the fracture surfaces of clinically failed NiTi instruments, presumably because the instrumentation time before fracture of the retrieved instruments was insufficiently long. These investigators concluded that separation of the used instruments, retrieved for their study, was generally caused by a single overload event that resulted in ductile fracture. By contrast, Cheung et al.⁵⁵ observed striations indicative of fatigue failure for numerous ProTaper instruments that had fractured during clinical use, and these authors concluded that fatigue failure is an important mode of separation during clinical instrumentation. An example of the fine-scale striations is shown in Figure 12 from a laboratory study by Luebke et al.⁵⁷ of

Figure 12 SEM photomicrograph of the in vitro fracture surface of a NiTi Gates Glidden drill tested to failure in bending fatigue, showing fine striations that form during fatigue crack propagation. Scale bar length is 0.7 μm . Reprinted from Luebke et al.⁵⁷ with permission from the American Association of Endodontists.

NiTi Gates Glidden drills subjected to cyclic cantilever bending.

In summary, numerous studies have shown that NiTi alloys for rotary instruments can possess significant ductility in bending and torsion, without experiencing separation in certain clinical cases, where the canals have substantial curvature or where rotation of the tip is hindered. Fracture initiation often appears to occur at machining grooves, with a possible role from retained dentin debris in these grooves. Retrieved instruments, which failed during clinical use, may fracture from cyclic fatigue after longer periods of use or from single overload events after relatively brief periods of use. Clearly, the manufacturing process for NiTi rotary instruments and the need for a starting NiTi wire alloy of high metallurgical quality are major factors for reducing the incidence of clinical failure of these instruments.

Strategies for Improved Nickel–Titanium Instruments

Several strategies have been employed to develop NiTi instruments that should have improved clinical performance. These strategies have included electropolishing the machined surfaces, ion implantation to create harder surfaces, and use of special surface coatings. Research has also suggested that heat

treatment of these instruments may yield beneficial results.

Tripi et al.⁵⁸ recently compared the effects of instrument design and surface treatment on the cyclic fatigue of ProFile, RaCe, K3, Hero, and Mtwo instruments. While the best fatigue resistance was found for the ProFile instruments, the electropolishing surface treatment for RaCe instruments increased their fatigue resistance by reducing the presence of microcracks, surface debris, and other machining damage.

Lee et al.⁵⁹ first proposed the application of ion implantation to NiTi instruments. They reported that boron-ion implantation more than doubled the surface hardness of Nitinol at the nanoindentation depth of 0.05 μm , yielding a hardness value greater than that of stainless steel.

Rapisarda et al.⁶⁰ subsequently employed both a thermal nitriding technique and nitrogen-ion implantation to increase the wear resistance of NiTi instruments. The ion-implanted samples had a higher N:Ti ratio, which suggested the presence of a titanium nitride layer. Both the thermal-nitrided and nitrogen-ion-implanted instruments had higher wear resistance and increased cutting ability in acrylic blocks compared with control instruments without surface modifications. An SEM study of nitrogen-ion-implanted instruments by these investigators⁶¹ revealed the absence of surface wear and morphology changes that occurred in control instruments after the same period of simulated clinical use.

Schäfer³⁶ used a physical vapor deposition (PVD) process to create a TiN surface coating on NiTi instruments. Surface-coated instruments had greater cutting efficiency (penetration into plastic samples with cylindrical canals) compared with control instruments, and their cutting efficiency was not altered by repeated autoclave or sodium hypochlorite sterilization.

Lastly, use of heat treatments for the NiTi instruments, or general modifications in proprietary thermomechanical processing procedures for the starting wire blanks, may provide other strategies.⁶² It has been noted that Kuhn and Jordan²⁵ explored the use of heat treatments at temperatures ranging from 350° to 700°C. They concluded that annealing around 400°C yields a suitable proportion of NiTi microstructural phases and a beneficial effect (limiting brittleness) on the mechanical properties of these instruments. Previous research on NiTi orthodontic wires has shown that heat treatment at 400°C does not affect the bending properties of superelastic wires, whereas heat treatment at 600°C causes loss of superelastic behavior.^{10,11} Heat treatment for 10 minutes at 500°C had minimal effect on the cantilever bending

plots, but 2 hours of heat treatment at this temperature decreased the average superelastic bending moment during unloading of the wire test span.

Heat treatment can alter the phase transformation temperatures for the NiTi alloy, such as reduction of the M_s temperature to subambient levels to yield a completely austenitic structure at room temperature.¹² Heat treatment within only the recovery annealing stage for the NiTi alloy would reduce residual stresses of potential importance for fracture behavior without altering the microstructure. Presumably, heat treatment at temperatures of 600°C and higher, causing recrystallization of the wrought microstructure,^{12,25} should be avoided for the rotary instruments. Given the special nature of the NiTi alloy phases and their transformations,⁹ one can envision the future development of complex thermomechanical processing cycles to optimize the starting NiTi wire blanks or new heat treatments to improve the cutting efficiency and fatigue resistance of the instruments after machining from these blanks.

C. INSTRUMENTS FOR CLEANING AND SHAPING

TIMOTHY A. SVEC

Instrumentation of the root canal system requires both hand and rotary files. No canal system can or should be instrumented with rotary files alone. The development of hand and engine-driven files will be discussed with an emphasis on nickel–titanium rotary files.

Basic Endodontic Instruments

After the introduction of standardized instruments,¹ about the only changes made were the universal use of stainless rather than carbon steel and the addition of smaller (Nos. 6 and 8) and larger (Nos. 110–150) sizes as well as color coding. It was not until 1976 that the first approved specification for root canal instruments was published (ADA Specification No. 28).

ENDODONTIC INSTRUMENT STANDARDIZATION

In 1959, a new line of standardized instruments and filling material was introduced to the profession:²

1. A formula for the diameter and taper in each size of instrument and filling material was agreed on.
2. A formula for a graduated increment in size from one instrument to the next was developed.
3. A new instrument numbering system based on instrument metric diameter was established.

This numbering system, last revised in 2002,³ using numbers from 6 to 140, is based on the diameter of the instruments in hundredths of a millimeter at the beginning of the tip of the blades, a point called D0 (diameter 1 mm) (Figure 1), and extending up the blades to the most coronal part of the cutting edge at D16 (diameter 2–16 mm in length). Additional revisions are under way to cover instruments constructed with new materials, designs, and tapers greater than 0.02 mm/mm.

Figure 1 Original recommendation for standardized instruments. Cutting blades 16 mm in length are of the same size and numbers as standardized filling points. The number of the instrument is determined by diameter size at D1 in hundredths of millimeters. Diameter 2 (D2) is uniformly 0.32 mm greater than D1, a gain of 0.02 mm/1 mm of cutting blades. Reproduced with permission from Ingle JI. In Grossman, LI, editor. *Transactions of the Second International Conference on Endodontics*. Philadelphia: University of Pennsylvania; 1958. p. 123.

Instruments with a taper greater than the ISO (International Standards Organization) standard of 0.02 mm/mm have become popular: 0.04, 0.06, 0.08, 0.10, and 0.12. This means that for every millimeter gain in the length of the cutting blade, the width (taper) of the instrument increases in size by 0.04, 0.06, 0.08, 0.10, or 0.12 of a millimeter rather than the ISO standard of 0.02 mm/mm. These new instruments allow for greater coronal flaring than the 0.02 instruments.

The full extent of the shaft, up to the handle, comes in three lengths: standard, 25 mm; long, 31 mm; and short, 21 mm. The long instruments are often necessary when treating canines over 25 mm long. Shorter instruments are helpful in second and third molars or in the patient who cannot open widely. Other special lengths are available.

Ultimately, to maintain these standards, the American Association of Endodontists (AAE) urged the American Dental Association (ADA) and the United States Bureau of Standards to appoint a committee for endodontic instrument standardization. A committee was formed and produced a specification package that slightly modified Ingle's original standardization.¹ Then a worldwide committee was formed: ISO, consisting of the Fédération Dentaire Internationale, the World Health Organization, and the ADA Instrument Committee. The ISO has now formulated international specifications using the ADA proposal as a model.

ANSI (American National Standards Institute)/ADA standards have also been set for other instruments and filling materials: No. 58, Hedstroem files; No. 63, rasps and barbed broaches; No. 71, spreaders and condensers; No. 95, root canal enlargers; as well as No. 57, filling materials; No. 73, absorbent points; and No. 78, obturating points. Committee work is continuing to make these standards comparable with ISO standards.

The relevant standards have tolerances for size maintenance (both diameter and taper), surface debris, cutting flute character, torsional properties, stiffness, cross-sectional shape, cutting tip design, and type of metal. Variations from these tolerances have been noted⁴⁻⁹ (Figure 2). More recently, Stenman and

Spångberg¹⁰ noted that few brands are within acceptable dimensional standards.

Cormier et al.⁶ have warned of the importance of using only one brand of instruments because of discrepancies in instrument size among manufacturers. Seto et al.⁷ noted that grinding the flutes in files rather than twisting them "does not improve the strength or ductility of the instrument... (and) may also create more undesirable fluting defects." Since then, however, grinding has improved and gained importance because most nickel-titanium instruments must be machined, not twisted. Several recent studies have indicated that this type of manufacturing does not weaken instruments. In fact, most studies indicate that both manufacturing processes produce files that meet or exceed ISO standards.¹¹⁻¹³

It has also been found that autoclaving has no significant deleterious effects on stainless steel or nickel-titanium endodontic instruments.^{14,15} Now made universally of nickel-titanium and stainless steel rather than carbon steel, K-type instruments are produced using one of two techniques. The more traditional is produced by grinding graduated sizes of round wire into various shapes such as square, triangular, or rhomboid. A second grinding operation properly tapers these pieces. To give the instruments the spirals that provide the cutting edges, the square or triangular stock is then grasped by a machine that twists it counterclockwise a programmed number of times—tight spirals for files, loose spirals for reamers. The cutting blades that are produced are the sharp edges of either the square or the triangle. In any instrument, these edges are known as the "rake" of the blade. The more acute the angle of the rake, the sharper the blade. There is approximately twice the

Figure 2 Comparisons of the condition of *unused* instruments from different manufacturers. **A**, New No. 30 K-file with consistently sharp blades and point. **B**, New No. 35 K-file, different brand, exhibiting dull blades. **C**, Cross-sectional profile of triangular No. 20 file showing consistency in angles. **D**, Cross-section of competing No. 20 file with dull, rounded angles of cutting blades. **E**, No. 15 file showing lack of consistency in the blade, reflecting poor quality control. **F**, New No. 08 file with no cutting blades at all.

number of spirals on a file than on a reamer of a corresponding size (Figure 3A and B).

The second and newer manufacturing method is to grind the spirals into the tapered wire rather than twist the wire to produce the cutting blades. Grinding is usually necessary for nickel–titanium instruments. Because of their superelasticity, they cannot be twisted.

Originally, the cross-section of the K-file was square and the reamer triangular. However, manufac-

turers have started using many configurations to achieve better cutting and/or flexibility. Cross-section is now the prerogative of individual companies.

K-Style Modification

K-style endodontic instruments came into a series of modifications beginning in the 1980s. Not wholly satisfied with the characteristics of their K-style instrument, the Kerr Manufacturing Company in

Figure 3 ISO Group I, K-style endodontic instruments. **A**, K-style file. **B**, K-style reamer. **C**, K-flex file.

1982 introduced a new instrument design that they termed the K-Flex File (Sybron-Endo/Kerr, Orange, CA), a departure from the square and triangular configurations (Figure 3C).

The cross-section of the K-Flex is rhombus or diamond shaped. The spirals or flutes are produced by the same twisting procedure used to produce the cutting edge of the standard K-type files; however, this new cross-section presents significant changes in instrument flexibility and cutting characteristics. The cutting edges of the high flutes are formed by the two

acute angles of the rhombus and present increased sharpness and cutting efficiency. The alternating low flutes formed by the obtuse angles of the rhombus are meant to act as an auger, providing more area for increased debris removal. The decreased contact by the instrument with the canal walls provides a space reservoir that, with proper irrigation, further reduces the danger of compacting dentinal filings in the canal. Schafer¹⁶ found that the cross-sectional design and the number of flutes will influence canal shape in severely curved canals when employing the same instrumentation technique.

Testing five brands of K-type files for stiffness, Roth et al.¹⁷ found K-Flex files to be the most flexible. Moreover, not a single K-Flex fractured in torque testing, even when twisted twice the recommended level in the ADA specification.

REAMERS

The clinician should understand the importance of differentiating endodontic files and reamers from burs. Burs are used for boring holes in solid materials such as gold, enamel, and dentin. Files, by definition, are used by rasping. Reamers, on the other hand, are instruments that ream (twisting)—specifically, a sharp-edged tool for enlarging or tapering holes (see Figure 3B). Endodontic reamers cut by being tightly inserted into the canal, twisted clockwise one quarter- to one half-turn to engage their blades into the dentin, and then withdrawn—penetration, rotation, and retraction. The cut is made during retraction. The process is then repeated, penetrating deeper and deeper into the canal. When working length is reached, the next size instrument is used, and so on.

FILES

The tighter spiral of a file (see Figure 3A) establishes a cutting angle (rake) that achieves its primary action on withdrawal, although it will cut in the push motion as well. The cutting action of the file can be effected in either a filing (rasping) or a reaming (drilling) motion. In a filing motion, the instrument is placed into the canal at the desired length, pressure is exerted against the canal wall, and while this pressure is maintained, the rake of the flutes rasps the wall as the instrument is withdrawn without turning. The file need not contact all walls simultaneously. For example, the entire length and circumference of large-diameter canals can be filed by inserting the instrument to the desired working distance and filing circumferentially around all of the walls.

To use a file in a reaming action, the motion is the same as for a reamer—penetration, rotation, and retraction. The file tends to set in the dentin more readily than the reamer and must therefore be treated more gingerly. Withdrawing the file cuts away the engaged dentin.

To summarize the basic action of files and reamers, it may be stated that either files or reamers may be used to ream out a round, tapered apical cavity but that files are also used as push-pull instruments to enlarge by rasping certain curved canals as well as the ovoid portion of large canals. In addition, copious irrigation and constant cleansing of the instrument are necessary to clear the flutes and prevent packing debris at or through the apical foramen.

Oliet and Sorin¹⁸ evaluated endodontic reamers from four different manufacturers and found “considerable variation in the quality, sharpness of the cutting edges, cross sectional configuration, and number of flutes of the 147 different reamers tested.” They further found that “triangular cross sectional reamers cut with greater efficiency than do the square cross sectional reamers,” but the failure rate of the triangular instruments was considerably higher. Webber et al.¹⁹ found that “instruments with triangular cross sections were initially more efficient but lost sharpness more rapidly than square ones of the same size.”

Oliet and Sorin¹⁸ also found that “wear does not appear to be a factor in instrument function, but rather instruments generally fail because of deformation or

fracture of the blades. Once an instrument became permanently distorted, additional rotation only caused additional distortion, with minimum cutting frequently leading to fracture.” A more recent *in vitro* study of stainless steel files demonstrated that significant wear and potential loss of efficiency occurred after only one use of 300 strokes. It was proposed that endodontic instruments should be available in sterile packaging for single-patient use.²⁰ Another study concluded that stainless steel instruments, in small sizes, should be used once, and the No. 30 could be used three times. The No. 30 nickel–titanium instruments, however, “even after five times, did not show appreciable abnormalities in shape.”²¹ Of course, this study was done with one type of hand nickel–titanium files, and there was no assessment of instrumentation time as compared with stainless steel files.²¹

Webber et al.¹⁹ used a linear cutting motion in moist bovine bone and found that “there was a wide range of cutting efficiency between each type of root canal instrument, both initially and after successive use.” Similar findings were found when comparing K-type files with five recently introduced brands in three different sizes, Nos. 20, 25, and 30.²² Significant differences were noted in the *in vitro* cutting efficiency among the seven brands. Wear was exhibited by all instruments after three successive 3-minute test periods. Depth of groove is also a significant factor in improving cutting ability (Figure 4).

Figure 4 Comparison between two competing brands of endodontic instruments showing widely different cutting ability related to the depth of the blade groove.

Neal et al.²³ also studied the cutting ability of K-type files. A wide variance in the cutting ability of individual files was found. This study appears to confirm what dentists have long noted: the wide variance in cutting ability among individual instruments, even from the same manufacturer. Contrary to the study by Newman et al.,²² this study reported an insignificant role played by wear in decreasing the cutting ability of regular K-type stainless steel files.²³ Current studies have shown that stainless steel hand files have better cutting efficiency than nickel-titanium hand files and are not adversely affected by sodium hypochlorite.^{24,25} A study by Schafer²⁶ also demonstrated that the cross-sectional design of stainless steel hand files has more of an influence on cutting efficiency than the number of flutes. In two other studies that compared a recently introduced stainless steel file with one that has been in use for 20 years, it was confirmed that stainless steel files that are more flexible have less machining efficiency than a stiffer file.^{27,28}

Studies by Oliet and Sorin,¹⁸ Webber et al.,¹⁹ and Neal et al.²³ all alluded to certain weaknesses in K-style instruments. In addition, Luks²⁹ has shown that the smaller reamers and files may be easily broken by twisting the blades beyond the limits of the metal until the metal separated. On the other hand, Gutierrez et al.³⁰ found that although the instrument did not immediately break, a progression of undesirable features occurred. Locking and twisting clockwise led to unwinding and elongation as well as the loss of blade cutting edge and blunting of the tip. With continued clockwise twisting, a reverse “roll-up” occurred. Cracks in the metal eventually developed that finally resulted in breakage. These findings were unusual in that breakage would have normally resulted long before “roll-up”

occurred. It may reflect a variance in the quality of metal used by manufacturing companies. This point was borne out in a study by Lentine,³¹ in which he found a wide range of values within each brand of instrument as well as between brands.

An additional study of 360° clockwise rotation (ISO revision of ADA Specification No. 28) found only 5 K-style files failing of 100 instruments tested. They were sizes 30 to 50, all from one manufacturer.¹⁷

Attempts to “unscrew” a locked endodontic file also present a problem. Chernick et al.³² demonstrated that “endodontic files twisted in a counterclockwise manner were extremely brittle in comparison with those twisted in a clockwise manner.” They warned that dentists “should exercise caution when ‘backing-off’ embedded root canal instruments.” This finding was supported by Lautenschlager et al.,³³ who found that “all commercial files and reamers showed adequate clockwise torque, but were prone to brittle fracture when placed in counterclockwise torsion.”

By contrast, Roane and Sabala³⁴ found that clockwise rotation was more likely (91.5%) to produce separation and/or distortion than counterclockwise rotation (8.5%) when they examined 493 discarded instruments. Seto et al.⁷ also found greater rotational failure in clockwise rotation and greater failure as well in machined stainless steel K-files over twisted K-files.

Sotokawa³⁵ also studied discarded instruments and indicted metal fatigue as the culprit in breakage and distortion. “First a starting point crack develops on the file’s edge and then metal fatigue fans out from that point, spreading towards the file’s axial center” (Figure 5). Sotokawa³⁵ also classified the types of damage to instruments (Figure 6). He found the No. 10 file to be the most frequently discarded.

Figure 5 Instrument breakage. **A**, Initial crack across the shaft near the edge of the blade, Type V (original magnification $\times 1,000$). **B**, Full fracture of file broken in a 30° twisting simulation, Type VI (original magnification $\times 230$).

Figure 6 A, Sotokawa's classification of instrument damage. Type I, Bent instrument. Type II, Stretching or straightening of twist contour. Type III, Peeling-off metal at blade edges. Type IV, Partial clockwise twist. Type V, Cracking along axis. Type VI, Full fracture. **B**, Discarded rotary nickel-titanium files showing visible defects without fracture. All files show unwinding, indicating a torsional defect, and are very dangerous to be used further. Reproduced with permission from Sattapan B, Nervo GJ, Palamara JEA, Messer, HH. *J Endod* 2000;26:161.

Figure 7 Instrument fracture by cracks and deformation. **A**, Broken Hedstrom file with starting point at (i) (far right) spreading to cracks (S) and ductile fracture (F). **B**, Broken K-Flex file with plastic deformations at (D) and axial fissure at (Fs). Reproduced with permission from Haikel Y, et al. *J Endod* 1991;17:217.

Haikel et al.³⁶ compared instrument fracture between traditional K and Hedström files and the newer “hybrid” instruments. They found that “the instruments with triangular cross sections, in particular the Flexofile (Dentsply/Maillefer, Tulsa, OK), were found to be the most resistant to fracture.” Starting-point cracks and ductile fracture as well as plastic deformations and axial fractures were found (Figure 7). Schafer and Tepel³⁷ showed that the cross-sectional design had more to do with a stainless steel files flexibility and its ability to resist fracture than the number of flutes.

Rowan et al.³⁸ compared rotation and torque to failure of stainless steel and nickel–titanium files of various sizes. An interesting relation was noted. Stainless steel had greater rotations to failure in a clockwise direction, and the nickel–titanium was superior in a counterclockwise direction. Despite these differences, the actual force to cause failure was the same. It should be noted that the test instrument used in this study is not the one specified in ADA Specification No. 28. To overcome the problems chronicled above—distortion, fracture—Walia et al.³⁹ suggested that nickel–titanium, with a very low modulus of elasticity, be substituted for stainless steel in the manufacture of endodontic instruments.

TIP MODIFICATION

Early interest in the cutting ability of endodontic instruments centered around the sharpness, pitch, and rake of the blades. By 1980, interest had also developed in the sharpness of the instrument tip and

the tip’s effect in penetration and cutting as well as its possible deleterious potential for ledging and/or transportation—machining the preparation away from the natural canal anatomy.

Villalobos et al.⁴⁰ noted that tip design, as much as flute sharpness, led to improved cutting efficiency. Felt et al.⁴¹ designed experiments to exclude tip design because the tip might “overshadow the cutting effects of flute design.” Later, it was reported that “tips displayed better cutting efficiency than flutes” and that triangular pyramidal tips outperformed conical tips, which were least effective.^{42,43}

At the same time that a pitch was being made for the importance of cutting tips, other researchers were redesigning tips that virtually eliminated their cutting ability. Powell et al.^{44,45} began modifying the tips of K-files by “grinding to remove the transition angle” from tip to first blade.

By 1988, Sabala et al.⁴⁶ confirmed previous findings that the modified tip instruments exerted “less transportation and more inner curvature preparation. The modified files maintained the original canal curvature better and more frequently than did the unmodified files.”

Powell et al.⁴⁵ noted that each stainless steel “file’s metallic memory to return to a straight position, increases the tendency to transport or ledge and eventually to perforate curved canals.” This action takes place on the outer wall, the convex curvature of the canal. They pointed out that when this tip “angle is reduced, the file stays centered within the original canal and cuts all sides (circumference) more evenly.” This modified-tip file has been marketed as the

Figure 8 Flex-R-file with noncutting tip. **A**, Note rounded tip. **B**, “Nose” view of a noncutting tip ensures less gouging of the external wall and reduced cavity transport. From Ingle JI, Bakland LK. *Endodontics*, 5th ed. 2002, Ingle JI. et al. *Endodontic Cavity Preparation*. Page 483.

Flex-R-file (Moyco/Union Broach, Miller Dental, Bethpage, NY) (Figure 8).

Rounded-tipped files, developed by Roane,³⁴ were compared with other files with triangular cross-sections and various forms of tip modification. Although the round-tipped files were the least efficient, they prepared canals more safely and with less destruction than did the other files.⁴⁷ This study was done with stainless steel hand files in plastic blocks with balanced forces instrumentation.⁴⁷

HEDSTROM FILES

H-type files are made by cutting the spiraling flutes into the shaft of a piece of round, tapered, stainless steel wire. Actually, the machine used is similar to a screw-cutting machine. This accounts for the resemblance between the Hedstrom configuration and a wood screw (Figure 9A).

It is impossible to ream or drill with this instrument. To do so locks the flutes into the dentin much as a screw is locked in wood. To continue the drilling action would fracture the instrument. Furthermore, the file is impossible to withdraw once it is locked in the dentin and can be withdrawn only by backing off until the flutes are free. This action also “separates” files. Zinelis and Margelos⁴⁸ stated that fatigue is the primary cause of failure of Hedstrom files, whereas Kosti et al.⁴⁹ feel that the instrumentation technique that is used with the Hedstrom files also can contribute to their failure. Kazemi et al.⁵⁰ used two different materials to fabricate identical Hedstrom type of instruments. One set was made with stainless steel

Figure 9 ISO Group I, H-style instruments. **A**, Maillefer Hedstrom file resembling a wood screw. **B**, Modified Hedstrom file (left) with noncutting tip. “Safety” Hedstrom (right) with flattened noncutting side to prevent “stripping.” Reproduced with permission from Keate KC, Wong M. *J Endod* 1990;16:488.

and the other with nickel–titanium. These files were then tested for flexibility and resistance to fracture. The torsional moment for the stainless steel files was

significantly higher than the nickel–titanium although the angular deflection for the nickel–titanium was significantly higher than the stainless steel.⁵⁰

Hedstrom files cut in one direction only—retraction. Because of the very positive rake of the flute design, they are more efficient as files per se.^{51–55} Yguel-Henry et al.⁵⁴ reported on the importance of the lubricating effect of liquids on cutting efficiency, raising this efficiency by 30% with H-style files and 200% with K-files. Mizrahi et al.,⁵² however, reported the proclivity that H-files have for packing debris at the apex. On the other hand, El Deeb and Boraas⁵⁵ found that H-files tended not to pack debris at the apex and were the most efficient.

Hedstrom files are not to be used in a torquing action. For this reason, ADA Specification No. 28 could not apply, and a new specification, No. 58, was approved by the ADA and the American National Standards Committee.⁵⁶

H-STYLE FILE MODIFICATION

The Hyflex file (Coltene/Whaledent/Hygenic, Mahwah, NJ) in cross-section presents an “S” shape rather than the single-helix teardrop cross-sectional shape of the true Hedstroem file. The “S” File (J-S Dental, Ridgefield, CT) also appears to be a variation of the H-style file in its double-helix configuration. Reports on this instrument are very favorable.⁵⁷ Buchanan has further modified the Hedstroem file, the Safety Hedstrom (Sybron-Endo/Kerr), which has a noncutting side to prevent ledging in curved canals (Figure 9, B).

U-FILE

An instrument for which there is no ISO or ANSI/ADA specification as yet is the U-File. It is marketed as ProFiles, GT Files (Dentsply/Tulsa Dental, Tulsa, OK), and LIGHTSPEED (LightSpeed Technology Inc., San Antonio, TX). The U-File’s cross-sectional configuration has two 90° cutting edges at each of the three points of the blade (Figure 10). The flat cutting surfaces act as a planing instrument and are referred to as radial lands. A noncutting pilot tip ensures that the file remains in the lumen of the canal, thus avoiding transportation and “zipping” at the apex. The files are used in both a push-pull and rotary motion and

Figure 10 Cross-sectional view of a U-File reveals six corners in cutting blades compared with four corners in square stock and three corners in triangular stock K-files. Courtesy of John McSpadden.

are very adaptable to nickel–titanium rotary instruments. ProFiles are supplied in a variety of tapers and ISO tip sizes of 15 through 80.

GT ProFiles, developed by Buchanan in the U-design, are unusual in that the cutting blades extend up the shaft only 6 to 8 mm rather than 16 mm, and the tapers start at 0.06 mm/mm (instead of 0.02), as well as 0.08 and 0.10, tapered instruments. They are made of nickel–titanium and come as hand instruments and rotary files. GT instruments all start with a noncutting tip ISO size 20.

LIGHTSPEED LSX

The distinctive design of LightSpeed instruments (Discus Dental, Culver City, CA) maximizes flexibility and allows larger apical preparations without unnecessary removal of dentin. The LSX has a non-cutting shaft and very short blade. After making straight-line access to about mid-root, the coronal third is flared with the instrument of choice (not with the LSX). After flaring, at least a #15 K-file is used to obtain patency to working length (WL). A #20 LSX and sequentially larger sizes are used to prepare the apical third. The final apical instrument size (FAS) is

Figure 11 The newly designed LightSpeed LSX NiTi rotary instrument (Discus Dental, Culver City, CA) maximizes flexibility that allows for enlarged apical preparations. The distinctive cutting head terminates a noncutting shaft. It should be used at 2500–3000 RPM and irrigation is required throughout the enlarging procedure. The new LSX is used to prepare a tapered and circular apical preparation in an ovoid canal.

the blade size that encounters 4mm or more of cutting resistance apically. A 4mm step back with the next larger (than the FAS) instrument completes the apical preparation. The mid-root is then cleaned and tapered with the next two or three sequentially larger LSX sizes, blending mid-root instrumentation with the previously prepared coronal third. Recapitulation usually is necessary only once – with the FAS – at the end of canal preparation. The new LSX is to be used at 2500 rpm, and irrigation is required throughout the procedure.

GATES GLIDDEN MODIFICATION

Another hand instrument also designed for apical preparation was the Flexogate (Dentsply/Maillefer), but it is no longer manufactured. Briseño et al.⁶² compared Flexogates and Canal Master (Brasseler, Savannah, GA) in vitro and found Flexogates less likely to cause apical transportation.

QUANTEC “FILES”

The Quantec instrument (Sybron-Endo/Kerr), although called a “file,” was more like a reamer. It was not designed to be used in the file’s push-pull action but rather in the reamer’s rotary motion. The radial lands of the Quantec were slightly relieved to reduce frictional contact with the canal wall, and the helix angle is configured to remove debris. It is no longer manufactured.

HAND INSTRUMENT CONCLUSIONS

The literature is replete with references to the superiority of one instrument or one method of preparation over all

others.^{55,63–66} Quite true is Briseño’s⁶⁷ statement, “Regardless of the instrument type, none was able to reproduce ideal results; however, clinically acceptable results could be obtained with all of them.” All too often clinicians report success with instruments and techniques with which they are most comfortable. No ulterior motive is involved, but often a report reflects badly on an instrument when it is the clinician’s inexperience with an unfamiliar technique that is unknowingly being reported. Stenman and Spångberg⁶⁸ said it “is difficult to assess, as results from published investigations often vary considerably.”

BARBED BROACHES

Barbed broaches are short-handled instruments used primarily for vital pulp extirpation. They are also used to loosen debris in necrotic canals or to remove paper points or cotton pellets. ISO Specification No. 63 sets the standards for barbed broaches. Rueggerberg and Powers⁶⁹ tested all sizes of broaches from three manufacturers and found significant differences in shape, design, and size, as well as results from torsion and deflection tests. The authors warned that a “jammed broach” should be removed vertically without twisting.

Broaches are manufactured from round wire, the smooth surface of which has been notched to form barbs bent at an angle from the long axis (Figure 12A). These barbs are used to engage the pulp as the broach is rotated within the canal until it begins to meet resistance against the walls of the canal. The broach should never be forced into a canal beyond the length where it first begins to bind. Forcing it farther apically causes the barbs to be

Figure 12 **A**, Barbed broach. As a result of a careless barbing process, the effective shaft diameter is greatly reduced. Size “coarse.” **B**, Ductile failure of size “xx fine” barbed broach fractured after axial twisting greater than 130°. Reproduced with permission from Rueggerberg FA, Powers JM. *J Endod* 1988;14:133.

compressed by the canal walls. Subsequent efforts to withdraw the instrument will embed the barbs in the walls. Increased withdrawal pressure to retrieve the instrument results in breaking off the embedded barbs or the shaft of the instrument itself at the point of engagement (Figure 12B). A broken barbed broach embedded in the canal wall is seldom retrievable.

Nickel–Titanium Endodontic Instruments

A new generation of endodontic instruments, made from nickel–titanium, has added a new dimension to the practice of endodontics.^{70,71} The superelasticity of nickel–titanium, the property that allows it to return to its original shape following significant deformation, differentiates it from other metals, such as stainless steel, that sustain deformation and retain permanent shape change. These properties make nickel–titanium endodontic files more flexible and better able to conform to canal curvature, resist fracture, and wear less than stainless steel files (see Chapter 25B, “Introduction of Nickel–Titanium Alloy to Endodontics”).

SUPERELASTICITY

Alloys such as nickel–titanium, that show superelasticity, undergo a stress-induced martensitic transformation from a parent structure, which is austenite. On release of the stress, the structure reverts back to austenite, recovering its original shape in the process. Deformations involving as much as a 10% strain can be completely recovered in these materials, as compared with a maximum of 1% in conventional alloys.

In a study comparing piano wire and a nickel–titanium wire, Stoeckel and Yu⁷¹ found that a stress of 2,500 MPa was required to stretch a piano wire to 3% strain, as compared with only 500 MPa for a nickel–titanium wire. At 3% strain, the music wire breaks. On the other hand, the nickel–titanium wire can be stretched much beyond 3% and can recover most of this deformation on the release of stress. The superelastic behavior of nickel–titanium also occurs over a limited temperature window. Minimum residual deformation occurs at approximately room temperature.⁷¹ A composition consisting of 50 atomic percent nickel and 50 atomic percent titanium seems ideal, both for instrumentation and manufacture.

MANUFACTURE

Today, nickel–titanium instruments are precision ground into different designs (K style, Hedstrom,

Flex-R, U-files, and drills) and are made in different sizes and tapers. The nickel–titanium alloy is difficult to machine as the properties of the alloy can be changed during the manufacturing process. Variables such as feed rate, lubrication, and heat treating during the fabrication process can influence the final product.⁷² Just now there are new manufacturing methods that employ casting of the alloy or stamping wire blanks. In addition, spreaders and pluggers are also available. Nickel–titanium instruments are as effective as or better than comparable stainless steel instruments in machining dentin, and nickel–titanium instruments are more wear resistant.⁷³ U and drill designs make it possible to use mechanical (i.e., rotary handpiece) instrumentation. Moreover, rotary motors now offer the potential for improved torque control with automatic reversal that may decrease rotary instrument breakage.

Finally, nickel–titanium files are biocompatible and appear to have excellent anticorrosive properties.⁷⁴ In addition, implantation studies have verified that nickel–titanium is biocompatible and acceptable as a surgical implant.⁷⁵

With the ability to machine flutes, many new designs such as radial lands have become available. Radial lands allow nickel–titanium files to be used as reamers in a 360° motion as opposed to the traditional reamers with more acute rake angles. Although the most common use of this new design has been as a rotary file, the identical instrument is available as a hand instrument. In addition, a converter handle is available that allows the operator to use the rotary file as a hand instrument.

TORSIONAL STRENGTH AND SEPARATION

The clinician switching from stainless to nickel–titanium hand instruments should not confuse nickel–titanium’s superelastic characteristics with its torsional strength and so assume that it has super strength. This misconception has led to unnecessary file breakage when first using this new metal. Studies indicate that instruments, whether stainless steel or nickel–titanium, meet or exceed ANSI/ADA Specification No. 28. However, when reviewing the literature on this subject the results are mixed. Canalda-Sahli et al.⁷⁶ found nickel–titanium files (Nitiflex and Naviflex) (Dentsply) to be more flexible than the stainless files tested (Flexofile and Flex-R). However, the stainless steel files were found to be more resistant to fracture. Both types of metal exceeded all ANSI/ADA specifications. Canalda-Sahli et al.,⁷⁷ in another study, compared identical instruments: CanalMaster (aka LIGHTSPEED) stainless steel and CanalMaster

nickel–titanium. Within these designs, the nickel–titanium values were superior in all aspects to those of stainless steel of the same design.

Tepel et al.¹² looked at bending and torsional properties of 24 different types of nickel–titanium, titanium–aluminum, and stainless steel instruments. They found the nickel–titanium K-files to be the most flexible, followed in descending order by titanium–aluminum, flexible stainless steel, and conventional stainless steel. When testing for resistance to fracture for 21 brands, however, they found that No. 25 stainless steel files had a higher resistance to fracture than their nickel–titanium counterpart.

Wolcott and Himel¹³ compared the torsional properties of stainless steel K-type and nickel–titanium U-type instruments. As in previous studies, all of the stainless steel instruments showed no significant difference between maximum torque and torque at failure, whereas the nickel–titanium instruments showed a significant difference between maximum torque and torque at failure. Essentially, this means that the time between “windup” and fracture in nickel–titanium instruments is extended, which could lead to a false sense of security.

While studying cyclic fatigue using nickel–titanium LightSpeed instruments, Pruett et al.⁷⁸ determined that canal curvature and the number of rotations determined file breakage. Separation occurred at the point of maximum curvature of the shaft.

Cyclic fatigue should be considered a valid term, even for hand instrumentation, in light of the fact that many manufacturers are placing handles on files designed for rotational use. From these studies, it seems that if the clinician is changing from a high-torque instrument, such as stainless steel, to a low-torque instrument, such as nickel–titanium, it would be wise to know that nickel–titanium instruments are more efficient and safer when used passively. Although instrument breakage should be rare, any instrument, hand or rotary, can break. It is the clinician’s knowledge and experience, along with the manufacturer’s quality control, that will ultimately minimize breakage. If breakage occurs, the fractured piece can occasionally be removed or bypassed using ultrasonics and hand instruments in conjunction with magnification. Dentists having problems with file breakage should seek help in evaluating one’s technique. One should practice on extracted teeth until a level of confidence is reached that will help ensure safe and efficient patient care.

The following is a list of situations that place nickel–titanium hand or rotary instruments at risk along with suggestions for avoiding problems.

Nickel–Titanium Precautions and Prevention

1. Often too much pressure is applied to the file. Never force a file! These instruments require a passive technique. If resistance is encountered, stop immediately, and before continuing, increase the coronal taper and negotiate additional length, using a smaller, 0.02 taper stainless steel hand file. Stainless steel files should be used in sizes smaller than a No. 15. If one is using more finger pressure than that required to break a No. 2 pencil lead, too much pressure is being used.
2. Canals that join abruptly at sharp angles are often found in roots such as the mesiobuccal root of maxillary molars, all premolars, and mandibular incisors and the mesial roots of mandibular molars. The straighter of the two canals should first be enlarged to working length and then the other canal, only to where they join. If not, a nickel–titanium file may reverse its direction at this juncture, bending back on itself and damaging the instrument.
3. Curved canals that have a high degree and small radius of curvature are dangerous.⁷⁸ Such curvatures (over 60° and found 3 to 4 mm from working length) are often seen in the distal canals of mandibular molars and the palatal roots of maxillary first molars.
4. Files should not be overused! Clinicians have experienced more fracture after files have been used a number of times. Remember that all uses of a file are not equal. A calcified canal stresses the file more than an uncalcified canal. A curved canal stresses the file more than a straight canal. One must also bear in mind operator variability and the use of lubricants, which will affect stress. Consider discarding a file after abusive use in calcified or severely curved canals even though it has been used only in one tooth. Use new files in hard cases and older files in easier cases. No one knows the maximum or ideal number of times a file can be used. Follow manufacturers’ instructions. Once only is the safest number.
5. Instrument fatigue occurs more often during the initial stages of the learning curve. The clinician changing from stainless steel to nickel–titanium should take continuing education courses with experienced clinicians and educators, followed

- by in vitro practice on plastic blocks and extracted teeth.
6. Ledges that develop in a canal allow space for deflection of a file. The nickel–titanium instrument can then curve back on itself. A nickel–titanium instrument should not be used to bypass ledges.
 7. Teeth with “S”-type curves should be approached with caution! Adequate flaring of the coronal third to half of the canal, however, will decrease problems in these cases. It may also be necessary to go through a series of instruments an additional time or two in more difficult cases.
 8. If the instrument is progressing easily in a canal and then feels as if it hits bottom, do not apply additional pressure! This will cause the instrument tip to bind. Additional pressure applied at this point may cause weakening or even breakage of the instrument. In this situation, remove the instrument and try a smaller, 0.02 taper hand instrument, either stainless steel or nickel–titanium, carefully flaring and enlarging the uninstrumented apical portion of the canal.
 9. Avoid creating a canal the same size and taper of the instrument being used. On removal from the canal, the debris pattern on the file should be examined. Debris should appear on the middle portion of the file. Except for negotiating calcified canals and enlarging the apical portion of the canal, the tip and coronal section of the file should not carry debris. Avoid cutting with the entire length of the file blade. This total or frictional fit of the file in the canal will cause the instrument to lock. If this occurs, rotate the instrument in a counterclockwise direction and remove it from the canal. The greater the distance a single file is advanced into the canal, the greater will be the chance of files “locking up.” When the file feels tight throughout the length of blade, it is an indication that the orifice and coronal one-third to two-thirds of the canal need increased taper. Instruments of varying design and/or taper can be used to avoid frictional fit. Nickel–titanium instruments with tapers from 0.04, 0.06, and greater, as well as Gates Glidden drills and sonic/ultrasonic instruments, serve this purpose well.
 10. Sudden changes in the direction of an instrument caused by the operator (i.e., jerky or jabbing movements) must be avoided. A smooth gentle reaming or rotary motion is most efficient.
 11. As with any type instrument, poor access preparation will lead to procedural errors.
 12. Advancing or pushing an instrument into a canal in too large an increment causes it to act as a drill or piston and greatly increases stress on the metal. Except for the most difficult cases and the necessity of using small instruments, the tip should not be used to cut into or drill into the canal; it should act only as a guide. Regardless of the technique being used, nickel–titanium instruments should be advanced in small increments with a more passive pressure than that used with stainless steel.
 13. Do not try to make nickel–titanium do more than it is designed to do.
 14. Inspection of instruments, particularly used instruments, by staff and doctor is critical. Prior to insertion and on removal, look at the blade. Rotate the file, looking for deflections of light. This indicates a damaged instrument. Also remember that, unlike stainless steel, nickel–titanium has an excellent memory. The file should be straight. If any bend is present, the instrument is fatigued and should be replaced.
 15. Do not assume that the length of files is always accurate; measure each file. Some files are longer from handle to tip than others. Files may also become longer or shorter if they are unraveled or twisted.

COMPARATIVE STUDIES

Nickel–titanium instruments function differently than those made of stainless steel, even when the cross-sectional design, taper, flutes, and tip are identical. Himmel et al.⁷⁹ compared hand nickel–titanium filing of plastic blocks with curved canals to stainless steel filing.

Working length was maintained significantly more often ($p < .05$) in the nickel–titanium group than in the stainless steel group. There was no ledging of canals using the more flexible nickel–titanium files compared with 30.4% ledging when stainless steel files were used. Apical zipping occurred 31.7% less often with the Nitinol files.⁷⁹ Stripping of the canal walls was less with the nickel–titanium files. An observation from these studies was the creation of a smooth belly shape on the outer aspect of the apical third of the canals instrumented with nickel–titanium instruments. This seemed to replace the ledging that occurred with stainless steel.

Using computed tomography, Gambill et al.⁸⁰ reamed extracted teeth with either stainless

steel or nickel–titanium files and reported that the nickel–titanium files caused less canal transportation, removed less dentin, were more efficient, and produced more centered canals. On the other hand, not all studies are in agreement concerning cutting efficiency. Tepel et al.⁸¹ tested 24 brands of hand instruments specifically for cutting efficiency. They found that flexible stainless steel files were more efficient than nickel–titanium. However, they did not address the quality of the completed canal.

Elliot et al.⁸² used resin blocks to compare stainless steel (Flexofiles) and nickel–titanium (Nitiflex) instruments used with either a balanced force or step-back technique. They concluded that it is preferable to use nickel–titanium instruments in a balanced force technique and stainless steel in a filing technique because stainless steel files can be precurved. Considering these results, nickel–titanium instruments should be used as reamers, not files.

ROTARY NICKEL–TITANIUM FILES

It needs to be emphasized that the previously stated guidelines apply to all of the rotary nickel–titanium files that are and will be available. Just as most of the preceding papers apply to hand nickel–titanium files, there now exists an extensive body of literature on rotary nickel–titanium files. This literature covers a variety of aspects from the metallurgy of the files to how well they clean and shape the canal system.

A number of studies have utilized a variety of test instruments to investigate the properties of new and used nickel–titanium rotary files. These researchers have used such things as X-ray diffraction (XRD), scanning electron microscopy (SEM), microhardness testing, differential scanning calorimetry (DSC), and temperature-modulated DSC (TMDSC). In a series of studies, Kuhn et al.^{83,84} have shown that the alloy of various files (both new and used) is fully austenitic at room temperature by means of XRD and DSC. They also exposed the files to various heat treatments to determine what if any influence these treatments would have on the flexibility of the files. Kim et al.⁸⁵ performed cryogenic treatment on nickel–titanium instruments. They showed that the microhardness of the files was increased but that there was no noticeable change in cutting efficiency, nor was there any change in the crystalline phase composition of the files. Although these results did show some differences, it is doubtful that the differences are clinically relevant. Brantley et al.⁸⁶ looked at two different types of rotary files as well as the wire blanks that

were used to fabricate the files. They compared new files with ones that had been used to instrument canals in extracted teeth. Their analysis with DSC showed that although there were differences between the files and the blanks, all of the instruments were still fully austenitic at room temperature. In another study that compared the wire blanks with the final product (ProFile instruments), Bahia et al.⁸⁷ found that cyclic loading did change the wire blanks as well as the instruments. However, these changes did not compromise the instruments, nor did DSC or XRD demonstrate any significant differences. Another study utilized DSC to compare five types of rotary nickel–titanium files and correlate these findings with torsional and bend testing of these instruments. It was seen that a lower transformation temperature as disclosed by DSC was correlated with an instrument that required a higher torsional load to fail and a higher load to bend to the maximum deflection of 4 mm.⁸⁸ Clinically, this would equate to an instrument that had increased stiffness. Whether this would be a noticeable increase in stiffness would depend in some degree on the operator. Some of these studies have remarked on machining defects that are revealed by SEM and speak to the possible relationship of these defects to the clinical failure of the instruments.

FATIGUE AND FLEXIBILITY OF ROTARY NICKEL–TITANIUM FILES

There have been a number of approaches to ascertaining the fatigue and flexibility of rotary nickel–titanium files. Some have looked at mathematical models and employed finite element analysis to develop theoretical values. In a comparison of a triple U (ProFile) versus triple helix (HERO 642) theoretical cross-sections, it was determined that the triple U was more flexible but had less torsional strength.⁸⁹ When these same cross-sections were used to calculate theoretical torsional and bending moments, it was determined that the triple U model had a larger and higher range for torsional stress and a higher maximum stress value.⁹⁰ The translation of these values into determining the clinical usability of the respective instruments is not easily done because there are so many other variables such as rpm, canal curvature, canal radius of curvature, and insertion rate/force that must also be considered.

In another study utilizing a computer model, the ProTaper instrument was compared with the ProFile instrument. Although the ProTaper was shown to be

a stiffer instrument, it was also shown that the stress distribution during torsional loading and bending loads was more evenly distributed. The authors suggest that the ProTaper design will accumulate less stress during usage and thus would be indicated for instrumenting small curved canals.⁹¹

In a finite element analysis of existing nickel–titanium instruments, it was confirmed that as the cross-sectional area of the files increases, the file is more resistant to torsional forces.⁹² Such an interpretation is limited by a number of factors including heat treating during manufacture, modification of the nickel–titanium alloy used, and changes in any number of parameters during fabrication such as feed rate or newness of the machining tools. A series of studies, more closely related to the clinical usage of rotary nickel–titanium files, have brought out some interesting results. One study stated that there was no significant difference in fatigue resistance between new and used ProFile instruments after clinical usage. However, the used instruments did fail sooner when rotated in a 90° curved tube.⁹³ Another study states there is a significant difference between the fatigue resistance of new and used files and that larger files will fail sooner after they are used.^{94,95} A clinical usage study by Bahia et al.⁹⁶ confirmed these results. These results were then verified in another study by Bahia et al.⁹⁷ done under more controlled conditions. They demonstrated that a used file will fail sooner than a new file. A number of other studies have verified these results.^{98–101} When other parameters are addressed such as angle and radius of curvature, it is seen that an increase in the angle of curvature or a decrease in the radius of curvature causes files to fail sooner.^{99,102,103} It is also seen that a larger file is more resistant to torque.^{104–106}

When Gates Glidden drills were fabricated from nickel–titanium, it was shown that the larger the size of the drill, the sooner it would fail when rotated in a device that imparted a bend to the instrument while being rotated.¹⁰⁷ An interesting sidelight in one report demonstrated that dry heat sterilization seemed to increase the files' ability to resist fatigue.⁹⁸ However, it required five cycles of dry heat sterilization to achieve these results. One could question the advisability of using a rotary file many times. Finally, a study looked at the cross-sectional geometry of five different types of rotary nickel–titanium files and determined that as the cross-section area increased, the file became more resistant to bending.¹⁰⁸ This would seem to verify the theoretical studies that were mentioned previously.

FORCES ENCOUNTERED

During canal preparation, forces are generated by the insertion of the rotating file into the canal system. In a series of studies utilizing a test instrument developed by Blum et al.,¹⁰⁹ they reported some interesting findings. They have shown that the crown-down technique with ProFile instruments produced less force than the step-back technique. In another study, they demonstrated that forces were lowest when there was less engagement of the file with the canal walls.¹¹⁰ When the same type of study was done with the ProTaper instrument in narrow and large canals, the same conclusions were reached. The more a file was in contact with the canal wall, the higher the forces on the instrument and the canal wall.¹¹¹ These results were confirmed by others utilizing different test instruments and test methods. When Quantec rotary files were used in extracted teeth, it was seen that a file with a larger taper generated more forces particularly in a smaller canal.¹¹² Peters¹¹³ confirmed these findings; when a ProTaper instrument was used in smaller canals, higher forces were generated. When a step-back technique utilizing RaCe rotary nickel–titanium instruments was compared with ProFile instrumentation, it was found that the RaCe instruments produced less force in the canal system.¹¹⁴

Another study compared the use of a sequence of 0.04 tapered instruments with a sequence using 0.04 and 0.06 instruments. The sequence using the two different tapers produced less force.¹¹⁵ A study performed with photoelastic material showed that with less engagement of the canal wall, there were smaller forces generated.¹¹⁶ It was also shown that when more flutes per unit length are engaged, higher forces are the result.¹¹⁷ Lubrication also influences the forces that can be generated during canal instrumentation. In particular, the use of an EDTA chelation solution significantly reduced maximum torque values for ProFile instruments.¹¹⁸

SEPARATION AND DISTORTION

A separated instrument is an undesirable occurrence during endodontic therapy. Unfortunately, it is very difficult to avoid when any type of rotary instrument is used in the canal system. Two recent studies looked at file separation and distortion. In one, only one file type (ProFile Series 29) was utilized. These files were used in only one patient before being discarded. The failure rate (separation) was less than 1%. The distortion rate was 15%. It is not known how many canals were treated with any one instrument.¹¹⁹ A similar study looked at the LightSpeed instrument and found

that for a total of 3,543 canals treated, the separation rate was 1.3%.¹²⁰ When ProFile instruments were used by dental students in their preclinical simulation laboratory, there was a separation rate of 0.31%.¹²¹ A clinical study that compared ProFile with ProTaper systems found a separation rate of 7% for ProFile and 14% for ProTaper.¹²² In this study, each instrument was used in at least four molars or 20 premolars or 50 incisors and canines. It would seem that these instruments were over used. In the other study, over 7,000 instruments of 8 different types were examined. The overall distortion rate was 12% and the fracture rate was 5%. However, these instruments were not discarded after being used in one patient. The mean use of the distorted instruments was three times, and the mean use of the undistorted instruments was four times.¹²³ In both studies, the patient treatment was done by endodontists. In other studies, an attempt has been made to delineate what factors are important in the distortion or separation of these files.

A series of studies considered rpm as a primary factor. Two studies concluded that higher rpm resulted in more separation and distortion.^{124,125} Another concluded that lower rpm resulted in more file distortion, but none were fractured in the study.¹²⁶ When two different file types were compared at the same rpm, there were no significant differences.¹²⁷ When canal curvature was factored in, Zelada et al.¹²⁸ stated that rpm was not a significant factor but that a canal curvature of greater than 30° was significant. However, when some of the same researchers did a similar study, they concluded that a higher rpm did result in more separated files.¹²⁹ They also stated that the angle of curvature was a significant factor in file breakage whereas the radius of curvature was not a factor. Yared et al.¹³⁰ considered other factors in a series of studies. In one study, they used sets of ProFile instruments up to 10 times. They concluded that a higher rpm resulted in more deformation and separation of the instruments. They also showed that changing the torque setting for the motors did not influence the results. In the final analysis, they determined that operator experience was a significantly important factor. In another study, they looked at the use of an air motor and compared it with a high-torque motor and a low-torque motor. There were no significant differences.¹³¹ When a similar study was done at a higher rpm setting, there were no significant differences when comparing the air motor with a high- or low-torque electric motor.¹³² Finally, they looked at operator experience as a factor with the ProTaper instrument. They concluded that operator experience was a significant factor in instru-

ment separation and deformation. Unfortunately, the use of a low-torque motor did not prevent the inexperienced operator from separating or deforming files.¹³³

A study affirming the comparison between the electric and air motors showed that there were no significant differences in file distortion when either of these types of motors was used.¹³⁴ In addition to considering separation and distortion of files, there have been those who have looked at the wear of nickel–titanium rotary files. Interestingly, they have found that in some aspects the files improve with use. That is, metal strips and pitted surfaces decreased after being used.¹³⁵ When a similar study was performed on GT rotary files, Tripi et al.¹³⁶ found that the frequency of defects such as disruption of the cutting edge, fretting, and craters increased. Both of these studies were done on human teeth. A study of ProTaper S1 instruments used clinically determined that multiple uses of these instruments resulted in microcrack formation in instruments that were not separated. It was also found that debris was seen to be trapped in crack-like structures.¹³⁷

SURFACE TREATMENT

In an effort to decrease the effects of usage, there have been attempts to modify the surface of the nickel–titanium alloy by various means. These methods include ion implantation^{138,139} and vapor deposition^{140–142} by various modalities. All of these methods were successful in changing the chemical composition of the nickel–titanium alloy surface as determined by XRD and other testing methods. However, in two studies, the efficacy of the vapor deposition was not confirmed by testing the wear or cutting efficiency.^{140,142} In two studies by Rapisarda et al.,^{138,139} they determined that there was better cutting efficiency and less wear because of the changes in the surface of the instruments. Schafer¹⁴¹ confirmed these findings by verifying that a vapor deposition of titanium nitride did increase the cutting efficiency of the instruments. However, when one considers the additional cost of modifying these instruments, there is a question as to whether the gain in wear resistance or cutting efficiency warrants the additional expense for an instrument that is already considered to be disposable after as little as one use.

IRRIGANTS AND STERILIZATION

The most common irrigant used during endodontic instrumentation is sodium hypochlorite. It is

important to know whether this or any other irrigant will have a deleterious effect on canal instruments. Haikel¹⁴³ showed that even lengthy exposure to sodium hypochlorite did not cause nickel–titanium files to fail at lower torsional moment values. In another study, Haikel²⁵ determined that the same long-term exposure to sodium hypochlorite did not decrease the cutting efficiency of nickel–titanium files. Stokes¹⁴⁴ determined that nickel–titanium files have a very high corrosion resistance even when immersed in full-strength sodium hypochlorite. A more recent study by Darabara et al.¹⁴⁵ showed that nickel–titanium files were highly corrosion resistant when exposed to sodium hypochlorite or R-EDTA. These instruments are also sterilized and, depending on clinical circumstances, may be sterilized multiple times before being discarded. Mize et al.¹⁵ looked at LightSpeed nickel–titanium instruments and found that multiple sterilization cycles did not influence the cyclic fatigue of these instruments. In a study that compared nickel–titanium files with stainless steel files, it was shown that even 40 sterilization cycles had no effect on the torsional moment at failure for either file type.¹⁴⁶

CANAL CLEANLINESS

Cleaning the canal system is a primary goal in endodontic therapy. Many instrumentation techniques and instruments have been developed to accomplish this important task. When only the removal of smear layer was considered, it was shown that the Quantec Series 2000 instruments removed significantly more of the smear layer in the apical third of the canal system when compared with K-file hand instrumentation.¹⁴⁷ Smear layer production by K3 was compared with ProFile, and it was found that K3 instruments produced less of a smear layer in the apical third of the canal system. However, both instruments did produce a smear layer.¹⁴⁸ In a comparison of RaCe and ProTaper rotary files, there was no difference in canal cleanliness, but in the apical third, the RaCe system did produce significantly less smear layer.¹⁴⁹ When the K3 system was compared with the NiTi-TEE system, there were no significant differences in canal cleanliness or smear layer removal.¹⁵⁰ When the K3 system was compared with the RaCe system and the Mtwo system, the Mtwo system was significantly better at cleaning the canal, but there were no significant differences for removal of the smear layer.¹⁵¹

Another study that compared nickel–titanium instrumentation with stainless steel hand files showed that canal cleanliness was equivalent if the size of the master

apical file was the same. However, with an increase in size of the apical preparation, it was found that a cleaner canal was the result regardless of the instrument type that was used.¹⁵² A similar study was performed utilizing GT files. All parameters except the size of the apical preparation were kept the same. The results were a larger apical preparation that left a canal system significantly cleaner.¹⁵³ These results are somewhat contradicted by the following studies. When Ahlquist et al.¹⁵⁴ compared stainless steel instrumentation with ProFiles, they found that the stainless steel instrumentation produced a significantly cleaner canal system in the apical third of the canal. When canal shape or curvature was considered, the results were similar. Barbizam et al.¹⁵⁵ found that oval canals were cleaned significantly better by hand instrumentation with stainless steel K-files. Schafer¹⁵⁶ reported the same results with stainless steel K-Flexofiles as compared with K3 rotary nickel–titanium files. Iqbal et al.¹⁵⁷ demonstrated that a combination technique was the best. The use of modified stainless steel Hedstrom files in combination with ProFile instrumentation produced the cleanest canals. In another study by Schafer,¹⁵⁸ hand instrumentation was compared with engine-driven stainless steel files and motor-driven ProFile instruments. None of the instruments produced a completely clean canal especially in the apical third of the canal system. Hand instrumentation with Hedstrom files produced the cleanest canals. When another engine-driven system of stainless steel files was compared with the ProFile or the HERO 642, it was shown that the HERO 642 produced the least amount of smear layer.¹⁵⁹ A more recent development in automated handpieces AET (Anatomic Endodontic Technology) utilizing stainless steel instruments was compared with the ProFile system and hand instrumentation with K-Flexofiles. The AET system produced significantly cleaner canal walls with significantly less smear layer.¹⁶⁰ These results were to be expected because the AET system specifies that the apical third of the canal is to be prepared with hand instruments.

No canal system can be properly prepared without the use of irrigants. Gambarini¹⁶¹ compared three irrigation regimes and concluded that the cleanest canal system was produced by a combination of EDTA, sodium hypochlorite, and a surfactant. LightSpeed instrumentation was compared with ProFile with two different irrigation techniques. There were differing results at different levels, but essentially there were no differences, particularly when consideration is given to the larger apical instrumentation with the LightSpeed group.¹⁶² When canal curvature was brought in as a variable, it was shown that the RaCe

instrument system produced a significantly cleaner canal system than the ProTaper instrument system.¹⁶³ In a comparative study with the Mtwo system, the ProTaper system produced a canal system that was as clean as the Mtwo system.¹⁶⁴ It may be presumed, if the canal system is being cleaned, that there is a reduction or elimination of bacteria. A group of studies has confirmed this presumption. Dalton et al.¹⁶⁵ compared stainless steel K-file instrumentation of the canal system with ProFile Series 29. There were no significant differences in the reduction of bacterial counts with saline irrigation. Another study compared hand nickel–titanium filing with the GT system with the ProFile Series 29 preparation of the canal system. There was no significant difference in bacterial counts with saline as an irrigant.¹⁶⁶

If sodium hypochlorite was used as an irrigant, there were no significant differences in the reduction of bacterial counts when comparing hand nickel–titanium preparation of the canal system with the GT system of canal preparation.¹⁶⁷ If a combination of irrigants (5.25% NaOCl, EDTA, and calcium hydroxide) was used with GT rotary instrumentation, bacterial counts were significantly reduced. It was also confirmed that larger apical instrumentation resulted in the removal of more bacteria.¹⁶⁸

As in the past, an additional concern with canal instrumentation is the amount of apical extrusion of debris. Ferraz et al.¹⁶⁹ compared two different stainless steel hand filing techniques (step-back versus balanced forces) with three different nickel–titanium instrument systems (ProFile versus Quantec 2000 versus Pow-R). As expected, there was significantly more debris extruded through the apical foramen by the step-back filing technique. In looking at the amount of bacteria that were extruded past the apex, a comparison was made between the ProTaper system and the GT system. There were no significant differences.¹⁷⁰ Unfortunately, these results were not compared with hand instrumentation or any other instrumentation technique. A recent study made comparisons between three rotary systems (ProTaper versus ProFile versus HERO). All systems produced apical extrusion of debris. ProTaper caused the extrusion of significantly more debris.¹⁷¹ The question remains as to how much bacteria or debris the body can tolerate. It is doubtful any instrumentation technique would be able to eliminate extruding any bacteria or debris.

A final concern in the cleanliness of the canal system is whether or not the instruments themselves may be clean before use or be able to be cleaned after being

used. Linsuwanont et al.¹⁷² showed that new rotary nickel–titanium files have metal filings and debris present on them. This will vary from manufacturer to manufacturer and from lot to lot. They also determined that most files can not be rendered completely clean after use. When a similar study utilized pre-soaking in an enzymatic cleaner and an ultrasonic bath, it was found that the enzymatic cleaner did not have a significant effect. However, the ultrasonic bath did render the instruments significantly cleaner but was not able to remove calcium hydroxide deposits on all of the files.¹⁷³

CANAL SHAPE

Just as canal anatomy may limit one's ability to clean the canal system, it also limits one's ability to shape the canal system before placing the obturation material. A major concern with any instrumentation system or technique is whether or not the canal system will be distorted in some fashion. When Schafer²⁴ compared hand nickel–titanium files with stainless steel files of the same cross-sectional geometry, he found that the nickel–titanium files removed less material than the stainless steel files. Another study compared hand filing of the canal system between nickel–titanium GT files, nickel–titanium K-files, and stainless steel K-files. In this study, Song et al.¹⁷⁴ found significantly less transportation with the nickel–titanium files. Whenever, in a series of studies, stainless steel hand filing was compared with either nickel–titanium hand filing or nickel–titanium rotary files, there was significantly less transportation of the canal system with the nickel–titanium files. This applied to LightSpeed nickel–titanium rotary files, GT nickel–titanium rotary files, ProFile Series 29, ProFile rotary files, Pow-R, K3, RaCe, and HERO 642 files.^{156,175–182} However, there were two exceptions. When Peters et al.¹⁸³ utilized high-resolution computed tomography to assess canal transportation, they found that the ProFile system transported the most when compared with stainless steel hand files or LightSpeed rotary nickel–titanium files. The other exception was the study by Imura et al.¹⁸⁴ that compared stainless steel Flex-R filing of the canal system with two rotary nickel–titanium systems and found that all of the instruments transported the canal system to some degree. However, when hand nickel–titanium filing was compared with rotary nickel–titanium filing, there were no significant differences in canal transportation.^{185–187} The same results were usually obtained when various rotary nickel–titanium

files were compared with each other. That is, there were no significant differences in canal transportation. This applied to ProFile versus Naviflex,¹⁸⁸ HERO 642 versus Quantec SC,¹⁸⁹ ProTaper versus K3,¹⁹⁰ Flexmaster versus HERO 642,¹⁹¹ ProFile versus GT rotary versus Quantec versus ProTaper,¹⁹² and ProTaper versus GT rotary.¹⁹³ Of course, there were exceptions. When ProTaper was compared with RaCe, the RaCe instruments had significantly less transportation.¹⁶³ However, when ProTaper was compared with ProFile Series 29, there was significantly more transportation at 4 mm from the working length with the ProFile Series 29 files.¹⁹⁴ But, ProFile instruments showed significantly less transportation than K3 files depending on canal curvature.¹⁹⁵

In later studies, some of the previous comparisons were confirmed and some were not confirmed. A study done in simulated S-shaped canals in plastic blocks compared the ProTaper system with K3 and RaCe instruments. It was found that the ProTaper system caused significantly more widening of the canal.¹⁹⁶ However, the clinical relevance of the results are questionable when one considers that the differences in canal widening were on the order of tenths of a millimeter. When comparing Mtwo with K3 and RaCe, it was found that the Mtwo system was significantly better at maintaining canal curvature.¹⁵¹ Again, what is the clinical relevance of the results when it was found that the differences in canal curvature were less than two degrees? When Paque et al.¹⁴⁹ compared ProTaper with RaCe in extracted teeth, they found no significant differences for canal straightening or canal shape.

What needs to be remembered here is that canal anatomy should dictate what instruments can be used and how they should be used. Any instrument or instrumentation system can cause irreversible damage to the canal system. Any instrument or instrumentation system can produce excellent results if they are properly employed.

Rotary nickel–titanium files are not only used to prepare the canal system, they are also used to remove gutta-percha during re-treatment procedures. One study showed that ProFile instrumentation alone leaves significantly less gutta-percha debris after re-treatment.¹⁹⁷ However, other studies have shown no differences when compared with other rotary systems or hand filing with chloroform.^{198,199} One study did show that hand K-files left significantly less debris than the Quantec SC system.²⁰⁰ Other studies have looked at a number of different methodologies to remove either gutta-percha or a polymer-based material. When K-files activated by the M4 or Endo-gripper automated hand-

pieces were compared with K-files alone or K3 rotary files, there were no overall differences in removing gutta-percha.²⁰¹ When H-files were compared with the ProFile system, there were no significant differences.²⁰² In a study comparing H-files, Flexmaster, ProTaper, and RaCe, it was determined that RaCe was significantly better than Flexmaster of H-files. It was also determined that there were no significant differences between ProTaper and all the other techniques.²⁰³

Finally, when H-files were compared with RaCe for the removal of gutta-percha or a polymer-based material, there were no significant differences between the techniques.²⁰⁴ In all of these studies, there was no technique or instrumentation system that was able to remove all of the obturation materials. One would not expect that this could occur because it is not possible to completely clean any canal system.

NITI SPREADERS

There are also nickel–titanium spreaders developed for use in canal obturation. Berry et al.²⁰⁵ showed these spreaders could penetrate further than stainless steel spreaders when used in curved canals. Schmidt et al.²⁰⁶ compared penetration depth and force required to insert the spreader to place with a master cone in place in a curved canal. The nickel–titanium spreaders required less force and penetrated deeper than stainless steel spreaders. Gharai et al.²⁰⁷ confirmed these results and tested the adequacy of the obturation by subjecting the molar teeth to a microleakage test. The nickel–titanium finger spreaders produced significantly less force, but there were no significant differences in microleakage.

ENGINE-DRIVEN INSTRUMENTS

Engine-driven instruments can be used in three types of contra-angle handpieces: a full rotary handpiece, latch or friction grip, a reciprocating/quarter-turn handpiece, or a special handpiece that imparts a vertical stroke but with an added reciprocating quarter-turn that “cuts in” when the instrument is stressed. In addition, there are battery-powered, slow-speed handpieces that are combined with an apex locator, designed to prevent apical perforations. Because the instruments used in these handpieces are generally designed for the type of action delivered, it is best to describe the handpiece before discussing their instruments.

ROTARY CONTRA-ANGLE HANDPIECE INSTRUMENTS

Instrumentation with a full rotary handpiece is by straight-line drilling or side cutting. Mounted with round or tapered burs or diamond points, full rotary contra-angle handpieces can be used to develop coronal access to canal orifices. Special reamers may be used to funnel out orifices for easier access, to clean and shape canals with slow-turning nickel–titanium reamer-type instruments, and to prepare post channels for final restoration of the tooth.

Because some of these instruments (stainless) do not readily bend and should be used in perfectly straight canals and because they are often misdirected or forced beyond their limits, they can cause perforations or break.

One solution to these problems is to use a slower handpiece: the Medidenta/Micro Mega MM 324 reduction gear Handpieces (Medidenta/Micro Mega, Woodside, NY), the Aseptico Electric Motor Handpiece (Aseptico International, Woodinville, WA), the Quantec ETM Electric torque control motor (Sybron-Endo, Irving, CA), and the Moyco/Union Broach Sprint EDM Electronic Digital Motor handpiece (Miller Dental). These electric motors are specifically designed to power the new nickel–titanium instruments in canal preparation. The speeds vary from 300 rpm suggested for ProFiles (Tulsa Dental) to 2,000 rpm recommended for LightSpeed instruments.

Electric handpieces are available wherein not only the speed can be controlled but the torque as well, that is, the speed and torque can be set for a certain size instrument and the handpiece will “stall” and reverse if the torque limit is exceeded. Some of these motors are the Aseptico ITR Motor handpiece (Aseptico International), the Nouvag TCM ENDO motor (Nouvag, Switzerland), the Endo-Pro Electric (Medidenta/Micro Mega), and the ProTorq motor handpiece (Micro Motors Inc., Santa Ana, CA).

There is also the Morita Tri Auto-ZX (J. Morita USA Inc., Irvine, CA), a cordless, battery-powered, endodontic, slow-speed (280 rpm) handpiece with a built-in apex locator. It uses rotary nickel–titanium instruments held by a push-button chuck. The Tri Auto-ZX has three automatic functions: The handpiece automatically starts when the file enters the canal and stops when the file is removed. If too much pressure is applied, the handpiece automatically stops and reverses rotation. It also automatically stops and reverses rotation when the file tip reaches the apical stop, as determined by the built-in apex locator. The Tri Auto-ZX works in a moist canal.

RECIPROCATING HANDPIECE

A commonly used flat plane reciprocating handpiece is the Giromatic (Medidenta/Micro Mega). It accepts only latch-type instruments. In this device, the quarter-turn motion is delivered 3,000 times per minute. Kerr has the M4 Safety Handpiece (Sybron-Kerr, Orange, CA), which has a 30° reciprocating motion and a chuck that locks regular hand files in place by their handles (Figure 13). The Kerr Company recommends their Safety Hedstrom Instrument be used with the M4. Zakariassen et al.^{208,209} found the M4, mounted with Safety Hedstrom files, to be somewhat superior to “step-back

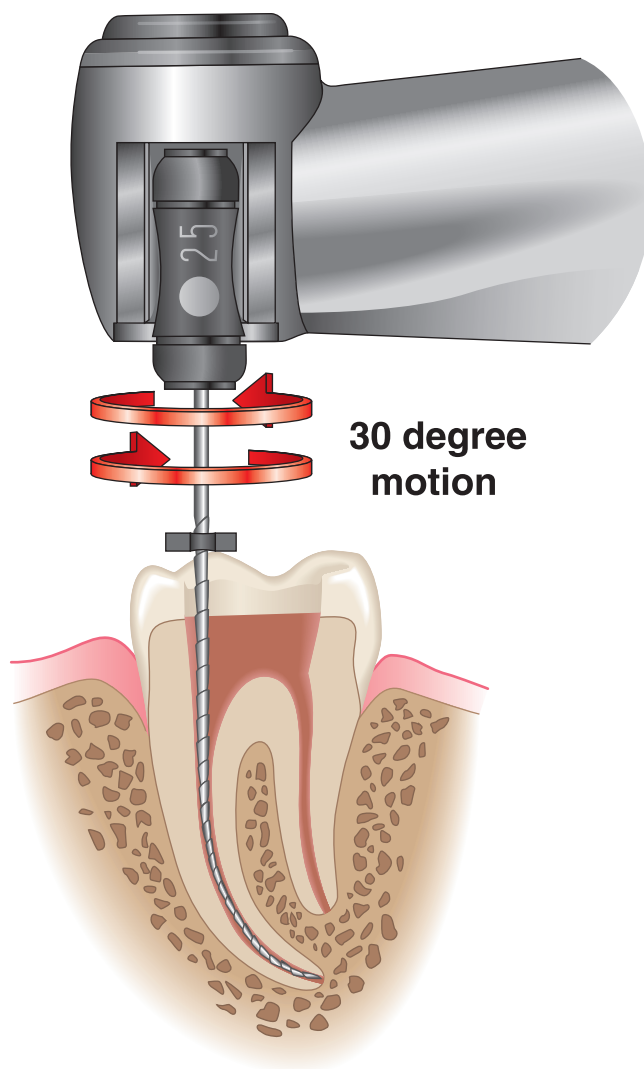

Figure 13 The M4 Safety Handpiece reciprocates in a 30° motion and locks regular hand files in place. The manufacturer recommends that Safety Hedstrom files be used. Courtesy of Sybron-Endo/Kerr.

hand preparations and a shorter time of preparation.” Hulsman and Stryga²¹⁰ found much the same for both the M4 and the Giromatic.

The Endo-Gripper (Moyco/Union Broach) is a similar handpiece, with a 10:1 gear ratio and a 45° turning motion. As with the Kerr M4, the Endo-Gripper also uses regular hand, not contra-angle, instruments. Union Broach recommends their Flex-R and Onyx-R files. In a comparison of nickel–titanium rotary engine-driven instruments with the Endo-Gripper and the Kerr M4, it was found that there were no significant differences among the groups for the direction of transportation. The one nickel–titanium rotary instrument that did have significant transportation has subsequently been redesigned.²¹¹

Giromatic handpiece instrumentation was not effective when broaches were used. Hedstroem-type files and K-style reamers were more effective.^{212–214} Micro Mega recommends that Rispi Sonic or Triocut instruments be used with the Giromatic handpiece. The reports are mixed, however, between “zipping” at the apical foramen versus round, tapered preparation.^{215–218}

VERTICAL STROKE HANDPIECE

The vertical stroke handpiece is driven either by air or electrically that delivers a vertical stroke ranging from 0.3 to 1 mm. The more freely the instrument moves in the canal, the longer the stroke. The handpiece also has a quarter-turn reciprocating motion that “kicks in,” along with the vertical stroke, when the canal instrument starts to bind in a tight canal. If it is too tight, the motion ceases, and the operator returns to a smaller file. The Canal Finder System (Marseille, France) uses the A-file, a variation of the H-file.

Rotary Instruments

Two of the most historic and popular engine-driven instruments are Gates Glidden drills and Peeso reamers (drills) (Figure 14, A and B). Gates Glidden drills are an integral part of instrumentation techniques for both initial opening of canal orifices and deeper penetration in both straight and curved canals. Gates Glidden drills are designed to have a weak spot in the part of the shaft closest to the handpiece so that, if the instrument separates, the separated part can be easily removed from the canal. They come in sizes 1 through 6.

Figure 14 Engine-driven instruments used in a slow-speed handpiece. **A**, Gates Glidden drills come in sizes 1 through 6, end cutting or non-end cutting, and are used extensively in enlarging the straight part of the canal. **B**, Peeso reamer (drill) used primarily for post preparation. Photos courtesy of Dentsply/Maillefer.

In a laboratory study, Luebke and Brantley²¹⁹ tested two brands of Gates Glidden drills by clamping the head of the drill and then twisting the handles either clockwise or counterclockwise. There was no specific pattern to their fracture except that some broke at the head and some high on the shaft near the shank. Luebke and Brantley^{220,221} later repeated the experiment, allowing the drill head to turn as it would in a clinical situation. This time, all of the drills fractured near the shank, “a major departure from the previous test.”

The Peeso reamer (Dentsply/Maillefer) is most often used in preparing the coronal portion of the root canal for a post and core. One must be careful to use the “safe-ended” Peeso drill to prevent lateral perforation. Gutta-percha should have previously been removed to post depth with a hot plugger.

ULTRASONIC AND SONIC HANDPIECES

Instruments used in the handpieces that move near or faster than the speed of sound range from standard K-type files to special broach-like instruments. “Ultrasonic endodontics is based on a system in which sound as an energy source (at 20 to 25 kHz) activates an endodontic file resulting in three-dimensional activation of the file in the surrounding medium.”²²² “The main debriding action of ultrasonics was initially thought to be by cavitation, a process by which

bubbles formed from the action of the file, become unstable, collapse, and cause a vacuum-like ‘implosion.’ A combined shock, shear and vacuum action results.”²²² Ultrasonic handpieces use K-files as a canal instrument. Before a size 15 file can fully function, however, the canal must be enlarged with hand instruments to at least a size 20.

Although Richman²²³ in 1957 must be credited with the first use of ultrasonics in endodontics, Martin and Cunningham^{224–232} were the first to develop a device, test it, and see it marketed in 1976. Ultimately named the Cavitron Endodontic System (no longer manufactured), it was followed on the market by the Enac unit (Osada Electric Co., Los Angeles, CA) and the Piezon Master 400 (Electro Medical Systems, SA, Switzerland).

These instruments all deliver an irrigant/coolant, usually sodium hypochlorite, into the canal space while cleaning and shaping are carried out by a vibrating K-file. The results achieved by the ultrasonic units have ranged from outstanding^{224–239} to disappointing.^{240–244} What is the explanation for such a wide variance in results? The answer seems to lie in the extensive experimentation on ultrasonic instruments carried out by Ahmad et al.^{245–247} They thoroughly studied the mechanisms involved and questioned the role that cavitation and implosion play in the cleansing process. It is believed that a different physical phenomenon, “acoustic streaming,” is responsible for the debridement. They concluded that “transient cavitation does not play a role in canal cleaning with the CaviEndo unit; however, acoustic streaming does appear to be the main mechanism involved.”²⁴⁵ They pointed out that acoustic streaming “depends on free displacement amplitude of the file” and that the vibrating file is “dampened” in its action by the restraining walls of the canal.

Ahmad et al.²⁴⁶ found that the smaller files generated greater acoustic streaming and hence much cleaner canals. After canals are fully prepared, by whatever means, they recommended returning with a fully oscillating No. 15 file for 5 minutes with a free flow of 1% sodium hypochlorite. In another study, Ahmad et al.²⁴⁷ found that root canals had to be enlarged to the size of a No. 40 file to permit enough clearance for the free vibration of the No. 15 file at full amplitude. Others, including Martin, the developer, have recommended that the No. 15 file be used exclusively.^{227,241} The efficacy of ultrasonography to thoroughly debride canals following step-back preparation was demonstrated by Archer et al.²⁴⁸ There was a difference in cleanliness between canals needle-irrigated during preparation and those canals prepared and followed by 3 min-

utes of ultrasonic instrumentation with a No. 15 file and 5.25% sodium hypochlorite.

Walmsley and Williams²⁴⁹ reached similar conclusions about the oscillatory pattern of endosonic files. They pointed out that the greatest displacement amplitude occurs at the unconstrained tip and that the greatest restraint occurs when the instrument is negotiating the apical third of a curved canal. This is the damping effect noted by Ahmad et al.,²⁴⁵ the lack of freedom for the tip to move freely to either cut or cause acoustic streaming to cleanse. Krell et al.²⁵⁰ observed the same phenomenon that the irrigant could not advance to the apex “until the file could freely vibrate.” Lumley and Walmsley²⁵¹ reported better results if K-files were precurved when used in curved canals.

Ahmad et al.²⁵² noted another interesting phenomenon about ultrasonic canal preparation—that, contrary to earlier reports, ultrasonics alone actually increased the viable counts of bacteria in simulated root canals. This was felt to be caused by the lack of cavitation and the dispersal effects of the bacteria by acoustic streaming. On substitution of sodium hypochlorite (2.5%) for water, however, all of the bacteria were killed, proving once again the importance of using an irrigating solution with bactericidal properties.

Ahmad and Pitt Ford²⁵³ also compared two ultrasonic units—CaviEndo versus Enac. They evaluated canal shape and elbow formation: “There was no significant difference...in the amount of apical enlargement.” They did find, however, that the Enac unit had a greater propensity for producing “elbows,” as well as apical deviation and change of width. Ahmad²⁵⁴ suggested that “the manufacturers of ultrasonic units consider different file designs.” She found the K-Flex to be more efficient than the regular K style.

ULTRASONIC CONCLUSIONS

One can draw the conclusion that ultrasonic endodontics has added to the practice of root canal therapy. There is no question that canals are better debrided if ultrasonic oscillation with sodium hypochlorite is used at the conclusion of cavity preparation. But the files must be small and loose in the canal, particularly in curved canals, to achieve optimum cleansing.

SONIC HANDPIECES

The principal sonic endodontic handpiece available today is the Micro Mega 1500 (or 1400) Sonic Air

Figure 15 Micro Mega 1500 Sonic Air handpiece. Activated by pressure from the turbine air supply, the Micro Mega 1500 can be mounted with special instruments easily adjusted to the length of the tooth. Water spray serves as an irrigant. Photo courtesy of Medidenta/Micro Mega.

Endo System (Medidenta International, Inc.; Woodside, NY) (Figure 15). Like the air rotor handpiece, it attaches to the regular airline at a pressure of 0.4 MPa. The air pressure may be varied with an adjustable ring on the handpiece to give an oscillatory range of 1,500 to 3,000 cycles per second. Tap water irrigant/coolant is delivered into the preparation from the handpiece.

Walmsley et al.²⁵⁵ studied the oscillatory pattern of sonically powered files. They found that out in the air, the sonic file oscillated in a large elliptical motion at the tip. When loaded, as in a canal, they found that the oscillatory motion changed to a longitudinal motion, up and down, “a particularly efficient form of vibration for the preparation of root canals.”

The strength of the Micro Mega sonic handpiece lies in the special canal instruments used and the ability to control the air pressure and hence the oscillatory pattern. The three choices of file that are used with the Micro Mega 1500 are the Rispi Sonic, the Shaper Sonic, and the Trio Sonic (Medidenta International, Inc.) (Figure 16). The Rispi Sonic resembles the old rat-tail file. The Shaper Sonic resembles a barbed broach. The Trio Sonic resembles a triple-helix Hedstroem file. All of these instruments have safe-ended noncutting tips.

The Rispi Sonic has 8 cutting blades and the Shaper Sonic has 16. The ISO sizes range from 15 to 40.

Figure 16 Three instruments used with the Micro Mega 1500 Sonic Air handpiece. **A**, Rispi Sonic. **B**, Shaper Sonic. **C**, Trio Sonic (aka Heliosonic or Triocut). Courtesy of Medidenta/Micro Mega.

Because graduated-size instruments have varying shaft sizes, the instrument must be tuned with the unit’s tuning ring to optimum tip amplitude of 0.5 mm. As with the ultrasonic canal preparation, these instruments must be free to oscillate in the canal, to rasp away at the walls, and to remove necrotic debris and pulp remnants. To accommodate the smallest instrument, a size 15, the canal must be enlarged to the working length with hand instruments through size No. 20. The sonic instruments, with the 1.5 to 2.0 mm safe tips, begin their rasping action this far removed from the apical stop. This is known as the “sonic length.” As the instrument becomes loose in the canal, the next-size instrument is used, and then the next size, which develops a flaring preparation. The sonic instruments are primarily for step-down enlarging, not penetration.

Three commonly held objectives of shaping the root canal are (1) developing a continuous tapering

conical form, (2) making the canal narrow apically with the narrowest cross-sectional diameter at its terminus, and (3) leaving the apical foramen in its original position spatially. To satisfy these requirements, two of the sonic instruments have been quite successful. Dummer et al.²⁵⁶ found the Rispi Sonic and Shaper Sonic files to be the most successful, the Trio Sonic less so. "In general, the Shaper Sonic files widened the canals more effectively than the Rispi Sonic files, whilst the Heliosonic [Trio Sonic] files were particularly ineffective...."²⁵⁶

Bolanos et al.²⁵⁷ found essentially the same results. They recommended that the Shaper Sonic files be used first and that the remaining two-thirds of the canal be finished with the Rispi Sonic. Ehrlich et al.²⁵⁸ compared canal apical transport using Rispi Sonic and Trio Sonic files versus hand instrumentation with K-files. They found no difference in zipping among the three instruments. Tronstad and Niemczyk²⁵⁹ also tested the Rispi and Shaper files against other instruments. They reported no complications (broken instruments, perforations, etc.) with either of the Sonic instruments. Miserendino et al.²⁶⁰ also found that the "Micro Mega sonic vibratory systems using Rispi Sonic and Shaper files were significantly more efficient than the other systems tested."

COMPARISONS IN EFFICACY AND SAFETY OF AUTOMATED CANAL PREPARATION DEVICES

Before making an investment in an automated endodontic device, one should know the comparative values of the different systems and their instruments. Unfortunately, the ultimate device and instrument has not been produced and tested as yet. Some are better in cutting efficiency, some in following narrow curved canals, some in producing smooth canals, and some in irrigating and removing smear layer, but apparently none in mechanically reducing bacterial content.

As stated above, Miserendino et al.²⁶⁰ found that the cutting varied considerably. They ranked the Rispi Sonic file at the top, followed by the Shaper Sonic, the Enac "U" file (Osada Electric Co.), and the CaviEndo K-file.

Tronstad and Niemczyk's²⁵⁹ comparative study favored the Canal Finder System in narrow, curved canals. On the other hand, the Rispi and Shaper files in the Micro Mega Sonic handpiece proved the most efficacious "in all types of root canals." The Cavitron Endo System was slow, blocked and ledged canals, and fractured three files in severely curved canals. They

also found the Giromatic with Rispi files to be effective in wide straight canals, less so in curved canals, where four Rispi files fractured.

Bolanos et al.²⁵⁷ also tested the Giromatic with Rispi files against the Micro Mega Sonic handpiece with Rispi and Shaper files. They found the Rispi Sonic best in straight canals, the Shaper Sonic best in curved canals, and both better than the Giromatic/Rispi and/or hand instrumentation with K-Flex files. The Shaper files left the least debris and the Giromatic/Rispi left "an extensive amount of debris."

Kielt and Montgomery²⁶¹ also tested the Micro Mega Sonic unit with Trio Sonic files against the ultrasonic Cavitron Endo and Enac units with K-files. Even though others found the Trio Sonic files less effective (than the Rispi or Shaper files), Kielt and Montgomery²⁶¹ concluded that "overall the Medidenta unit was superior to the other endosonic systems and to the hand technique (control)." Zakariasen et al.²⁶² reported success in combining hand instrumentation with sonic enlargements using the Micro Mega 1500.

Walker and del Rio²⁶³ also compared the efficacy of the Cavitron Endo and Enac ultrasonic units against the Micro Mega Sonic unit and found "no statistically significant difference among the groups, however, liquid extruded from the apical foramen in 84% of their test teeth." They felt that "sodium hypochlorite may improve the debridement of the canal."

Yahya and El Deeb²⁶⁴ tested ultrasonic units against sonic units. The researchers found the Micro Mega Sonic to be the fastest in preparation time and caused the "least amount of straightening of the canals." On the other hand, Reynolds et al.²⁶⁵ found hand preparation with the step-back technique superior to sonic and ultrasonic preparation except in the important apical area, where they were similar. Lumley et al.²⁶⁶ found that ultrasonic and sonic files best cleaned ovoid canals.

Lev et al.²⁶⁷ prepared the cleanest canals using the step-back technique followed by 3-minute use of a CaviEndo ultrasonic file with sodium hypochlorite.

Stamos et al.²⁶⁸ also compared cleanliness following ultrasonic debridement with sodium hypochlorite or tap water. Using water alone, the Enac system was more effective, but when sodium hypochlorite was used, the CaviEndo unit (which has a built-in tank) was superior. They also reported ultrasonic preparation to be "significantly faster" than hand instrumentation.

Goldman et al.²⁶⁹ tested sonic versus ultrasonic units and concluded that they were all effective in

canal preparation but judged the Micro Mega Sonic Air System, using Rispi and Shaper Sonic files, “as the best system tested.”

Pugh et al.²⁷⁰ compared four techniques according to the amount of debris extruded from the apex. The sonic technique extruded the least and hand instrumentation the most debris. Ultrasonic was halfway between. Whether the debris discharged into the apical tissue contains bacteria was of the utmost importance. Using sterile saline as an irrigant, Barnett et al.²⁷¹ found sodium hypochlorite to be four times more effective than sterile saline. Fairbourn et al.²⁷² found essentially the same thing.

COMPARATIVE CONCLUSION OF AUTOMATED DEVICES

It appears safe to say that no one automated device will answer all needs in canal cleaning and shaping. Hand instrumentation is essential to prepare and cleanse the apical canal, no matter which device, sonic or ultrasonic, is used. Recent research has confirmed the previous findings. Sonic or ultrasonic instrumentation

is significantly better than hand instrumentation of the canal system as far as producing a cleaner canal system.^{273–275} In one study, Lee et al.²⁷⁶ confirmed that ultrasonic instruments perform better in a larger canal space. In a similar study by van der Sluis et al.,²⁷⁷ it was found that there was a tendency for ultrasonic irrigation to produce a cleaner canal system in a larger canal, but the differences were not significant. Another study by Lee et al.²⁷⁸ demonstrated that the volume of irrigant is also essential in ridding the canal system of dentinal debris.

D. ELECTRONIC APEX LOCATORS

ADAM LLOYD, JOHN I. INGLE

The dentin–cementum junction has been recommended as an ideal apical termination for root canal preparation.^{1–3} The position of this histologic entity varies around the internal circumference of the canal by up to 3 mm across opposing walls.^{4,5} It is located approximately 1 mm away from the apical foramen.⁶ An apical constriction usually occurs in the region of the dentin–cementum junction and often forms a natural apical matrix. It is the narrowest portal of entry of the pulpal vasculature from the periapical tissues and would be the smallest wound following pulp removal.⁷ The topography of the apical constriction is variable⁸ and undetectable radiographically. Kuttler⁹ investigated the root apices of teeth and provided a dimensional analysis of the apical morphology. He noted that the distance from the apical constriction to the vertex of the root increased with age and was recorded as between 0.5 and 0.6 mm. This distance was considered as a measurement to subtract from the radiographic apex to approximate the location of the apical constriction.¹⁰

Working length, the apical extent of canal preparation and obturation, is often the main variable in determining success or failure.^{11–16} Seltzer et al.¹⁷ were the first to report greater success in terminating cleaning and obturating the root canal system just short of the radiographic apex, rather than overfilling or underfilling. Sjögren et al.¹⁸ investigated endodontic outcomes over an 8- to 10-year period in over 350 patients. They reported the best outcome was when the root canal filling was between 0 to 2 mm short of the radiographic apex. Distances beyond the radiographic apex, or more than 2 mm short of this point, resulted in significantly lower success rates. These findings are in agreement with research conducted by other investigators^{14–19} and most recently by meta-analysis of the literature.²⁰

Chugal²¹ found variations in success rate of teeth root filled at different levels. Teeth with normal preoperative pulps and periapical tissues enjoyed a higher success rate when filled over 1 mm from the radiographic apex. On the other hand, teeth with necrotic pulps and apical periodontitis showed greater success

when the canal filling was closer to the level of the radiographic apex. From all the evidence cited, it is clearly prudent to be able to accurately prepare and fill root canals to a predetermined location in the canal short of the actual apical foramen—ideally the dentin–cementum junction.

The common method of determining root canal length for the past 100 years has been by radiography (see Chapter 15A, “Endodontic Radiography”). This method unfortunately often leads to inaccuracies, even though various techniques for improved radiographic length determination have been developed.^{22–29} Interpretation of the file’s position on the radiograph and the surrounding anatomy is also prone to errors when using the bisecting angle technique.²⁹ Estimation of the canal length often varies greatly from actual working length. The long-cone paralleling technique has been shown to be more accurate.²⁹ Furthermore, radiographs only provide a two-dimensional representation of the three-dimensional object and can also be interpreted differently between clinicians.^{30,31} In fact, reports of observer agreement in determining file position found that agreement decreased as the distance from the radiographic apex increased.³²

Many digital radiographic techniques do not easily permit obtaining endodontic working films with the long-cone paralleling technique, which necessitates using the bisecting angle method.³³ The use of digital radiography has reduced radiation exposure of patients,^{34,35} increased the speed of delivery, and created the ability to “enhance” images.³⁶ However, studies have shown that digital radiographs have no greater resolution than conventional radiographs.^{37–41}

In addition to radiography, tactile sensation has been used with questionable success, plus the drawbacks cited about radiographic length determination, along with the increasing concern about radiation exposure, the introduction and development of the electronic apex locator (EAL) has been received with enthusiasm by clinicians performing endodontic procedures.

The first reported use of electric current to measure root canal working length was in 1918 by Custer.⁴² He noted a marked increase in the conductivity of a tooth at the apical foramen when the canal was dry or filled with a nonconductive medium. By placing a broach inside a tooth and applying a voltage across it and the alveolus, Custer was able to identify the apical foramen by observing a change in the value on the milliammeter of the time.⁴²

Suzuki⁴³ found that an electrode placed on the oral mucosa, and an instrument placed in the root canal, gave consistent measurements of electrical resistance. This is the basis for the resistance-based EALs. As the advancing file, surrounded by insulating dentin and cementum, approaches the conductive periodontal ligament, the resistance decreases until the circuit is complete.

Sunada⁴⁴ used this principle to create a device, using direct current, to estimate the root canal length *in vivo*. He found that when the file reached the canal terminus, regardless of tooth shape, tooth type, or age of the patient, the resistance measured was consistent at 6.5 K Ω . Furthermore, the same resistance was recorded when the file encountered an accidental perforation.⁴⁴

Direct current apex locators have also been associated with patients experiencing electric shocks.^{45–46} Suchde and Talim⁴⁵ proposed changing to alternating current, which would result in less tissue damage and increased stability of the electrolyte's resistance in a wet canal. The disadvantage, however, in determining canal length in this manner, is the change in the capacitance of the circuit, along with many other variables that affect accuracy.^{45,47} Meredith and Gulabivala⁴⁸ discovered that impedance in a tooth and periradicular tissues consists of resistive and capacitance circuits that provide a model for EALs.

The *first* generation of EALs was based on resistance, and the resistance was measured between the two electrodes to determine location within a canal. The *second* generation employed single-frequency impedance, in which impedance measurements instead of resistance was used to measure location within a canal. The improvement of the second over the first generation was essentially that it would gather more information. Impedance is a complex property comprised of resistance and capacitance. Whereas resistance has constant amplitude, impedance is sinusoidal. The frequency of an impedance-based unit can be varied to compensate for canal conditions. The *third* generation of EAL was similar to the second, but it used multiple frequen-

cies to determine distances from the end of the canal. The *fourth* generation of EALs breaks impedance down into its primary components (resistance and capacitance) and measures them independently during use. This eliminates erroneous readings because different combinations of these properties provide the same impedance reading. This prevents EALs from being “jumpy” and erratic. Multiple frequencies are still used to compensate for canal conditions. The Elements Diagnostic Unit (SybronEndo, Glendora, CA) (Figure 1) does not make calculations internally as third-generation units do. Instead, all combinations of capacitance and resistance relating to location within the canal have been loaded into a matrix database within the unit (Figure 2). This decreases processing time, making the displayed information much more stable.

Accuracy of Electronic Apex Locators

A concern for accuracy in determining working length has generated many investigations using various EALs. Concern for accuracy also affected its acceptance for use in practices which has varied from 10% in the United States to 90% in Japan.^{49–54}

RESISTANCE-BASED ELECTRONIC APEX LOCATORS

As the file approaches the periodontal ligament, the voltage change divided by the current (amperes) results in decreasing resistance, per Ohm's law, until a value of 6.5 K Ω is reached.⁴⁴ The accuracy of resistance-based apex locators can be high provided certain conditions are adhered to. Dry canals provided the most accurate readings. Strong electrolytes such as endodontic irrigants, purulence, excess hemorrhage, or pulp tissue lead to inaccurate and even unstable results.^{55–59} In 1969, Bramante and Berbert⁶⁰ looked at the first commercially available apex locator, the Root Canal Meter, and found it to be consistently more accurate than radiographs in the palatal roots of maxillary molars and premolars. The original device, however, often elicited a painful response by the patient. Further refinements were made in later EAL models measuring resistance such as the Endodontic Meter and the Endodontic Meter S II.⁶¹ The more recent resistance-based apex locators provided accurate location of the apical constriction 55 to 75% of the time.⁶² However, their accuracy was still diminished in the presence of fluids.⁶³

Figure 1 The Sybron Elements Diagnostic Unit is an example of a current electronic apex locator with a vitality scanner. **A**, Elements Diagnostic Unit; **B**, file clip; **C**, vitality probes; **D**, lip hook; **E**, satellite.

Figure 2 Matrix database for the Elements Diagnostic software: The left axis identifies the measured resistance in ohms, the right axis identifies the measured capacitance in microfarads, and the vertical axis illustrates the resultant apex location that is displayed. It is shown in segments on the unit display, "41 segments" being the "0" reading, "37 segments" being "0.5 mm," and so on.

LOW-FREQUENCY APEX LOCATORS

The resistance-based circuit proved insufficient to accurately and consistently measure root canal length.^{48,64,65} Impedance rather than resistance became the characteristic used to mark the depth of canal penetration. In 1972, the Sono-Explorer was introduced by Inoue^{64,66} on the premise that although the many parameters that determine impedance are varied in different canals under altered conditions, the impedance between the oral mucosa and depth of the gingival sulcus should be coincident with the impedance value of a circuit across the oral mucosa and the periodontal ligament. Thus, the device would indicate the canal terminus when the two impedance values approached each other. The frequency of the impedance was heard as an audible “marker tone” that signaled the endpoint of the canal, generated by low-frequency oscillation. The device had to be calibrated at the periodontal sulcus before each use. This involved placing a file, shielded along its length except for its tip, into the gingival sulcus, and listening for the “gingival crevice sound.” A file was then introduced into the canal, and when the sound became identical to the “gingival crevice sound,” the canal terminus had been reached. A disadvantage of the first model Sono-Explorer was the depth at which the probe could be placed into the gingival sulcus. If the reference tuner was placed deeper than 0.5 mm into the crevice when tuning the device, the gingival frequency increases resulted in the tip of the file protruding through the apical foramen.⁶⁷ The Sono-Explorer II rectified this with a coated gingival frequency measuring probe, but the accuracy still remained disappointing.

HIGH-FREQUENCY APEX LOCATORS

The Endocater was introduced by Hasegawa in 1979^{59,62} with the premise that operating with a high-frequency wave (400 kHz) as a measuring current produces a more stable single electrode.^{68,69} The device is able to perform accurate measurements in the presence of electrolytes and pulp tissue due to the file having a special coating except for the exposed tip, thereby decreasing the variable capacitive properties.⁷⁰ Accuracy with the Endocater has been reported between 67 and 93.4%.^{62,65,71} A problem occurred in constricted canals when the coating of the file caused it to bind prematurely.⁶⁵ In addition, the coating did not withstand repeated autoclaving.⁷² Fouad et al.⁶² tested the Endocater with uncoated files and found grossly inaccurate results.

VOLTAGE GRADIENT APEX LOCATORS

Custer⁴² and subsequently Sunada⁴⁴ relied on a constant resistance value of 6.5 K Ω between the canal and the periodontal membrane, and Ushiyama⁷³ used both monopolar and bipolar electrodes coated in lacquer with just the tip exposed, similar to the Endocater. Ushiyama found the voltage gradient was greatest at the most constricted point in the canal, where the current density is the highest. The principle of Ushiyama's device differs from Sunada's⁴⁴ resistance-based device in that separate electrodes are used to apply current to the probe and to record the voltage. Ushiyama pointed out a potential flaw in the resistance value of 6.5 K Ω quoted by Sunada⁴⁴ reporting that this more likely reflected the resistance of the metal electrode in contact with the canal contents, as a result of the polarization produced. The effect was minimized by Ushiyama's coated electrodes. Further investigation, using the monopolar and bipolar electrodes, respectively, were found to be successful in all but two cases tested.⁷⁴ Unfortunately, the thickened bipolar electrodes did not allow them to travel freely to the constriction in narrow canals.

DUAL-FREQUENCY ELECTRONIC APEX LOCATORS

In 1990, Saito and Yamashita⁷⁵ investigated the use of the Endex, developed by Yamaoka, describing the method of determining the canal terminus as the difference between two impedance values at two different frequencies. Calibration of the device in the coronal region is required to compensate for the dielectric capacity of the electrolyte in the canal. The findings from the study concluded that there were no differences in locating the apical foramen when different file sizes were used, a different apical diameter was encountered, or in the presence of saline, 5% sodium hypochlorite, 14% EDTA, or 3% hydrogen peroxide. The Endex was also marketed under the Apit brand name and further studied by Fouad et al.,⁶³ who also found the Endex superior to other apex locators in the presence of electrolytes, especially where the apical foramen was widened.

In 1993, Frank and Torabinejad,⁷⁶ using the Endex, took canal measurements of 99 teeth *in vivo* and were able to locate the file tip, in moist canals, to within 0.5 mm of the apical constriction in nearly 90% of the specimens. Mayeda et al.⁷⁷ studied the Endex to determine whether there were differences in accuracy in vital or necrotic cases *in vivo*, finding

that there was no statistical difference based on pulpal status, and that generally file tips were found between +0.50 mm to 0.86 mm from the apical foramen.

Felippe and Soares⁷⁸ investigated 350 extracted teeth *in vitro* and found the Endex to locate the apical foramen within 0 to 0.5 mm in 96.5% of the specimens studied. Arora and Gulabivala⁷⁹ compared the Endex with the RCM Mark II EAL *in vivo*. They used sodium hypochlorite, pus, water, and vital and necrotic pulp tissue as possible electrolytes. They also exposed a radiograph before extracting the tooth and then examined the file position visually. What was evident from the study was an overestimation of the file's position based solely on the radiograph, with the file extending beyond the foramen. The extensions were affected by the canal's contents. The Endex was found to be within 0.5 mm of the apical foramen 71.7% of the time, whereas the RCM Mark II AEL had only a 43.5% rate of accuracy. The Endex performed better than the RCM Mark II in the presence of sodium hypochlorite.

MULTIPLE-FREQUENCY ELECTRONIC APEX LOCATORS

By the ratio method of canal length determination, these dual-frequency AELs overcame differences in the changing dielectric constant of different electrolytes left in the root canal system.^{80,81} The position of the file tip is derived from the simultaneous measurement of the impedance of two different frequencies that are used to calculate the quotient of the impedances. The Root ZX (J. Morita Manufacturing Co., Kyoto, Japan) was one of these. It was initially introduced between 1991 and 1994 by Kobayashi and Suda.⁸² The Root ZX simultaneously uses two waveforms, a high (8 kHz) and low (400 Hz) frequency waveform. As the content of the fluid changes within the root canal, the ratio of the impedances would be modified by the same rate as each other, yielding a ratio that would not differ. This results in the same positioning of the file tip regardless of the canal contents.⁸² *In vitro* studies of the Root ZX have shown it to be accurate in the presence of electrolytes.⁸³ Varying concentrations of sodium hypochlorite made no significant difference in performance.^{84,85} The accuracy of the Root ZX has been reported to range from 64% to 100%. If 1.0 mm difference is deemed acceptable, the accuracy is reported at 100%.⁸⁶ Lesser deviations from the apical constriction are reproducible.^{87,88}

The Bingo 1020 (Forum Technologies, Rishon LeZion, Israel) compared favorably with the Root ZX regardless of canal contents or irrigants. Both were deemed more reliable than the radiographic interpretation.⁸⁹ An *in vitro* study also found the Bingo 1020 and the Root ZX performed equally well in the hands of clinicians with varying degrees of experience.⁹⁰ The Bingo 1020 is also marketed as the Raypex 4 (Roydent Dental Products, Johnson City, TN) and as the ProPex (Dentsply Maillefer, Ballaigues, Switzerland).

Welk et al.⁹¹ tested the accuracy of the five-frequency Endo Analyzer Model 8005 (Analytic, Sybron Dental, Orange, CA) against the Root ZX and found the latter able to locate the apical foramen ± 0.5 mm over 90% of the time with a mean difference less the 0.2 mm, compared with the Endo Analyzer at over 1.0 mm. Lucena-Martin et al.⁹² found the Root ZX to be consistently reliable at 85%. A similar clinical comparison was conducted in Hungary in 2006, where Gyorfi et al.⁹³ determined the working lengths of 10 canals using radiographs and then compared these findings with four different apex locators. The Root ZX and the Foramatron D10 (Parkell Co., Edgewood, NY) agreed with the radiographic analysis in all 10 canals. The Apex Finder AFA 7005 (Analytic, Sybron Dental) agreed on seven canals and the ProPex (Dentsply Maillefer) agreed on five canals.

Tselnik et al.⁹⁴ recently tested the Elements Diagnostic EAL (Sybron Endo, Sybron Dental, Orange, CA) against the Root ZX *in vivo*. Both devices were accurate to 75% of the time to ± 0.5 mm from the minor diameter. Haffner et al.⁹⁵ reported a similar finding for the latter at 78%. Plotino et al.⁹⁶ tested the Root ZX, the Elements Diagnostic Unit, and the ProPex unit and found their accuracy at 97.4, 94.3, and 100%, respectively, although the majority of the ProPex readings were beyond the apex.

In 2005, Goldberg et al.⁹⁷ compared the Root ZX, the ProPex (Dentsply Maillefer), and the NovApex (Forum Technologies) for accuracy in re-treatment cases. At 0.5 mm from the foramen, they reported an accuracy level of 95, 80, and 85%, respectively.

Foramina of unusual width can cause unreliable apex locator readings, particularly if a fine diameter file is used. However, Ebrahim et al.⁹⁸ concluded that when a tight-fitting file was used to determine working length of canals with large diameter foramina, the Foramatron D10 (Parkell Co.) and the Root ZX were significantly more accurate than the Apex NRG (Kibbutz Afikim, Israel) or the Apit 7 (Osada, Tokyo, Japan).

A number of other studies have been done assessing the qualities of these newest AELs. It was found, for instance, that stainless steel and nickel–titanium files were equally effective as canal “electrodes.”⁹⁹ It was also noted that EALs are effective devices in determining resorptive defects and their location¹⁰⁰ and in measuring the working length in resorbing deciduous teeth.¹⁰¹

Morita has modified the Root ZX, applying the principle to the Solfy ZX, marketed only in Japan, which enables the operator to stop at any distance from the desired length,⁶⁸ as well as the Tri-Auto ZX and the Dentaport ZX that combine the apex locator with plug-in and/or cordless battery-operated handpieces that have an auto-reverse feature when the apex is reached or if the instrument binds in the canal.^{102–104}

Parameters for Use of Electronic Apex Locators

The original apex locators proved to be more reliable in a dry canal than in the presence of saline or distilled water.⁴⁵ Manufacturers of newer models claim the ability of their apex locators to work in both dry and wet conditions, including in the presence of blood, pulp tissue, and the common endodontic irrigants. Although these claims have now shown the accuracy to be between 83 and 96%,^{59,83,84,88,105,106} there are other factors that need to be considered in using an apex locator in practice. Contemporary root canal preparation with nickel–titanium rotary endodontic instruments typically involves crown-down preparations and some form of preflaring and removal of coronal obstructions. It has been shown that preflaring increases the accuracy of EAL.^{107,108} Furthermore, the choice of file alloy, stainless steel, or nickel–titanium appears to have no bearing on apex locator accuracy.⁹⁰ Choosing a file that closely matches the canal diameter appears to no longer be a concern in locating the working length, with studies showing files of sizes much smaller than the canal, working equally well.^{106,109} Contact of the file or probe to metallic restorations or fluid in contact with the metallic restorations will cause the apex locator to give a false reading.

Garofalo et al.¹¹⁰ connected EALs directly to a pacemaker in an *in vitro* study and found that four of five EALs showed no effect on cardiac pacemaker function. However, the Bingo 1020 produced an

irregular pace recording and oscilloscope pattern. Wilson et al.¹¹¹ recently demonstrated no effect on implanted cardiac pacemakers or cardioverters/defibrillators with either the Root ZX or the Elements Diagnostic EALs. However, manufacturers of EALs continue to warn against the use of their devices in patients with cardiac pacemakers. It is recommended to contact the patient’s physician or cardiologist for specific guidance regarding the use of any electrical devices.

E. LASERS IN ENDODONTICS

ADAM STABHOLZ, JOSHUA MOSHONOV, SHARONIT SAHAR-HELFT, JEAN-PAUL ROCCA

The rapid development of laser technology, as well as a better understanding of laser interaction with biological tissues, has widened the spectrum of possible applications of lasers in endodontics. The development of new delivery systems, including thin and flexible fibers as well as new endodontic tips, has made it possible to apply this technology to various endodontic procedures, including pulpal diagnosis, pulp capping/pulpotomy, cleaning and disinfecting the root canal system, obturation of the root canal system, endodontic retreatment, and apical surgery.

Although interest in the clinical use of laser systems for endodontic procedures is increasing, there are still some concerns associated with their use, mainly, lack of sufficient well-designed clinical studies that clearly demonstrate advantages of lasers over conventional methods and techniques. Selection of suitable wavelengths from the various laser systems requires advanced training and an educated understanding of the different characteristics in each laser system. The purpose of this chapter is to describe the principles of operation and discuss possible clinical applications of lasers in endodontics.

Principles of Operation

Dental lasers used today for clinical procedures and research operate in the infrared, visible, or ultraviolet range of the electromagnetic spectrum¹ (Figure 1). The word LASER is an acronym for Light Amplification by the Stimulated Emission of Radiation. Although “L” stands for light, the actual physical process that takes place within the laser device is amplification by stimulated emission of radiation. A light beam is composed of packets of energy known as photons such as produced by a light bulb or other light sources. The natural state of an atom when all its electrons are moving around its nucleus is the ground state. When an atom is excited by an external energy

source, an electron moves to a higher energy level. As the atom tendency is to revert to its ground level, the electron falls back to its basic orbit, while emitting energy in the form of photons.² This emission is called “spontaneous emission” because it occurs without additional interference and results in the formation of “individual” waves from each atom not in phase with one another that is, a non-coherent, broadband spectrum (polychromatic) light.

The laser beam, on the other hand, implies stimulated emission of radiation. It is a single wavelength (monochromatic), collimated (very low divergence), coherent (photons in phase), and intense.² The laser principle accounts for the creation of this kind of light: The construction of a light source based on stimulated emission of radiation requires an active medium, a collection of atoms or molecules. The active medium that can be a gas, liquid, or a solid material and is contained in a glass or ceramic tube has to be excited to emit the photons by stimulated emission. Energy in the form of electric current or a flash lamp is applied to the medium, and once there are more atoms in the excited state than in the ground state, a population inversion is created. By adding a mirror to each end of the laser medium, a population of photons can be directed back and forth through the medium stimulating the emission of radiation from multiple excited electrons. Some of the photons produced can be released by allowing them to pass through one of the mirrors. The light can be coupled to a delivery device and used as a “surgical” beam³ (Figure 2).³

The medium producing the beam is what identifies the laser and distinguishes one from another. Different types of lasers used in dentistry, such as carbon dioxide (CO₂), erbium (Er), and neodymium (Nd), and various other substances used in the medium [e.g., yttrium, aluminum, garnet (YAG) and yttrium, scandium, gallium, garnet (YSGG)], and argon, diode, and excimer types, all produce light of a specific

Figure 1 The wavelengths of various types of lasers according to their emission spectra.

Figure 2 Schematic diagram of a laser.

wavelength. The CO₂, the Er:YAG, the Er, Cr:YSGG, and the Nd:YAG lasers emit invisible beams in the infrared range (10.6 μm, 2.94 μm, 2.79 μm, and 1.06 μm, respectively). The Argon laser emits a visible light beam at 488 or 514 nm, while the excimer lasers emit invisible ultraviolet light beams at various predetermined wavelengths (ArF, 193 nm; KrF, 248 nm; and XeCl, -308 nm).⁴

Laser photons interact with tissue in one of four ways: they are transmitted through tissue, reflected from tissue, scattered within tissue, or absorbed by tissue.⁵ Transmission of light transfers energy through the tissue without any interaction and thus does not cause any effect or injury. Reflection results in little or no absorption, so that there is no thermal effect on the tissue. When scattered, light travels in different directions and energy is absorbed over a

greater surface area, producing a less intense and less precise thermal effect; when absorbed, light energy is converted into thermal energy (Figure 3).⁶ A single laser device cannot perform all the required functions as the beam is absorbed or reflected according to its wavelength and the color of the object impacted.³

The particular properties of each type of laser and the specific target tissue render them suitable for various procedures. The CO₂ laser is highly absorbed by all biological soft and hard tissues and thus is most effective in tissues with high water content, such as the soft tissues of the oral cavity. However, its high thermal absorption makes this laser unsuitable for drilling and cutting enamel and dentin as damage to the dental pulp may occur.⁷

The Er:YAG laser is the most efficient for drilling and cutting enamel and dentin as its energy is well absorbed by water as well as by hydroxyapatite. Argon lasers are more effective on pigmented or highly vascular tissues, whereas Nd:YAG laser photons are transmitted through tissues by water and interact well with dark pigmented tissue.

The excimer lasers generate light in the ultraviolet range of the electromagnetic spectrum and function by breaking molecular bonds and reducing the tissue to its atomic constituents before their energy is dissipated as heat. Different types of lasers may have various effects on the same tissue, and the same laser can have varying effects on diverse tissue.

Unlike the CO₂ and the Er:YAG lasers, the Nd:YAG, argon, and excimer laser beams can be delivered through fiber optic, allowing greater

Figure 3 Four basic types of laser interactions occur when light hits the target tissue: reflection, scattering, transmission, and absorption.

accessibility to different areas and structures in the oral cavity.⁷ The extent of the interaction of laser energy with a tissue is generally determined by two dependent variables: the specific wavelength of the laser emission and the optical characteristics of the particular target tissue.⁵ These variables dictate absorption (i.e., the ability to effect tissue changes and generation of heat) and are important for pulp protection.⁸ The clinician controls four parameters when operating the laser: (1) the level of applied power (power density), (2) the total energy delivered over a given surface area (energy density), (3) the rate and duration of the exposure (pulse repetition), and (4) the mode of energy delivery to the target tissue (i.e., continuous versus pulsed energy and direct contact or no contact with the target tissue).

Pulpal Diagnosis

A diagnosis of pulp vitality may be, at times, difficult to assess, in view of the fact that current vitality tests are poor indicators. A false diagnosis may lead to an unnecessary removal of the pulp tissue. Histological evaluation of the exact state of the pulp tissue is not feasible since an opening into the pulp chamber will result with the need to remove this tissue and subse-

quently perform a root canal treatment. Laser Doppler flowmetry (LDF) was developed to assess blood flow in micro vascular systems. It also can be used as a diagnostic system for measurements of blood flow in the dental pulp.^{9,10} Laser Doppler flowmetry (LDF), is discussed in Chapter 14C.

Pulp Capping and Pulpotomy

Pulp capping, as defined by the American Association of Endodontists,¹¹ is a procedure in which a dental material such as calcium hydroxide $\text{Ca}(\text{OH})_2$ or mineral trioxide aggregate (MTA) is placed over a pulpal wound to encourage the formation of reparative dentin. Pulpotomy entails surgical removal of the coronal portion of the pulp as a means of preserving the remaining radicular pulp tissues.

Pulp capping is recommended when the exposure is very small, 1.0 mm or less,^{12,13} and the patients are young; pulpotomy is recommended when the young pulp is already exposed to caries and the roots are not yet fully formed (open apices). The traditionally used pulp capping agent is $\text{Ca}(\text{OH})_2$.^{14,15} When it is applied to pulp tissue, a necrotic layer is produced subjacent to which a dentin bridge is expected to form. The same may occur when a pulpotomy procedure is done. The disadvantage of both techniques is

that the necrotic zone may allow bacterial growth if the restoration permits microleakage that results in pulpal problems.

MTA shows favorable results when applied to exposed pulp. It produces more dentinal bridging in a shorter period of time with significantly less inflammation than when $\text{Ca}(\text{OH})_2$ is used. However, 3 to 4 hours are necessary for complete setting of the MTA.¹⁶⁻¹⁸

The success rate of pulp capping, whether direct or indirect, ranges from 44 to 97%. In pulpotomy, the same agents are used until root formation has been completed. It is debatable whether full root canal treatment should then be initiated.^{19,20} Both pulp capping and pulpotomy are more fully discussed in Chapter 35, "Vital Pulp Therapy" and Chapter 36, "Endodontic Considerations in Dental Trauma."

Since the introduction of laser to dentistry, several studies have shown the effect of various laser devices on dentin and pulpal tissue. While the ruby laser caused pulpal damage, Melcer et al.²¹ showed that the CO_2 laser produced new mineralized dentin formation without cellular modification of pulpal tissue when tooth cavities were irradiated in beagles and primates. Shoji et al.²² applied CO_2 laser to the exposed pulps of dogs, using a focused and defocused laser mode and a wide range of energy levels (3, 10, 30, and 60 W). Charring, coagulation necrosis, and degeneration of the odontoblastic layer occurred, although no damage was detected in the radicular portion of the pulp. Jukic et al.²³ used CO_2 and Nd:YAG lasers with an energy density of 4 and 6.3 J/cm^2 , respectively, on exposed pulp tissue. In both experimental groups, carbonization, necrosis, an inflammatory response, edema, and hemorrhage were observed in the pulp tissue. In some specimens, a dentinal bridge was formed.

In patients in whom direct pulp capping treatment was indicated, Moritz et al.²⁴ used the CO_2 laser. An energy level of 1 W at 0.1-second exposure time with 1-second pulse intervals was applied until the pulps exposed areas were completely irradiated. They were then dressed with $\text{Ca}(\text{OH})_2$ (Kerr Life, Orange, CA). In the control group, the pulps were only capped with $\text{Ca}(\text{OH})_2$. Symptoms were recorded and vitality tests were made after 1 week and monthly for 1 year: 89% of the experimental group had no symptoms and responded normally to vitality tests versus only 68% of the control.

The importance of pulp capping that considerably improves the prognosis of the tooth justifies the quest for new techniques and technologies: the most recent literature reports more predictable results (~90%) with capping performed using laser of different wavelengths, compared to traditional procedures that report a success rate of approximately 60%. Laser

technology proved effective in improving the prognosis of pulp capping procedures on teeth affected by deep caries pathology.²⁵

The laser and Vitrebond (3M Espe, St. Paul, MN) direct pulp cap produce a significantly more predictable pulp response after the first 6 months than the Dycal (Dentsply International, York, PA) direct pulp cap. The survival rate of teeth treated with the laser and Vitrebond direct pulp cap is significantly greater than those treated with Dycal direct pulp cap over intervals of 9 to 54 months. Direct pulp capping is a worthwhile procedure that should be performed when indicated, especially in light of the 90.3% survival rate achieved with the laser and Vitrebond direct pulp cap at 54 months.²⁶

In cases of deep and hypersensitive cavities, indirect pulp capping could be considered. A reduction in the permeability of the dentin, achieved by sealing the dentinal tubules, is of paramount importance. Nd:YAG and 9.6 μm CO_2 lasers can be used for this purpose. The 9.6 μm CO_2 laser beam is well absorbed by the hydroxyapatite of enamel and dentin and causes tissue ablation, melting, and re-solidification.²⁷ The use of a 9.6 μm CO_2 laser did not cause any noticeable damage to the pulpal tissue in dogs.²⁸ The effect of the Nd:YAG laser on intrapulpal temperature was investigated by White et al.²⁹ They found that the use of pulsed a Nd:YAG laser, with an energy of below 1 W, a 10-Hz repetition rate and overall 10-second exposure time, did not significantly elevate the intrapulpal temperature. According to their results, these may be considered safe parameters, as the remaining dentinal thickness in cavity preparations cannot be measured in vivo. It is recommended, therefore, that clinicians choose laser parameters lower than these safety limits.

In a study of the effects of Nd:YAG laser pulpotomy on human primary molars, it was shown that 66 out of 68 laser-treated teeth were clinically successful with no signs or symptoms of pathosis. The clinical success rate was 97% and the radiographic success rate was 94.1%. In the formocresol control group (69 teeth), the clinical success was 85.5% and the radiological success was 78.3%.³⁰ More clinical studies are required to verify the advantages of the use of lasers in pulp capping and pulpotomy procedures.

Cleaning and Disinfecting the Root Canal System

Bacterial contamination of the root canal system is considered the principal etiologic factor for the

development of pulpal and periapical lesions.^{31–33} Obtaining a root canal system free of irritants is a major goal of root canal therapy. Biomechanical instrumentation of the root canal system has been suggested to achieve this task. However, because of the complexity of the root canal system, it has been shown that the complete elimination of debris and achievement of a sterile root canal system is very difficult^{34,35} and that a smear layer containing bacteria, covering the instrumented walls of the root canal, is formed.^{36–38}

The smear layer consists of a superficial layer on the surface of the root canal wall approximately 1 to 2 μm thick and a deeper layer packed into the dentinal tubules to a depth of up to 40 μm .³⁸ It contains inorganic and organic substances including microorganisms and necrotic debris.³⁹ In addition to the possibility that the smear layer may be infected, it can also protect the bacteria already present in the dentinal tubules by obstructing intra-canal disinfection agents.⁴⁰ Pashley⁴¹ considered that a smear layer containing bacteria or bacterial products might provide a reservoir of irritants. Thus, complete removal of the smear layer would be consistent with the elimination of irritants from the root canal system.⁴² Peters et al.⁴³ moreover demonstrated that 35% of the canals' surface area remained unchanged following instrumentation of the root canal prepared with four Ni-Ti preparation techniques.

Because most currently used intra-canal medications have a limited anti-bacterial spectrum and a limited ability to diffuse into the dentinal tubules, it has been suggested that newer treatment strategies designed to eliminate microorganisms from the root canal system should be considered. These must include agents that can penetrate the dentinal tubules and destroy the microorganisms, located in areas beyond the host defense mechanisms, where they cannot be reached by locally administered antibacterial agents.⁴⁴

Numerous studies have documented that CO_2 ,⁴⁵ Nd:YAG,^{45–47} argon,^{45,48} Er,Cr:YAG,⁴⁹ and Er:YAG^{50,51} laser irradiation has the ability to remove debris and smear layer from the root canal walls following biomechanical instrumentation. The task of cleaning and disinfecting a root canal system that contains microorganisms gathered in a biofilm became very difficult; certain bacterial species become more virulent when harbored in biofilm, demonstrating stronger pathogenic potential and increased resistance to antimicrobial agents as biofilm has the ability to prevent the entry and action of such agents.⁵²

Bergman et al.⁵³ tried to define the role of laser as a disinfection tool by using Nd:YAG laser irradiation on

some endodontic pathogens *ex vivo*. They concluded that Nd:YAG laser irradiation is not an alternative but a possible supplement to existing protocols for canal disinfections, as the properties of laser light may allow a bactericidal effect beyond 1 mm of dentin. Endodontic pathogens that grow as biofilms are difficult to eradicate even upon direct laser exposure.

However, there are several limitations that may be associated with the intra-canal use of lasers that cannot be overlooked.⁵⁴ The emission of laser energy from the tip of the optical fiber or the laser guide is directed vertically along the root canal and not necessarily laterally to the root canal walls.⁵⁵ Thus, it is almost impossible to obtain uniform coverage of the canal surface using a laser.^{54,55} Furthermore, thermal damage to the periapical tissues is potentially possible, so safety of the procedures must always be considered.⁵⁵ Direct emission of laser irradiation from the tip of the optical fiber in the vicinity of the apical foramen of a tooth may result in transmission of the irradiation beyond the foramen into periapical tissues. This, in turn, may also be hazardous in teeth in close proximity to the mental foramen or to the mandibular nerve.⁵⁵ In their review, *Lasers in Endodontics*, Matsumoto et al.⁵⁶ emphasized the possible limitations of the use of lasers in the root canal system. They suggested that "removal of smear layer and debris by laser is possible, however it is difficult to clean all root canal walls, because the laser beam is emitted straight ahead, making it almost impossible to irradiate the lateral canal walls." They strongly recommended improving the endodontic tip to enable irradiation of all areas of the root canal walls. The Er:YAG laser has gained increasing popularity among clinicians following its approval by the US Food and Drug Administration for use on dental hard tissues.⁵⁷

Stabholz et al.⁵⁵ recently reported the development of a new endodontic tip to be used with an Er:YAG laser system. The beam of the Er:YAG laser is delivered through a hollow tube, with an endodontic tip that allows lateral emission of the irradiation (side-firing), rather than direct emission through a single opening at its far end. This new endodontic side-firing spiral tip was designed to fit the shape and the volume of root canals prepared by Ni-Ti rotary instrumentation. It emits the Er:YAG laser irradiation laterally to the walls of the root canal through a spiral slit located all along the tip. The tip is sealed at its far end, preventing the transmission of irradiation to and through the apical foramen of the tooth (Figures 4 and 5).

The efficacy of the endodontic1 side-firing spiral tip, in removing debris and smear layer from distal and

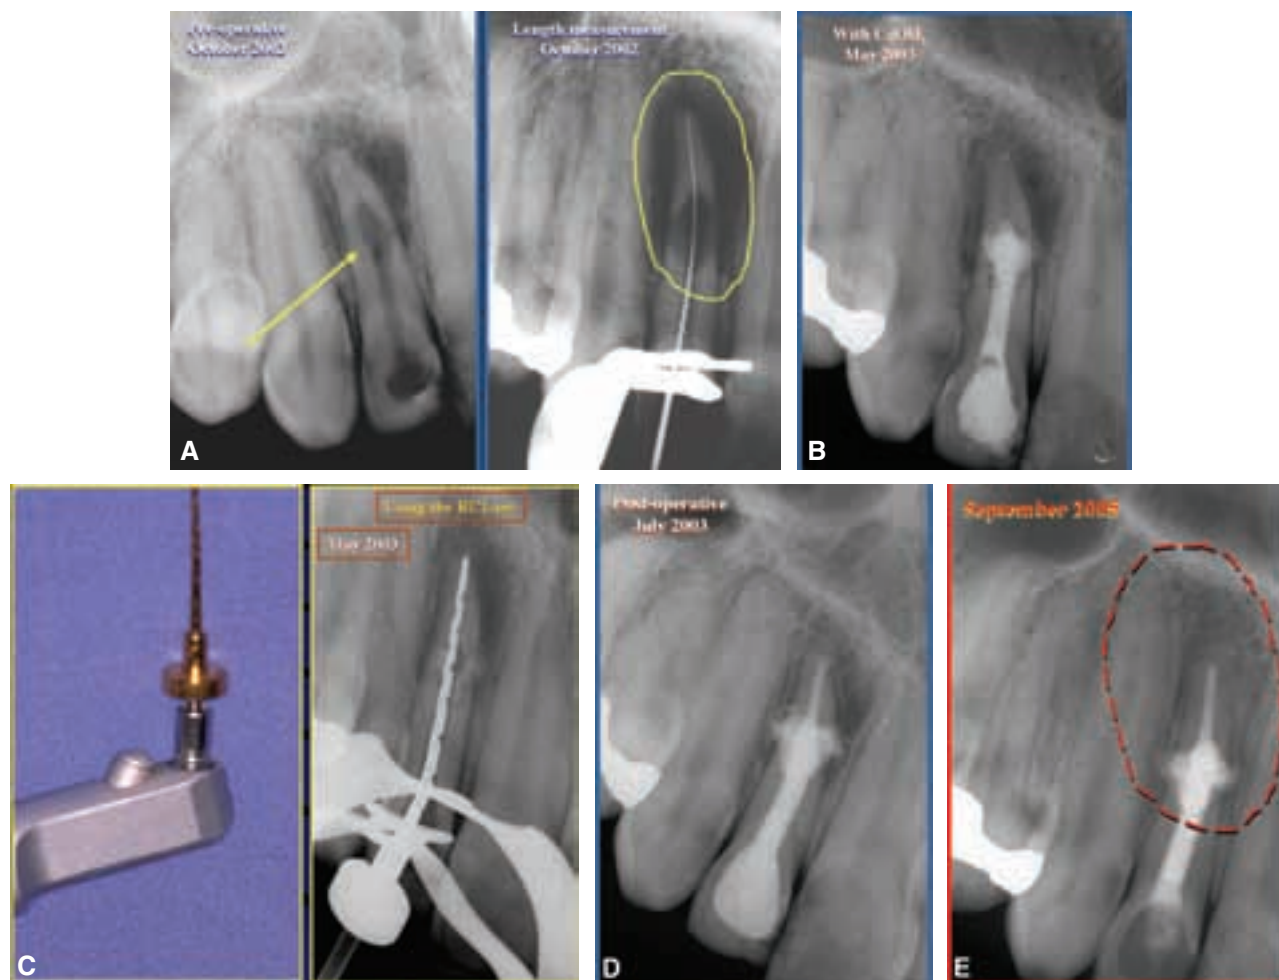

Figure 4 An 18-year-old patient came to the endodontic clinic complaining about a bad taste in her mouth and a lesion on the gums in the anterior area of the mouth. The clinical examination revealed a sinus tract opening close to the apex of the maxillary right lateral incisor. **A**, The radiograph showed an area of internal resorption and a large radiolucent area around the root apex. A diagnostic/length measurement radiograph suggested the presence of root perforation associated with the internal resorption. The patient was given the option of root canal treatment with poor prognosis, or replacing the tooth with an implant. The patient chose endodontic treatment. **B**, After cleaning and shaping the canal, Ca(OH)_2 was placed and replaced after 3 months. After 6 months, the sinus tract was still present with no sign of healing. **C**, The patient was offered the opportunity to have the tooth treated with the newly developed prototype of the RCLase Side Firing Spiral Tip that might provide better disinfection of the root canal system. The picture shows the RCLase tip positioned in the contra angle (left) and the radiograph shows the tip inside the root canal. **D**, Radiograph shows the lateral incisor following completion of the root canal filling using warm gutta-percha technique. **E**, A two-year follow-up radiograph shows complete healing of the periapical lesion. The sinus tract had disappeared and the patient was free of symptoms.

palatal root canals of freshly extracted human molars, was examined. Scanning electron microscopy (SEM) of the lased root canal walls revealed clean surfaces, free of smear layer and debris.⁵⁵ The dentinal tubules in the root run a relatively straight course between the pulp and the periphery, in contrast to the typical S-shaped contours of the tubules in the tooth crown.⁴¹ Studies have shown that bacteria and their byproducts, present in infected root canals, may invade the dentinal tubules. Their presence in the tubules of infected teeth, at junction, was also reported.^{58,59} These findings

justify the rationale and need for developing effective means of removing the smear layer from root canal walls following biomechanical instrumentation. This would allow disinfectants and laser irradiation to reach and destroy microorganisms harbored in the dentinal tubules.

In various laser systems used in dentistry, the emitted energy can be delivered into the root canal system by a either thin optical fiber (Nd:YAG, KTP-Nd:YAG, Er:YSGG, argon, and diode) or by a hollow tube (CO_2 and Er:YAG). Thus, the potential

Figure 5 **A**, Radiograph of a 42-year-old male patient with a suspected vertical root fracture on the second mandibular right molar. The tooth had been restored 12 years earlier after root canal therapy. He reported several episodes of pain and swelling during the past several years. **B**, At the first appointment, the leaky restoration and the screw post were removed, the distal root canal was thoroughly cleaned and irrigated using sodium hypochlorite, and Ca(OH)_2 dressing was placed. **C**, On a later appointment, the canal was treated with the prototype of the RCLase Side Firing Spiral Tip. **D**, The endodontic treatment was completed 6 months later (May 2003). Follow-up radiographs that were taken 1, 2 and 4 years after the completion of the endodontic treatment show complete healing of the periapical lesion.

bactericidal effect of laser irradiation can be effectively utilized for additional cleansing and disinfecting of the root canal system following biomechanical instrumentation. This effect was extensively studied using lasers such as CO₂,^{60,61} Nd:YAG,^{62–65} KTP-Nd:YAG,⁶⁶ excimer,^{67,68} diode,⁶⁹ and Er:YAG.^{70–72}

The emerging consensus is that laser irradiation emitted from laser systems adapted to dentistry has the potential to kill microorganisms. In most cases, the effect is directly related to the amount of irradiation and to its energy level.

Obturation of the Root Canal System

The purpose of obturating the prepared root canal space is twofold: (1) to eliminate all avenues of leakage from the oral cavity or from the periapical tissues and (2) to seal within the system any irritants that cannot be fully removed during the cleaning and shaping procedures.⁷³ The rationale in introducing laser technology to assist in obturating the root canal system is based on two major assumptions: the ability to use the laser irradiation as a heat source for softening the gutta-percha to be used as obturating material and for conditioning the dentinal walls before placing an obturating bonding material.

The concept of thermoplasticized compaction is not new and covers any technique based entirely on heat softening gutta-percha combined primarily with vertical compaction. The pioneering technique using vertical compaction of warm gutta-percha was described 40 years ago by Schilder⁷⁴ as a way to fill canals in all dimensions and is an example of thermoplasticized compaction.

The first laser-assisted root canal filling procedure involved using the wavelength of Argon 488 nm laser. This wavelength that can be transmitted through dentin was used to polymerize a resin that was placed in the main root canal. The ability of this biomaterial to penetrate into accessory root canals was tested and it was shown that the resin in the lateral canals was readily polymerized at low energy levels (30m W). Further use of this wavelength became irrelevant due to its unsuitable properties in other dental procedures.⁷⁵

Anic and Matsumoto⁷⁶ were the first to compare different root canal filling techniques for single-rooted teeth. Lateral condensation, vertical condensation, low-temperature gutta-percha (Ultrafil, Coltène/Whaledent, New York, NY), and laser-cured resin with different wavelengths (Argon, CO₂, and Nd-YAG) were the techniques used. The apical sealing ability achieved by the various filling techniques was compared by measuring the apical dye penetration following placement of the samples in a 1% solution of

methylene blue. Gutta-percha softened with Argon laser created an apical seal similar to that obtained with lateral condensation and Ultrafil techniques.

Maden et al.⁷⁷ used the dye penetration method to measure apical leakage by comparing lateral condensation, System B technique, and Nd-YAG softened gutta-percha. No statistically significant differences were reported. In another study, Anic and Matsumoto⁷⁸ demonstrated that the temperature elevation induced on the outer root surface when Nd-YAG and Argon lasers were used ranged from 12.9°C (Argon laser) to 14.4°C (Nd-YAG laser). Such an increase in temperature may be detrimental to the tissues of the attachment apparatus of the teeth. The implication of such methodologies remains questionable.

In order to examine whether laser irradiation improves the adhesion of endodontic materials to the dentinal walls and thus reduce apical leakage, Park et al.⁷⁹ used different sealers and two root canal filling techniques. Using an Nd-YAG laser irradiation at the end of the root canal preparation (5 W, 20 Hz), they concluded that Nd-YAG irradiation reduced apical leakage regardless of the sealer or the technique used.

Kimura et al.⁸⁰ used Er-YAG laser (170 to 250 mJ, 2 Hz) and showed that irradiation of the root canal did not affect apical leakage following obturation when compared with conventional methods. They later demonstrated that the use of Nd-YAG laser was useful for the reduction of apical leakage.⁸¹ Because Nd:YAG laser irradiation is very well absorbed by black color, an absorbent paper point soaked with black ink was introduced to working length and the apical root canal walls were painted.⁸¹

Significant improvement in the quality of the apical sealing of root canals was reported by Gekelman et al.⁸² who used an Nd:YAG laser (100 mJ/pulse, 1 W, 10 Hz). It has also been demonstrated that application of Er-YAG laser beam (200 mJ, 4 Hz) for 60 seconds enhanced the adhesion of epoxy resin-based sealers in comparison with zinc oxide-eugenol-based root canal sealers.⁸³

The clinical evidence from reported studies concerning the use of lasers to assist in obturating root canals is currently not sufficient. For example, it has not been determined whether the use of an optical fiber as a heat source to soften gutta-percha is safe for the surrounding structures of the tooth. It is also not clear if the softening of gutta-percha is homogeneous in all parts of the filling when vertical condensation techniques were described.⁸⁴ The significant role of endodontic sealers, when warm gutta-percha compaction techniques are employed, has been clearly demonstrated.⁸⁵ It is recognized that root canal sealers affect the quality of the apical seal of vertically

condensed gutta-percha and that without a sealer significantly more apical leakage occurs.

Some questions remain concerning the effectiveness of lasers contributing to the obturating procedures of root canals: what is the most suitable wavelength and what are adequate parameters? These areas should be explored and assessed.

Endodontic Retreatment

Endodontic failures can be attributed to inadequacies in cleaning, shaping, and obturation, iatrogenic events, or re-infection of the root canal system. Regardless of the initial cause, the sum of causes is bacterial contamination. The objective of non-surgical retreatment is to eliminate from the root canal space sources of irritation to the attachment apparatus.⁸⁶ Some of these failures may be managed by endodontic retreatment, proven to be effective in eliminating clinical and radiographic signs of pathosis. A variety of techniques have been described to remove deficient root canal filling and/or metallic obstructions that may lead to undesirable results⁸⁷ (see Chapter 31 “Retreatment of Non-Healing Endodontic Therapy and Management of Mishaps”)

The rationale for using laser irradiation in non-surgical retreatment may be ascribed to the need to remove foreign material from the root canal system that may otherwise be difficult to remove by conventional methods. Farge et al.⁸⁸ examined the efficacy of the Nd-YAP laser (1340 nm) in root canal retreatment (200 mJ and a frequency of 10 Hz). They attempted to remove gutta-percha and zinc oxide-eugenol sealer previously placed. In addition, they also reported an attempt to remove silver cones and broken instruments. They concluded that using laser radiation alone would not completely remove debris and obturating materials from the root canal.

Yu et al.⁸⁹ used an Nd-YAG laser at three output powers (1, 2, 3 W) to remove gutta-percha and broken files from root canals. They were able to remove filling material in more than 70% of the samples while broken files were removed 55% of the time.

Anjo et al.⁹⁰ reported that the time required for removal of any root canal-filling materials using laser ablation was significantly shorter than that required using conventional methods. It appeared that following laser irradiation, some orifices of dentinal tubules were blocked with melted dentin. They concluded that Nd:YAG laser irradiation is an effective technique for removal of root canal-filling materials and may offer advantages over conventional methods.

The efficacy of the Er-YAG laser in removing zinc oxide sealers and phenoplastic resins has also been studied.⁹¹ In straight root canals, laser irradiation with

250 mJ/pulse and 10 Hz frequency was useful in eliminating zinc oxide sealers.

Hand instruments without the use of any specific solvent were also used. In curved root canals, however, the procedure had to be stopped because of the risk of lateral root perforation. Under the same experimental conditions when laser irradiation was delivered to remove phenoplastic resins, ledging of the root canal occurred and it was not possible to return to the previously established working length.

A clinical advantage that should be further explored is the possibility of eliminating the use of toxic solvents when removing semi-solid materials from root canals. Although it was shown⁸⁹⁻⁹² that root canal-filling materials can be removed from the root canal using lasers, such as the Nd:YAG and the Er:YAG, the decisive advantage in using lasers for this purpose still remains to be confirmed.

Apical Surgery

Surgical endodontic therapy is indicated when teeth have responded poorly to conventional treatment or when they cannot be treated appropriately by non-surgical means. The goal of endodontic surgery is to eliminate the disease and prevent its recurrence.⁹³ Surgical options should be considered only when better results cannot be achieved by non-surgical treatment.^{94,95}

Egress of irritants from the root canal system into the periapical tissues is considered the main cause of failure following apicoectomy and apical filling. The irritants penetrate mainly through gaps between the filling and the dentin.⁹⁶ A second possible pathway for irritants to egress into the periapical tissues is through dentinal tubules on the cut root surface. It has been shown that the dentin of apically resected roots is more permeable to fluids than the dentin of non-resected roots.⁹⁷

The first attempt to use a laser in endodontic surgery was performed by Dr. Weichman at the University of Southern California (at the suggestion of Dr. Ingle). He attempted to seal the apical foramina of extracted teeth from which the pulps had been extirpated.⁹⁸ The apices of those specimens were irradiated using a high power CO₂ laser. Melting of the cementum and dentin was observed with a “cap” formation that could, however, be easily removed.

Miserendino⁹⁹ used a CO₂ laser to irradiate the apex of a tooth during apicoectomy. He described the advantages associated with laser application for periapical surgery such as improved hemostasis and concurrent visualization of the operative field. He also emphasized the potential sterilizing effect of the contaminated root apex as well as the reduction in permeability of the root surface dentin. Moreover, he

described re-crystallization of the apical root dentin that appeared to be smooth and suitable for placement of an apical filling material. Duclos et al.¹⁰⁰ used a CO₂ laser to perform apicoectomies in patients and advocated the use of a mini contra-angle head for efficient delivery of the laser irradiation at a 90° angle to the root apexes of teeth in the posterior areas.

However, unfavorable results of an *in vivo* study on dogs where the success rate following apicoectomies using the CO₂ laser was not improved have failed to support the rationale previously described by Miserendino.⁹⁹ A prospective study of two apical preparations with and without CO₂ laser, in which 320 cases were evaluated, did not show that CO₂ laser use improved the healing process.¹⁰² *In vitro* studies^{103–106} with Nd:YAG lasers have shown a reduction in penetration of dye or bacteria through resected roots. It was suggested that the reduced permeability in the lased specimens was probably the result of structural changes in the dentin following laser application.¹⁰⁴ Although SEM examination showed melting, solidification, and re-crystallization of the hard tissue, the structural changes were not uniform and the melted areas appeared connected by areas that looked like those in the non-lased specimens. It was postulated that this was the reason why the permeability of the dentin was reduced, but not completely eliminated. It is reasonable to assume that homogeneously glazed surfaces would be less permeable than partially glazed ones.

Ebihara et al.¹⁰⁷ used Er:YAG laser for apical cavity preparations of extracted teeth. They found no significant difference in dye penetration between the laser-treated groups and those in which ultrasonic tips were used. These results were not surprising as the Er:YAG laser neither melts nor seals the dentinal tubules; therefore, any reduction in dentin permeability should not be expected. A different result was obtained by Gouw-Soares et al.¹⁰⁸ who evaluated the marginal permeability in teeth after apicoectomy and apical dentin surface treatment using two different lasers (Er:YAG and 9.6 μm TEA CO₂). Both laser systems showed a reduction of permeability to methylene blue dye.

Recently it has been reported that when using an Er:YAG laser in a low output power in apical surgery, it was possible to resect the apex of extracted teeth. Smooth and clean resected surfaces devoid of charring were observed.^{109,110} It was also found that although the cutting speed of the Er:YAG laser was slightly slower than conventional high-speed burs, absence of discomfort and vibration and less chance for contamination at the surgical site, as well as reduced risk of trauma to adjacent tissues may compensate for the additional time required.¹¹¹

In a 3-year clinical study, Gouw-Soares et al.¹¹² reported a new protocol for use in apical surgery. An Er:YAG laser was used for osteotomy and root resection, whereas the Nd:YAG laser irradiation served to seal the dentinal tubules to reduce possible bacterial contamination of the surgical cavity. Improvement in healing was achieved by the use of a LILT Ga-Al-As diode laser. The radiographic follow-up showed significant decrease in the radiolucent periapical areas with no adverse clinical signs and symptoms.¹¹²

The preparation of apical cavities by Er:YAG laser and ultrasonics was also studied by Karlovic et al.¹¹³ They found lower values of microleakage when the root end cavities were prepared with the Er:YAG laser irrespective of the material used to seal those cavities.

It has been suggested that after the appropriate wavelength to melt the hard tissues of the tooth has been established, the main contribution of laser technology to surgical endodontics is to convert the apical dentin and cementum structure into a uniformly glazed area that does not allow egress of microorganisms through dentinal tubules and other openings in the apex of the tooth. Hemostasis and sterilization of the contaminated root apex will have an additional significant input.¹¹⁴

F. VISUAL ENHANCEMENT

JAMES K. BAHCALL

Visualization during surgical and conventional endodontic treatment has historically been limited to two-dimensional dental radiography representative of a three-dimensional biologic system and what could be seen with the naked eye (perhaps enhanced by loupes). Today, endodontic treatment is to a large extent viewed as a microsurgical procedure. The principle upon which all microsurgery is based is the observation that the hand can perform remarkably intricate micromanipulations as long as the eye can see a magnified field and it can be interpreted by the mind.¹ Magnification affects vision by increasing the size of an image on the retina. "Visual image" is the basic parameter used to describe how large something appears, and is expressed in units of degree or cycles/degree.² The use of optical magnification instruments such as loupes, microscopes, endoscopes, and oroscopes enables the endodontist to magnify a specified treatment field beyond that perceived by the naked eye.

Optical Definitions

Working Distance: The distance measured from the dentist's eye to the treatment field being viewed.

Depth of Field: The amount of distance between the nearest and furthest objects that appear in acceptably sharp focus.

Convergence Angle: The aligning of two oculars to be sure they are pointing at the identical distance and angle to the object or treatment field.

Field of View: The area that is visible through optical magnification.

Viewing Angle: The angular position of the optics allowing for a comfortable viewing position for the operator.

Loupes

Dental loupes are the most common magnification system used in dentistry. All loupes use convergent lenses to form a magnified image.³ The simplest form of optical magnification is *single-lens loupes* (ie, jeweler's flip-down magnifiers). Single lenses have a fixed focal length and working distance.⁴ The advantages of these types of loupes are low cost and light weight as they are made of plastic. The disadvantage of single-lens loupes is poor image resolution compared with multi-lens glass optics (telescopic loupes and microscopes).⁵ Because single-lens loupes provide a set working distance, the dentist may find the ergonomics incorrect and may need to compensate with poor body posture, causing the possible neck and back strain.

In order to overcome the disadvantages of single-lens loupe optics, the use of *multi-lens optic* system is recommended. This type of glass multi-lens configuration is known as a Galilean optical system (Figure 1). It provides a higher level of magnification, improved depth of field and working distance, and higher optical resolution compared with single-lens optics.⁴ Telescopic loupes use Galilean optics. Ideal magnification with telescopic loupes is $\times 2.5$. This offers a good compromise between weight, optical performance, and cost. Galilean lens systems cannot offer magnification much greater than $\times 2.5$ without incurring weight, size, and image resolution problems.⁵ Silber recommends the use of $\times 2.5$ operating loupes because magnification of loupes greater than $\times 2.5$ limits the depth of field and working distance during treatment.¹ Any head movement of the operator, while using loupes with magnification greater than $\times 2.5$, will move a treatment field in and out of focus, very distracting and irritating to the clinician. When need for higher magnification is required (up to $\times 6$), *prism optics* are

Galilean Telescope Image Appears Erect

Figure 1 Diagram of Galilean optics. Illustration courtesy of Designs for Vision, Inc., Ronkonkoma, NY.

available. This optical system is based on the Keplerian astronomic telescope, which uses five lenses and two prisms. The advantages of this optical system are superior optical clarity and a flatter view from edge to edge. However, the disadvantages are expense and added weight to loupes.⁵ And as the magnification in loupes increases, the need for more illumination is required.⁶ Loupe manufacturers have designed portable clip-on

light sources to accommodate demand for increased light.

Microscopes

Baumann⁷ was the first to report the use and benefits of an operating microscope for conventional endodontics. Since then, the use of the *surgical operating microscope* (SOM) has evolved in the field of endodontics as an invaluable optical magnification instrument⁸⁻¹⁰ (Figure 2). Today, this visual evolution in endodontics, from using loupes and headlamps to the use of the microscope, parallels a similar transition in medical specialties, such as ophthalmology and neurosurgery.¹¹ On January 1, 1998, the American Dental Association Accreditation Standards for Advanced Specialty Education Programs in Endodontics were revised; formal microscope training must be included in surgical and nonsurgical endodontic treatment.¹¹

The magnification needs in endodontic treatment range from $\times 3$ to $\times 30$.¹² A SOM accommodates these magnification requirements. Although loupes can have a magnification as high as $\times 6$, they are not able to provide the same depth of field at $\times 6$ magnification compared with the microscope,¹ and fiber optic light source of the SOM provides two to three times the light emitted from a surgical headlamp.¹³

Similar to loupes, microscopes use the Galilean lens system. The magnification of the SOM is

Figure 2 Clinical use of surgical operating microscope. Photo courtesy of Jedmed, St. Louis, MO.

Figure 3 A schematic diagram of the surgical operating microscope. The eyepiece connected to binocular field glasses allows adequate focal length. The objective lens increases the magnification. The magnification changer adds to the flexibility of the microscope.

determined by the magnification power of the eyepiece, the focal length of the binoculars, the magnification changer factor, and the focal length of the objective lens (Figure 3).^{12,14} The eyepiece has adjustable diopter settings ranging from -5 to $+5$. Diopter settings help the clinician focus the lens of the eyes and adjust for refractive error, which is the degree to which a person needs to wear corrective eyeglasses.¹²

The benefits of using an SOM for optical magnification in conventional endodontic treatment are well documented in the literature.¹⁵⁻¹⁹ They are increased visualization of the treatment field, enhanced visualization in locating canals, aid in the removal of separated instruments, diagnosis of micro fractures, perforation repair, and case documentation.

The advantages of using an SOM during surgical endodontic treatment are enhanced view of the surgical treatment field, need for taking fewer radiographs during the surgical procedure, and the ability to document the treatment.²⁰

When viewing an endodontic treatment field through a microscope, the use of a standard dental

mirror or micromirror is usually required, in conjunction with the microscope, to overcome the angulation difficulties of certain tooth positions in the mouth. Saunders and Saunders¹⁵ have stated that the most common reasons for endodontists not using the SOM during treatment: positional difficulties, inconvenience, and increased treatment time.

Rod-Lens Endoscope

The use of a *rod-lens endoscope* in endodontics was first reported in 1979.²¹ In 1996, the rod-lens endoscope was recommended as a magnification instrument for conventional and surgical endodontic procedures.^{22,23} The rod-lens endoscope (Figure 4) is made up of rods of glass working in junction with a camera, light source, and monitor (Figure 5). The option of a digital recorder (either streaming video or still capture) may be added to the system for documentation.

The rod-lens endoscope allows clinicians' greater magnification than that achieved with loupes or a microscope, with optical resolution comparable with that of microscopes and/or loupes. Although the endoscope can be used as a visualization instrument for conventional endodontic treatment, it can be bulky and difficult to maintain a fixed field of vision compared with a microscope. A fixed field of vision is defined as "viewing a treatment field from one single angle and distance."²⁴ The use of the endoscope is therefore recommended for visualization of surgical endodontic treatment.²²⁻²⁷ The

Figure 4 A rod-lens endoscope (Jedmed, St. Louis, MO).

Figure 5 Endoscope visual system (EVS) (Jedmed, St. Louis, MO).

visualization advantage, in surgical endodontic treatment, the endoscope provides over the microscope, is the ability to view a surgical treatment field in a nonfixed field of vision. This is defined as the ability to view a treatment field at various angles and distances without losing depth of field and focus.²⁴

The recommended rod-lens endoscope sizes, for endodontic surgical application, are a 2.7 mm lens diameter, 70° angulation, 3 cm length rod-lens, and a 4 mm lens diameter, 30° angulation, and 4 cm length rod-lens.²⁴ A pair of $\times 2$ to $\times 2.5$ loupes should be used for visualization prior to the use of the endoscope.^{1,24} Loupes aid the endodontist during surgery when reflecting gingival tissue, removing cortical and medullary bone, and isolating root ends. The clinician should hold the endoscope while the assistant retracts gingival tissue and suctions.²⁴ This maintains good eye-hand coordination during examination or treatment. The clinician and the assistant(s) view the magnified image on the monitor.

Hemostasis of the surgical field must be obtained before the endoscope is used because the scope cannot provide a discernible image when placed in blood. The warmth of the blood can also create lens condensation and a blurred image. If this occurs, the use of suction and irrigation, or an antifogging agent, will eliminate the fogging effect. The tips of the endoscope should be placed on bone around the surgical crypt in order to stabilize the scope. Prior to usage, a protective metal sheath is placed over the endoscope to add rigidity and allow the endoscope to be held in a stable position. It is not recommended to use the endoscope to also retract gingival tissue while viewing a surgical treatment field. This will not allow free movement of the scope by the operator while also having difficulty keeping the gingival tissue out of the line of sight.

Orascope

An orascope is a *fiber optic endoscope* and like the rod-lens endoscope works in conjunction with a camera, light source, and monitor. Fiber optics are made of plastics and therefore are small, lightweight, and flexible. It is important to note that image quality from fiber optic magnification has a direct correlation with the number of fibers and size of the lens used. The fiber optic endoscope is designed for intracanal visualization.²⁸ The orascope has a 0.8 mm tip diameter and 0° lens and the working portion is 15 mm in length (Figure 6). The orascope is

Figure 6 An orascope (Jedmed, St. Louis, MO).

Figure 7 Cross-section of oroscope probe showing the distribution of fiber optic image bundle and the light transmission fibers.

made up of 10,000 parallel visual fibers. Each visual fiber is between 3.7 and 5.0 μm in diameter. A ring of much larger light transmitting fibers surrounds the visual fibers for illumination of a treatment field (Figure 7).

Prior to the placement of the 0.8 mm fiber optic scope, it is recommended that $\times 2$ to $\times 2.5$ loupes or a SOM be used for conventional endodontic visualization during access to the canal(s). A canal must be prepared to a minimum size of a 90 file in the coronal 15 mm of the canal. If the canal is under-instrumented, a wedging of the oroscope may damage some of the fiber optic bundles within the scope. The proper canal enlargement also allows the full 15 mm of the scope to penetrate within the canal. The canal must also be dried before the 0.8 mm fiber optic scope is placed. Although the scope will see through sodium hypochlorite, this solution has a high light-refractive index. This will cause greater amounts of light that will be reflected, thus making it difficult to see details of the canal.

The focus and depth of field of an oroscope is from 0 mm to infinity. This allows the oroscope to provide imaging of the apical third of the root with-

out actually having to be placed in this region of the canal.

Similar to the endoscope, the endodontist holds the oroscope while viewing the image from the monitor.²⁸ Temperature and humidity difference between the dental operatory and the canal can cause moisture to condense on the fiber optic lens, causing fogging. The use of a lens antifog solution helps eliminate lens condensation build-up.

Microscope–Endoscope Combination

In conventional and surgical endodontic treatment, there are different visualization parameters for each type of treatment, when magnification beyond loupes is required. Although both the microscope and rod-lens endoscope can be used for magnification for either type of endodontic treatment, the advantages for using a microscope for conventional endodontic treatment and a rod-lens endoscope for surgical visualization led to the development of a microscope coupler (Jedmed, St. Louis, MO) that enables the endodontists to combine both technologies (Figure 8). The combination unit also allows for the use of the oroscope and digital documentation.

Magnification versus Differentiation

Magnification is defined as making an object or treatment field greater in size. *Differentiation* is defined as making something distinct or specialized.²⁹ The need to differentiate a magnified treatment field, when looking for a fracture in conventional endodontic therapy, or in surgical endodontic therapy when trying to identify the periodontal ligament space, an isthmus, or marginal leakage around a previous root-end filling, is important. Methylene blue, a nontoxic, biocompatible dye, can be used in conjunction with endodontic visualization instruments to help differentiate a treatment field in order to aid the endodontist in identifying etiology³⁰ (Figure 9).

Figure 8 Combination microscope–endoscope visualization system (Jedmed, St. Louis, MO).

Figure 9 **A**, Magnification of a root end without differentiation. **B**, Magnification of a root end with methylene blue added for differentiation.

Summary

The ability to enhance vision during endodontic procedures has significantly increased the comfort level of endodontists in terms of identifying fracture lines, locating minuscule canal orifices, and confidently determining anatomic variations in teeth and supporting structures. Technological advances are continuously being made in advanced vision equipment, promising an even brighter future.

CHAPTER 27

PREPARATION OF CORONAL AND RADICULAR SPACES

OVE A. PETERS, RAVI S. KOKA

It has been well established over the past 30 years that endodontic disease, the presence of apical periodontitis, has a microbial pathogenesis.^{1,2} Consequently, root canal treatment is performed to treat endodontic disease by eradicating bacteria from the root canal space. It is widely accepted that disinfection and subsequent obturation of the root canal space require mechanical enlargement of the main canals,³ and the vast majority of techniques and instruments today are based on this objective. Therefore, this chapter will focus on the principles of preparation of coronal and radicular canal spaces; it breaks this down into two distinct steps: first, preparation of the coronal access cavity and second, radicular canal shaping.

Coronal Access Cavity Preparation

The objective of the coronal access preparation is to provide a smooth free-flowing tapered channel from the orifice to the apex that allows instruments, irrigants, and medicaments to attempt cleaning and shaping of the entire length and circumference of the canal, with as minimal a loss of structural integrity to the tooth as possible. The access preparation generally refers to that part of the cavity from the occlusal table to the canal orifice. However, its design is dependent on the position and curvature of the entire length of the canal, not just the position of the orifice, and is therefore not a simple cavity.

In this first section on coronal access cavity preparation, the section on principles is intended for all teeth in general. The following sections will deal with the individual nuances in access preparation for each tooth.

General Principles

“DO NO HARM”

No practitioner performs treatment with the intent to harm and yet substandard quality does occur. The problem seems to stem partially from a lack of awareness and knowledge. In addition, the daily stresses within the practice environment compound this issue, and the stage is set for inadvertently causing harm or damage to the tooth and ultimately the patient. To minimize the frequency of harm clinicians may cause, learning and awareness should be lifelong objectives. A “mindful practice” is the objective that continuously monitors and reevaluates results and techniques over time with introspection.

CONFIRMATION OF ETIOLOGY OF PULPAL PATHOSIS

Part of the objective of the access preparation is to confirm the etiology of pulpal breakdown assessed during diagnosis. The only proven etiological factors are bacterial contamination (via caries, coronal leakage under restorations, fractures) and trauma (e.g., resorption, thermal, mechanical, and physical). As the pulp chamber is entered, the clinician must visually inspect the state of its contents to check that it matches with the preoperative diagnosis. It is disconcerting to expose the vital tissue when a preoperative diagnosis of necrosis has been made. Also the etiology of the pulpal breakdown has to be discerned. At times, it is easy to confirm the etiology, for example, the presence of a carious lesion, but in the absence of obvious clinical evidence, the practitioner must make a conscious effort to search for the cause. Clinically, presentation of microleakage and cracks is

extremely subtle and difficult to detect. Staining, high-power magnification under a microscope, transillumination may all help discover these sources.

ASSESSMENT OF RESTORABILITY

Although it is tempting to develop an “endodontics mode” mindset, once root canal treatment has been diagnosed, another major objective is to check the restorability of the tooth prior to root canal treatment. Existing restorations, caries, and unsupported enamel and dentin should be removed and the remaining tooth structure examined under a microscope. The operator should search for the presence of cracks, height, and thickness of the remaining dentinal walls for ferrule effect, the relationship of the remaining coronal tooth margins relative to the osseous crest, root length, location of the furcation, amount and quality of attached gingiva, and position of the tooth in the arch. This can result in several advantages:⁴

- Before root canal treatment is started, the patient can be forewarned of risks, benefits, and alternatives of any further procedures and/or costs to restore the tooth completed, for example, crown lengthening, gingivectomy, extrusion, or placement of orthodontic bands.
- A more educated opinion on long-term prognosis can be provided by the clinician to enable the patient to choose whether root canal treatment or implant therapy is more beneficial.
- Leakage of bacteria back into the root canal space under a preexisting defective restoration can be prevented.
- Cracks on the remaining tooth structure can be more readily assessed. This may change the clinician’s decision to extract versus restore, to place build up immediately, to perform cuspal reduction or warn the patient more emphatically of the chance of fracture postoperatively.

However, in certain situations it can be argued that a portion of the restoration should be left in place until the root canal treatment is almost complete. This provides a circumferential matrix to enable a seal by the rubber dam or help hold the clamp in place (as long as no leakage can be seen under higher magnification).

A more difficult situation arises when an existing crown is present on the tooth that requires endodontic treatment. Accessing through a crown has several distinct disadvantages: the amount of remaining tooth structure, the quality of the build-up restoration, the extent of any decay, and the quality of the crown seal cannot be thoroughly assessed. In fact, Abbott⁴ found that there was less than 60% chance to detect caries, fractures, and marginal breakdown, without complete removal of restorations. All of these factors have a profound effect on the long-term success of the root canal treatment, and longevity of the tooth. However, it is impractical to suggest removing all crowns prior to root canal treatment, and therefore a careful assessment of the integrity of the crown must be attempted through history-taking and clinical examination before and during treatment.

STRAIGHT-LINE ACCESS

It is well documented that to prepare the apical third of the canal circumferentially, a straight path for the cutting instrument from the orifice to the apex is imperative.^{5,6} As the curvature of the canal increases, a file that enters into the canal is deflected at its tip by the force exerted by the dentin. However, according to Newton’s Law, the file tip exerts back an equal and opposite reaction upon the dentin, that is, force on the outer dentinal surface of the canal as the file attempts to straighten back to its original dimension. If the dentin exerts a greater force than the file, the file bends, but this changes as the file size increases. Eventually, the file will cut the dentin rather than bend. At this point, the outer dentinal wall of the curvature is cut preferentially, known as gouging, which is the start of ledging and transportation. This effect is accentuated with cutting-tip files compared with non-cutting tips and with a vertical filing motion versus rotational motion.

A concomitant problem develops as the file tip exerts a force back on the dentin. A fulcrum point develops, which is the most protuberant point of contact on the furcal dentinal surface. Therefore, preferential cutting occurs on the furcal surface also, the site of a most common procedural error, known as stripping that can lead to perforation.

The term “straight-line access” (SLA) describes a preparation that provides a straight or outwardly

flared, unimpeded path from the occlusal surface to the apex. This allows the file to reach the apex with minimal deflection (Figure 1). The main corollary is

that it has to be accomplished without compromising the furcal surface of the canal that could ultimately lead to strip perforation. Access is continually

Figure 1 Straight line access in a mandibular third molar **A**, The orifice opening and path of insertion preoperatively is indicated by a black line. The mesial wall had to be cut to obtain a straight-line access **B**, The handles of the files are standing upright without crossing over each other indicating adequate Straight-line access **C**, However, often the distal canals are angled such that the file handles project out of the orifice mesially while still maintaining SLA.

adjusted until the selected master apical file (MAF) reaches the working length (WL) without undue stress upon it. A more aggressive SLA is required as the size of the file used and/or the degree of canal curvature increases. In this context, “aggressive” suggests that the orifice wall leading to the canal has to be moved and flared more obtusely toward the corresponding line angle.

The diameter of the apical preparation also effects the access preparation. To prepare a larger apical diameter, correspondingly larger, stiffer files that have a stronger tendency to straighten the canal have to be taken to the apex. In order to avoid stripping on the furcal surface or transporting the apex, one must achieve SLA beforehand. Unfortunately, the literature does not provide a consensus on the ideal apical diameter. However, *in vitro* studies have measured canal diameters.^{7,8} Other studies^{9–12} have measured canal cleanliness after a small versus larger diameter apical preparation and have shown better cleanliness with the larger diameters. One study, however, found that improvement gained with larger diameters was not statistically significant and concluded that small apical diameters were sufficient for adequate bacterial reduction.¹³

Radiographically, canal curvature in the mesiodistal plane can be directly observed; however, Cunningham and Senia¹⁴ demonstrated that canals possess a three-dimensional curvature. Therefore to obtain an SLA, sometimes tooth structure must be removed more on the buccal or the lingual surface than just on the mesial or the distal surface.

SLA involves the selective removal of the outer canal tooth structure to protect the furcal surface. Various methods have been advocated for this. The so-called “anticurvature” filing (see below) involves cutting only on the outward stroke away from the furcal surface but is not effective beyond curvatures. Gates Glidden (GG) burs allow the selective removal of dentin when used with a laterally directed motion and similarly stiffer nickel–titanium (NiTi) rotaries have significant lateral cutting ability (Paque F and Peters OA, unpublished data).

Peters et al.,^{15,16} using microcomputed tomography, have shown that significant portions of canals

are not touched during instrumentation due to the irregularities and curvature of the canals. This reiterates the importance of achieving SLA.

Mannan et al.⁵ tested whether SLA would allow mechanical cleaning of all the walls of the root canal in a single-rooted anterior tooth with a simple root canal anatomy. They prepared three types of access cavity designs: a “lingual cingulum” just coronal to the cingulum, a “lingual conventional” where the cavity was extended to within 2 mm of the incisal edge, and an access cavity involving the “incisal edge” but not the labial surface. They found that none of the cavity designs allowed complete planing of the root canal walls although the incisal edge design allowed a greater proportion of the root canal walls to be filed than the other two. This study, however, determined the MAF size as three sizes larger than the first file to bind, which had already been shown by other researchers to be an ineffective technique to properly clean the apical canal third.⁸ Another possible deficiency was that they did not extend the access cavities onto the labial surface, which is often necessary for true SLA as shown earlier.^{17,18} However, the study did emphasize that SLA provides the best chance of débridement of the entire canal.

THREE-DIMENSIONAL POSITION OF TEETH IN JAWS

The true three-dimensional position that teeth hold in each jaw cannot be assessed accurately by clinical or radiographic perspectives. Therefore, using the occlusal table of the tooth as a guide to the location of the chamber can be quite misleading. Figure 2 shows the lingual and mesial inclination of the mandibular molars, the mesial inclination of the maxillary molars, and the labial inclination of all the incisors.¹⁹ Correspondingly, when accessing, the bur must be angled to mimic these inclinations in both mesiodistal and buccolingual planes. However, other factors that limit the ideal angulation come into consideration. A compromise is reached, for example, trying to avoid encroaching on the incisal edge when accessing anterior teeth, or trying to avoid breaking through a marginal ridge. Improper angulation results in the

Figure 2 Schematic views of the three-dimensional positions of teeth in jaws in frontal and sagittal views with long axes of the teeth displayed. It is prudent during access to mimic these angulations to avoid unnecessary gouging. Root types are indicated by symbols on arrows. **A**, Maxilla. Note the mesial and buccal angulation of the molars and proclination of the anteriors. **B**, Mandible. Note the mesial and lingual angulation of the molars and proclination of the anteriors. common occurrence of unnecessary gouging of the dentinal walls that weakens the remaining tooth structure and in extreme cases leads to external perforation (Figure 3).

Part of the reason that these angulations are hard to transfer to the clinical setting is that the operator usually sits in the 10, 11, or 12 O'clock position with the patient reclined. This can be disorienting. The tooth is not viewed from the perspective shown in the figure, and is not in line with any external horizontal or vertical plane landmarks.

The operator has to physically move to view the angle of the bur relative to the patient's vertical and horizontal planes. This is similar to taking a radiograph by the paralleling technique.

EXTERNAL ROOT SURFACE AS A GUIDE

External root anatomy is determined by the internal pulp. The mesenchymal pulp tissue gives rise to odontoblasts that in turn lay down the dentin. As

Figure 3 Examples of unnecessary gouging of axial or furcation dentin due to improper angulation of the bur during access preparation. **A**, Preoperative and postoperative radiographs showing gouging of furcal dentin in the entrance to the mesiobuccal canals due to underextension of the mesial wall during initial instrumentation. **B**, Proper angulation was maintained allowing minimal tooth structure loss. **C**, Vertical instead of distal angulation while searching for distal canals.

the long axis of the tooth cannot be seen in the clinical setting, the next best guide is the external root surface. Acosta and Trugeda²⁰ sequentially reduced the clinical crowns of 134 extracted maxillary molars and examined the pulp chamber at the level of the pulpal floor. They found the pulp chamber in the center of the tooth, closely matching its outer contour and maintaining the same distance from the mesial, distal, buccal, and lingual surfaces.

This finding was confirmed more recently using mathematical models based on microtomography data.²¹ It was noted that the shape of the pulp chamber was trapezoidal, and it was therefore recommended shaping the access preparation in the same way.²⁰

In another study,²² 500 teeth were used of which 400 were sectioned at the cemento-enamel junction (CEJ), 50 buccolingually, and 50 mesiodistally. The

Figure 4 The pulp chamber is usually centered at the cementoamel junction (CEJ) level allowing the use of external root surfaces as a guide for access. patterns in orifice location, size, color, shape, and several conclusions were noted (Figure 4):

Law of Centrality: The floor of the pulp chamber is always located in the center of the tooth at the level of the CEJ.

Law of Concentricity: The walls of the pulp chamber are always concentric to the external surface of the tooth at the level of the CEJ, that is, the external root surface anatomy reflects the internal pulp chamber anatomy.

Law of the CEJ: The distance from the external surface of the clinical crown to the wall of the pulp chamber is the same throughout the circumference of the tooth at the level of the CEJ—the CEJ is the most consistent repeatable landmark for locating the position of the pulp chamber.

Law of Symmetry 1: Except for the maxillary molars, the orifices of the canals are equidistant from a line drawn in a mesial–distal direction, through the pulp chamber floor.

Law of Symmetry 2: Except for the maxillary molars, the orifices of the canals lie on a line perpendicular to a line drawn in a mesial–distal direction across the center of the floor of the pulp chamber.

Law of Color Change: The color of the pulp chamber floor is always darker than the walls.

Law of Orifice Location 1: The orifices of the root canals are always located at the junction of the walls and the floor.

Law of Orifice Location 2: The orifices of the root canals are located at the angles in the floor–wall junction.

Law of Orifice Location 3: The orifices of the root canals are located at the terminus of the root developmental fusion lines.

As the external root surface is a reliable guide, it can be quite frustrating to place the rubber dam, which completely obscures it. Therefore, in difficult cases, it is prudent to prepare the initial access shape and find the pulp chamber or at least one orifice prior to rubber dam placement. Alternatively, multiple teeth can be isolated by clamping one tooth more posterior so that the CEJ and the relationship of adjacent teeth are visible and palpable on the treated tooth. The Silker-Glickman clamp (Silk Pages Publishing, Deerwood, MN) was designed for this purpose. Otherwise, a single tooth clamp may be used and the dam flossed between the mesial contacts.

KNOWLEDGE OF PERCENTAGES FOR THE NUMBER OF CANALS WITHIN A ROOT

It has been known that roots contain multiple complex canal systems since at least 1925 as described by Hess and Zurcher.²³ Since then, research has focused on determining their classification and incidence. Data for canal numbers and configurations extracted from selected references are presented in Chapter 6, “Morphology of teeth and their root canal systems”. Some factors that affect such data have been noted, for example, methods and materials, type of magnification, in vivo, ex vivo, but many factors have not been noted, for example, case report articles, ethnic groups, age groups,

individual interpretation of classification systems by the various researchers.

From the material presented in Chapter 6, “Morphology of teeth and their root canal systems”, it can be extrapolated that studies report the incidence of multiple canals from 0% to as high as 95% for certain roots. Therefore the clinician must, to increase chances of finding them, have a thorough knowledge of the number, incidence, location, and the variability of the canal systems of each tooth and root, in order to design the access cavity. Selective removal of otherwise solid tooth structure can be justified only when the operator is confident of the knowledge that further canal systems may exist more apically and that the subsequent weakening of the tooth is offset by the significant advantage to long-term prognosis in finding another canal system.

MINDSET

Knowing that roots can have multiple complex canal systems, how zealous should the clinician be in looking for them? Obviously, the downside in removing the tooth structure to look for canals without success is the decrease in structural integrity and reduced long-term prognosis. Also, clinicians are trained to conserve as much tooth structure as possible. A tooth should be entered under the assumption that every root has multiple canals. This assumption can be proved wrong only after adequate searching, defined by objective criteria, for example, troughing through the lighter-colored dentin of the walls compared to the darker dentin of the pulpal floor or drilling approximately 5 to 7 mm below the furcal floor. Clinicians can then regularly self-assess, by comparison to the actual figures presented in the various studies and by discussion with peers. There is a balance between selectively extending the access cavity to search for canals and unnecessary overextension—the art is in determining this line.

MAGNIFICATION/MICROSCOPE

Little controversy remains over the effectiveness of the dental operating microscope. Several studies have shown that it increases the dentist’s ability to find canals, allows precise repair of perforations, aids in removing separated files, and improves surgical visibility (see Chapter 26F, Visual Enhancement for more details).

Clinical Armamentarium

Access preparation requires few standard hand instruments, but a wide range of equipment for differing

situations. The basic requirements are a mirror, a DG16-type endodontic explorer (e.g., HuFriedy, Chicago, IL), high- and low-speed handpieces, a range of burs, and a microscope. A standard set of burs (Figure 5) should include at least a #2 round diamond, a #1 round carbide, a transmetal bur (Dentsply Maillefer, Ballaigues, Switzerland), various cylindrical diamonds (e.g., 859–010, 859–012, 859–014, BrasselerUSA, Savannah, GA), and an EndoZ bur (Dentsply Maillefer).

The following are accessory items for differing situations or routine use depending on the practitioner’s preference. Bendable and differently sized heads of mirrors (eie2, San Diego, CA) allow improved maneuverability and visibility but can be particularly helpful in cases of difficult access due to the distal location of the tooth or the patient’s inability to open widely (see Figure 5). An endodontic explorer that is finer than the regular DG16 is also available, the Micro JW17 endodontic explorer (CK Dental, Orange, CA).

Some clinicians find the Micro-Openers and Micro-Debriders (Dentsply Maillefer) helpful. The former have 7 mm of K-type flutes in 0.04 and 0.06 tapers in ISO sizes #10 and #15, and the latter have 16 mm of Hedström-type cutting flutes in sizes #20 and #30. Both are mounted as a handheld instrument at a double angle and can be useful for initial orifice location and widening.

BURS

Safe-ended diamonds and tungsten carbide burs that do not cut at their tip, for example, Endo Access, Endo Z burs, LA Axxess burs (SybronEndo, Orange, CA), can be beneficial in avoiding gouging. However, these burs are wide and should be used for final refinement after precise extension has already been determined with thinner cylindrical diamonds. The Mueller bur (BrasselerUSA) is a latch-grip surgical length round carbide bur available in sizes 0.9, 1.0, 1.2, 1.4, 1.6, and 1.8 mm diameters. Similarly, Munce Discovery burs (CJM Engineering, Santa Barbara, CA) are 34-mm-long, narrow-shafted, nonflexible round carbide burs available in sizes 1/4 (0.5 mm diameter), 1/2 (0.6 mm), 1 (0.8 mm), 2 (1.0 mm), 3 (1.2 mm), and 4 (1.4 mm). The extended length of both these burs reduces the head of the handpiece blocking the operator’s view. The Munce burs are not as flexible as the Mueller burs due to a slightly greater shaft diameter and are available in smaller sizes. Both these burs are useful for deep troughing to find canals, opening isthmuses, or reaching separated instruments and seem to leave an easier-to-read dentin surface than ultrasonics (see Figure 5).

ROTARY INSTRUMENTS

For gaining SLA in the coronal portion of the canals, rotary instruments that selectively cut laterally are useful to minimize excess removal of the furcal dentin. GG drills (sizes 1 (ISO #50), 2 (#70), 3 (#90), 4 (#110), 5 (#130), and 6 (#150)) have been used for many years and are efficient and relatively inexpen-

sive. Some of the stiffer NiTi rotaries also have lateral cutting ability.

ACCESSORY INSTRUMENTS

The Stropko Irrigator (Vista Dental Products, Racine, WI) is an adapter that connects to the air/water syringe and accepts standard Luer-lock needle tips for

pinpoint irrigation or aeration. It regulates air or water flow to between 2 and 7 psi and provides a very precise delivery. It aids visibility at high-power magnification under a microscope.

Ultrasonically powered instruments with well-adapted tips from various manufacturers have now become indispensable (see Figure 5E). They allow for deep troughing with minimal collateral tooth structure removal. Visibility is better than with burs, and the tips can be diamond-coated to increase their efficiency. However, all tips develop significant heat and can cause necrosis of the surrounding bone if used without a coolant. Some practitioners finish their access preparations with sandblasting or finishing burs; this practice may have an impact on composite bonding.²⁴

Clinical Guidelines

PREOPERATIVE CLINICAL GUIDELINES

Determination of the point of penetration: Usually entry is in the center of the occlusal table but in certain teeth (e.g., maxillary molars) it is deceiving, as the center of the occlusal table does not reflect the center of the pulp chamber. Anatomy and strategies for access is detailed in sections on individual teeth below.

Assessment of occlusal and external root form: Once the point of entry has been determined, the bur's angulation in three dimensions has to be mentally envisaged. This is determined by taking into account the angulation of the teeth in the jaws (see Figure 2) and assessing the external root surface at the level of the CEJ.

Radiographic measurement of the depth of the pulp chamber roof from the occlusal table: The initial bur in the high-speed handpiece is placed against a radiograph or a measurement determined from a calibrated digital image.

Assessment of complicating factors: Rotations/tipping of tooth, calcifications (stones, deep restorations, buccal/lingual restorations (mid-root calcification), root length, width, curvature) affect the angle of entry and the degree of extension of the access cavity in the horizontal and vertical dimensions.

Radiographic assessment: Angled views should be taken in an attempt to visualize the breadth of the roots and the centeredness of the canal within it. One also has to assess the angle at which the canal leaves the pulp chamber—the root may not seem curved but if there is a sharp angle between the chamber and the canal, SLA will require a significant reduction of the orifice walls. To aid in orientation, the access preparation can be started without rubber dam until the pulp chamber is located.

Access Cavity Preparation

Access cavity design has undergone changes throughout the years. Originally, it was thought that the cavities should be round in anterior teeth, oval in premolars, and triangular in molars. This gave way to triangular cavity shapes in anterior teeth and quadrilateral shapes in molars.²⁵

It was considered acceptable to state “make access cavities large.” Also, “make them like an inlay preparation,” where circumferentially around the access cavity, every point coronal from the pulpal floor is wider. However, these protocols resulted in excessive, unnecessary tooth structure removal. With the advent of microscopes, visibility has greatly improved and far more precision is now possible. Therefore, an access cavity should be made in such a way that only that tooth structure necessary for the objectives of cleaning and shaping is removed, and absolutely no more. It has been shown by several researchers that a difference of 0.5 to 1 mm of the remaining dentin tooth structure can improve a tooth's fracture resistance with statistical significance. Sorensen and Engelman²⁶ showed that 1 mm of ferrule significantly increased fracture resistance, while Libman and Nicholls²⁷ demonstrated that there was a significant improvement between 1 and 1.5 mm of dentin ferrule height. A 5-year prospective clinical study²⁸ showed that the remaining dentin thickness and height affected survivability but found no difference in survivability among cast post and core, prefabricated post and core, and composite-only cores. Tan et al.²⁹ showed a significant difference between a uniform, circumferential 2-mm ferrule and a nonuniform ferrule with only 0.5 mm proximal but 2 mm buccal and lingual dentin height (see Chapter 40, Restoration of Endodontically treated Teeth).

It must be remembered that just having remaining outer tooth structure around the access preparation is not sufficient; the long-term prognosis is more accurately assessed after both access preparation and crown preparation are completed. A developing concern is that full porcelain crowns require more dentin removal to allow adequate strength to the crowns and are becoming more popular due to their improved esthetics. Therefore, the practitioner should not base the access cavity design on the ease of visibility, but only on removing what is absolutely necessary and no more. The common retort is that restricting the access cavity will jeopardize the success of the root canal treatment, as visibility will be impaired. However, it will be shown that all the objectives necessary for cleaning and shaping can be adequately met, without restriction of visibility or instrument access, as

unnecessary tooth structure removal is avoided. If the access cavity has to be extended to facilitate visibility, it should be done with precision.

An access cavity should be considered specific and individual for each tooth and for each patient, as is a class II restorative cavity or crown preparation. The access cavity will vary according to the degree of curvature within the canal (i.e., the angle at which the canal leaves the pulp chamber may be very different from the root curvature), the position of the canal apex relative to its cusp tip, canal length, degree of calcification, size, shape, and position of the tooth in the jaw. It is suggested that only the initial entry point on the occlusal table should be based on a standardized protocol but once the pulp chamber has been found, the cavity should be “tailor-made.”

The sequence of steps for access preparation will be discussed here and can also be followed in Figure 6. The *first objective* is to penetrate through the occlusal surface. Penetrating enamel or precious metal is predictable using a high-speed handpiece with a tungsten carbide bur. Porcelain and nonprecious metals, however, present more difficulties, in particular with chipping when a steel round bur is used. Diamond burs easily penetrate porcelain but are generally much less efficient with metal. Stokes and Tidmarsh³⁰ evaluated the cutting efficiency of diamond and tungsten carbide burs through metal crowns. They tested coarse grit round and dome-ended cylinder diamonds and six-bladed tungsten carbide cross-cut fissure or round burs. They found that for precious alloys, tungsten carbide burs were significantly quicker. For the

Figure 6 Sequential steps in endodontic access preparation on an extracted lower molar. Initial entry **A**, with bur is angled toward buccal and distal; narrow entry is sufficient to find the pulp chamber **B**. A K-file size #10 or #15 is then used to find the position of orifices **C**. Further extension based on the position of orifices **D**, and a file is now placed into the coronal portion of the canal to determine the location of the restrictive dentin. The restriction can be seen under the microscope at the orifice level, and further extension of the occlusal surface is not warranted at this time. The buccal surface is undercut to remove the pulp chamber roof minimizing the removal of occlusal dentin/enamel **E**. Similar extension is done for lingual, mesial, and distal surfaces **F**. Large pulp stones are removed by sectioning, not widening the cavity **G**. Once the restrictive dentin at the orifice is removed, a file starts to contact the entire wall. Now only that slice of dentin contacted by the file from the occlusal surface to the orifice level is cut with a flared-out angle with a narrow tapered diamond bur **H**, so that a slot-shaped preparation starts to develop **I**. This is repeatedly extended after checking each time for location of dentinal contact with a file **J**. Completed access preparation shows straight-line access (SLA) into the mesiobuccal **K**, and mesiolingual canal **L**, after root canal filling. The fin between the mesiobuccal and mesiolingual canals can be identified under the microscope as blind-ended. In case of less than ideal visibility, the mesial wall would have to be straightened and flared for deeper access and visibility. **M**, A clinical example of a file placed at working length (WL) without undue strain from the outer wall and precisely in its slot. A similar clinical example shows gutta-percha cones prior to taking master cone radiograph **N**.

precious alloys, though no difference initially, after five cavity preparations, only the dome-ended cylinder diamond cuts significantly faster than other bur types. They found the diamond burs to be smoother with less “chatter” during cutting than the tungsten carbide burs. They concluded that cutting efficiency appears to relate not only to grit size but to bur shape as well. Teplitsky and Sutherland³¹ showed that of the 56 porcelain crowns, none fractured after access preparation with diamond burs, whereas tungsten carbide burs dulled rapidly and were ineffective. Cohen and Wallace³² showed that of the Dicor crowns cemented with zinc phosphate, porcelain chipped and the seal was lost after accessing. However, when a bondable cement was used (polycarboxylate), none of the crowns lost retention. When penetrating a porcelain-fused-to-metal crown, the porcelain should be removed with a dome-ended cylindrical or a #2 round diamond and the nonprecious metal penetrated with a #1 round carbide bur or a tungsten carbide transmetal bur.

The *second objective* is to find the pulp chamber. A narrow opening is maintained initially and the penetrating bur is taken to a premeasured depth gauged by measuring the distance between the cusp tip and the pulp chamber roof from the preoperative radiograph. As the access preparation has not yet been extended, the clinician relies on having premeasured the depth and correct judgment of the angle of penetration of the bur based on the parameters described above. If the pulp chamber is large and the angulation is correct, the bur can be felt to “drop” through into the chamber. However, relying on this feeling is dangerous for it is unpredictable. If the chamber is calcified or deep, the “drop” is often not discernable, and unnecessary gouging of the walls or floor or even perforation can occur, if the clinician is not exactly on target. Therefore, the bur should penetrate only to the premeasured distance, and if the chamber is not found, the access should be minimally extended into a narrow slot in the anticipated direction of the canals using the microscope with good illumination to look for signs of the chamber. Often a pulp horn may already be exposed or the cavity already overextended in certain spots. Extending the cavity without visualization usually results in unnecessary tooth structure loss, and therefore extreme care must be paid. When searching for the pulp chamber, tapered instruments should never be forced but be allowed to cut their own way with a light touch by the operator. When forced, they will act as a wedge. This may cause the enamel to “check” or “craze” and will materially weaken the tooth.

The *third objective* is to “unroof” the dentin that covers the pulp chamber. This is carefully done under the microscope with a thin needle diamond cylinder

(e.g., #859–010, BrasselerUSA) so as to avoid unnecessary widening of the isthmus. The bur is angled to undercut the occlusal surface thereby maintaining as much tooth structure as possible. Ultrasonic tips can also be used very precisely to accomplish this. Round burs should be avoided during access preparation other than perhaps for initial penetration as they cause indiscriminate gouging of the walls. Safe-ended cutting burs can be used but their width is rather large for use at this time. In this step, the clinician depends mostly on the “feel” of the bur deep inside the tooth, against the roof and walls of the pulp chamber, to judge the extensions that are necessary.

The entire roof of the pulp chamber is removed. In this operation high-speed equipment should be operated with vision and is not generally employed in a blind area where reliance on tactile sensation is necessary.

The *fourth objective* is to obtain uniform contact of the file with the access cavity wall. A file is placed in one of the canals and is viewed under the microscope to evaluate the specific points along its length where it is being held up by the access cavity or the canal dentin. Then, with a thin needle diamond, only that area of the cavity wall is relieved. The file is reinserted and the process repeated until the file contacts dentin evenly along its length in the chamber without undue strain. If the restraining dentin is determined to be within the coronal portion of the canal, GG burs or other instruments that can cut a “relief channel” laterally may be used, rather than extend the entire wall.

The *fifth objective* is to obtain SLA. The clinician must assess the degree of taper to be imparted to the dentin access wall in the one line the file is uniformly contacting. A radiograph can be used to help assess. This single “slice” of dentin is then flared out to an obtuse angle relative to the pulp chamber floor, creating a slot-like extension. All other points of the walls are kept flared in or undercut or at as acute an angle as possible that allows complete visibility of the floor when viewed under a microscope. The floor and canals will not be visible in one view—the mirror has to be moved.

The diameter of the bur that cuts the slot extension should only be the maximum diameter of the largest file that is necessary at the canal orifice. A taper is not required for that part of the access preparation between the orifice and the occlusal table as compaction forces for obturation will not apply. The “010” suffix of cylinder and tapered diamond burs connotes the maximum cutting shaft diameter is 1 mm and of “012” is 1.2 mm, etc. It should be remembered that with natural hand movement, the diameter of the cut made by these burs would be still larger. Therefore,

usually a #859–010 is large enough. The operator should also be aware of the maximum diameters of the files chosen, for example, GG4 (1.1 mm) and ProTaper (1.2 mm). A 35/0.06 Profile is 1.3 mm at D16, which will necessitate a larger access cavity than is usually required for cleaning and shaping. An orifice diameter can generally be maintained between 0.9 and 1.1 mm for adequate cleaning and shaping while minimizing the loss of root strength.

The canal access slot is continually moved to the outer surface to prevent cutting on the furcal surface during cleaning and shaping as the larger files that require more and more space are introduced.

The mesiodistal width of the access preparation can be kept as small as possible. It has been shown that the average dimensions between walls at the pulp chamber floor are 2.2 mm mesiodistally and 5.1 mm buccolingually.²⁰ Examples of basic access cavity preparations, before individual slot extensions for SLA, as well as plates covering common clinical errors, may be seen on the DVD accompanying this text.

Maxillary Central Incisors

ANATOMY AND MORPHOLOGY

The tip of the root and the incisal edge are on the midline from a proximal view (Figure 7).³³ It is very rare for these roots to have true second canals^{34,35} but quite common to have lateral canals. The roots are straight and have the least incidence of dilacerations.³⁶ Kasahara et al.³⁷ used 510 extracted maxillary central incisors with no abnormalities and decalcified them in nitric acid for 48 hours. They suggested that over 60% showed accessory canals that were impossible to clean mechanically. Most lateral branches were small, 80% were size #10 reamer or less, and 3% were larger than a #40 reamer. Eighty percent of all apical foramina

were located within 0.5 mm of the apex and 95% within 1 mm.

There are many case reports showing two canals (and one showing four canals) but usually the crowns and/or roots are unusually large, suggesting fusion, gemination, or presence of a dens-in-dente. However, case reports of maxillary centrals with two roots/canals and normal crowns have been reported.^{38,39}

CLINICAL

Initial penetration should be approximately in the middle of the lingual surface of the tooth, just above the cingulum almost perpendicular to the lingual surface. After locating the canal, long tapered diamonds can be used to extend the access into a roughly triangular outline. However, this extension when carried out under the microscope can be made precisely to each tooth to only uncover the pulp chamber and horns and to provide continuous smooth walls down the chamber into the canal.

Even though it has been shown that a better SLA can be achieved through an incisal access cavity,¹⁸ the lingual approach is used in order to maintain as much tooth structure on the labial surface as possible for esthetic reasons. The reciprocal compromise is that a lingual triangle is formed, which has to be removed to achieve SLA. In fact, LaTurno and Zillich¹⁸ showed that only 10% of the 50 maxillary central canals examined projected solely onto the lingual surface with an SLA. Eighty-four percent of the configurations involved at least the incisal edge and 6% were solely on the buccal (Figure 8).

After initial penetration into the chamber, the access cavity has to be extended precisely in both the labiolingual and mesiodistal dimensions. In the labiolingual plane, there are two particular areas generally described as the lingual and labial triangles that have

Figure 7 Example of a maxillary central incisor showing labial, mesial, and incisal views **A**, The access preparation can be assessed from a more incisal view and a lingual view **B**, The width of the preparation in the cingulum is 1.1 mm. Note also the extension of the mesial and distal incisal areas to open up the pulp horns.

to be removed to obtain an SLA. However, the labial triangle can often be a quadrilateral as shown in Figure 9.

With regard to mesiodistal extension, all access cavities should uncover the pulp horns, but special attention has to be paid to the maxillary incisors as the pulp horns are not in the direct line of vision of

the access cavity. If even minute amounts of tissue remain in the pulp horns, they will subsequently discolor the remaining tooth structure over time. Complete extensions can be accomplished by feeling the extension of the pulp horns under each mesial and distal angle with a cowhorn explorer (HuFriedy). Fine extensions that require opening with a half-round

Figure 8 Impact of initial entry into pulp chambers of incisor teeth, from labial (1) to incisal (2) and the usual oral access (3). **A**, Schematic diagrams for maxillary and mandibular incisors. **B**, Original micrographs with access from incisal (top) and oral (bottom). Reprinted with permission from Sonntag D et al.⁶

carbide bur often occur. These extensions should be blended into the main access chamber so that residual debris, sealer, or gutta-percha does not become trapped and cause discoloration. Younger patients have more pronounced pulp horns and require particular care to remove the remaining potential tissue.

Due to the lingual approach, the points of restriction on the files are against the coronal portion of the lingual wall and the most incisal portion of the labial wall. Khademi⁴⁰ suggests notching the midpoint on the labial preemptively to accommodate the larger files more easily.

There is a debate as to how far the incisal extension should be taken. As we know that most anterior teeth have a better SLA from the buccal or the incisal surface, the operator has to assess on a case-by-case basis and sometimes the extension will be more aggressive than others.

Maxillary Lateral Incisors

ANATOMY AND MORPHOLOGY

These teeth have a function very similar to centrals and are therefore similar except for a smaller scale in all dimensions except root length. They have more rounded incisal angles and the root typically curves to the distal although some can be straight or curving to the mesial. There is often a deep developmental groove running along the cingulum on the lingual surface.³³

Again it is very rare to find more than one canal,^{34,35} but several case reports have shown more canals with separate apices.⁴¹⁻⁴⁴ The pulp horns may not be quite as pronounced, but the concept of lingual shelf removal and extending the pulp horns till it can be verified with a cowhorn explorer that the angles are smooth still holds.

Regarding SLA, LaTurno and Zillich¹⁸ as well as Zillich and Jerome¹⁷ showed that of the 131 teeth examined, only 0.8% of canals had a coronal projection that was entirely lingual and did not involve the buccal (see Figure 9). Therefore, the clinician should be more fastidious about the removal of the lingual triangle for these teeth. Compounding the difficulty of achieving SLA from a lingual approach is that these teeth tend to have a curvature to the distal.

It must also be noted that incisors can have many anomalies that severely increase the difficulty in treatment of these cases, for example, radicular palatal grooves, fusion with supernumerary teeth, gemination, dens invaginatus, dens evaginatus, incomplete apical closure; it is beyond the scope of this chapter to cover these treatment protocols.

Figure 9 Potential design of access into a maxillary incisor with schematic drawings based on an original radiograph **A**, The preoperative relation of the canal within the root can be estimated **B**, note how the true straight-line access (SLA) is labial to the incisal edge **C**, The initial access entry site and angulation **D**, tan-colored highlights) show the restrictive dentin impeding SLA. The completed lingual access preparation with SLA **E**, can be compared to a completed access preparation done from a labial approach **F**, Note how far more tooth structure may be conserved with a labial access but at the cost of disrupting the labial esthetic surface.

Maxillary Canines

ANATOMY AND MORPHOLOGY

The labiolingual measurement of the crown is about 1 mm greater than that of the maxillary central incisor and the mesiodistal measurement is approximately 1 mm less (Figure 10). The position of the cusp tip

relative to the long axis of the root is in line with the center of the root tip in the labial view but lies labial in the proximal view.³³ LaTurno and Zillich¹⁸ showed that none of the 48 maxillary canines examined projected solely onto the lingual surface with an SLA. About 98% of the configurations involved the incisal edge (of which 43% involved incisal and lingual) and 2.1% were purely on the buccal. Usually one root

canal is present,^{34,35} but cases with two canals have also been reported⁴⁵ (see Figure 8).

CLINICAL

These teeth have a point of entry just about the cingulum with the tip of the bur aiming for the center point at the CEJ level. The occlusal outline form is oval as the single pulp horn does not tend to fan out to the mesial or distal; however it is broad labiolingually. Again, this is checked with a cowhorn explorer and is adjusted according to the individual tooth. The extension to the buccal or lingual is done only as necessary to clearly uncover the horns and to allow unheeded insertion of any file.

It is usually the longest tooth and the largest root in the mouth and is critical to the occlusion. The canal often curves apically. As with the central and lateral incisors, the lingual triangle must be removed. The main difficulty with these teeth is that they can be long—often over 30 mm. This will affect the access cavity in that to provide an adequate apical preparation size, SLA becomes more important.

Maxillary First Premolars

ANATOMY AND MORPHOLOGY

From the occlusal aspect, the tooth resembles roughly a hexagonal structure, and it is much broader buccolingually than mesiodistally (Table 1, Figure 11). As in all posterior maxillary teeth, the measurement from the buccal cusp tip to the lingual cusp tip is less than the buccolingual measurement of the root at its cervical level. As more of the buccal cusp is seen than the lingual, the access preparation is angled buccally into the cervical areas but not extended to the same degree on the occlusal table. There is a marked

Figure 11 Example of a maxillary first premolar showing buccal, mesial, and occlusal views **A**, and a typical access preparation **B**. Note how the buccal part of the preparation has been extended mesiodistally to explore a potential second buccal canal.

developmental depression on the mesial surface that extends from just below the mesial contact point between the roots and ends at the bifurcation. There is also a well-defined developmental groove in the enamel of the mesial marginal ridge that runs into the central groove on the occlusal table. This can be deceiving during access as off-angulation of the bur can result in perforation. It must be assumed that at least two canals are present, and the third canal is shown to exist in high enough numbers that the access preparation must be designed to search for it (either mesiobuccal or distobuccal canals, abbreviated MB or DB). When three canals are present, the pulp chamber morphology resembles that of a maxillary molar, and they have been termed “mini-molars.” The width of the access can be kept minimal between the canal orifices.

CLINICAL

The point of entry is centrally in the fossa, aiming at the center point at the CEJ. The outline is an elongated slot and can extend almost to the cusp tips depending on the angle. However, the operator must search for a third canal—usually the mesiobuccal canal. If three canals are found, the orientation is very similar to that of the maxillary molar (Figure 12).

Maxillary Second Premolar

ANATOMY AND MORPHOLOGY

The occlusal table is very similar to that of the first premolar (see Figure 11), presenting without a

Figure 12 Two examples of maxillary first premolars with three canals that were endodontically treated. A clinical view of the access cavity is provided in **A**.

depression in the mesial root surface (Figure 13). It has a more rounded crown form and has a single root when compared with the first premolar. Internally, the incidence of two canals is significantly less but

Figure 13 Example of a maxillary second premolar showing buccal, mesial, and occlusal views. The access preparation is virtually identical to the one of maxillary first premolar (see Figure 11).

when present they are not spaced so far apart from each other.

Maxillary First Molar

ANATOMY AND MORPHOLOGY

It is the largest tooth in the maxillary arch with four well-defined cusps and a supplemental cusp of Carabelli of the mesiolingual cusp (Tables 2–4, Figure 14). From the occlusal view, it has a roughly rhomboidal outline. The distobuccal cusp becomes progressively smaller on the second and third maxillary molars. There are two major fossae (central fossa mesial to the oblique ridge and the distal fossa distal to the oblique ridge) and two minor fossae (the mesial and distal triangular fossae that lie just distal to the mesial marginal ridge and just mesial to the distal marginal ridge, respectively). The oblique ridge crosses the occlusal surface from the ridge of the distobuccal cusp to the distal ridge of the mesiolingual cusp.

CLINICAL

For the purpose of access cavities, the molars can be viewed as having a triangular arrangement of the

Figure 14 Example of a maxillary molar shown in buccal, mesial palatal and occlusal views. **A**, Access into both mesiobuccal canals and distobuccal and palatal canals is gained. **B**, Note that the preparation has not been extended much on the occlusal table for the distobuccal canal as the canal projects distally naturally. All canals accept a size #40 or #50 hand file to working length (WL); access preparations may have to be extended further slightly to accommodate larger step-back files.

Figure 15 **A, B**, Schematic diagrams of maxillary molar access preparation based on the original radiograph **C**, Access penetration and angulation shows an initial narrow opening on the occlusal surface. **D, E**, Dentin (blue areas) is removed carefully so that a file can stand upright to show exactly where the access preparation must be extended further. Note how the distobuccal wall does not need to be extended significantly as it naturally projects distally.

cusps (without the distolingual cusp). In fact the access cavity is made without encroaching onto the distolingual cusp and is usually kept mesial to the oblique ridge.

Maxillary molars are widely recognized as being one of the most difficult teeth to treat endodontically. They can present with mild to severe curvatures and usually have two or three canals in any root (but most commonly in the mesiobuccal root). Locating the second mesiobuccal canal (MB2) orifice routinely can be difficult as it is often buried under a bridge of dentin. The canal can have a severe curvature to the mesial and the buccal in its coronal section and is usually much smaller than the principal first mesiobuccal canal (MB1) (Figure 15). A dentin bridge may occur due to the secondary dentin formation from aging and/or reparative dentin from carious attack or restorative procedures. This secondary or reparative dentin is usually whiter than the pulpal floor and can be selectively removed under magnification. The access shape should be quadrilateral to allow for troughing 2–3 mm lingual to MB1 to search for MB2 (Figure 16). The clinician should keep an eye on the mesial external root surface as a guide to avoid perforating furcally or mesially. Endodontists have reported troughing well over 4 mm below the pulpal floor before uncovering the MB2 orifice. In the following, each root will be described separately (Figure 17).

In principle, all maxillary molars can be accessed following a similar strategy. Entry should be in the mesial fossa and should be kept small initially. Under

Figure 16 Variations in access cavity shapes in maxillary molars.

Figure 17 **A**, The isthmus between the two mesiobuccal canals is troughed and no further fin or isthmus is evident. **B**, Measurement of troughing depth with a periodontal probe gives the practitioner an objective perspective. **C**, Incorrect angulation of ultrasonic tip during troughing due to inadequate extension of the mesial wall resulting in the removal of furcal dentin.

higher-power magnification, it can be extended selectively. Initial penetration may be aimed at the large palatal canal orifice. There is ample evidence to demonstrate that the mesiobuccal root has a second canal with such frequency that it must be accommodated for in the initial access and always searched for. *In vivo*, Stropko⁶⁷ reported finding two canals in 73.2% of first molars before using the microscope and 93% after; 90% of the MB2s were negotiable to the apex. He classified it as a canal if he could instrument 4 mm into it. Baldassari-Cruz et al.⁷⁰ located MB2 canals in 51% of the cases with the naked eye compared to 82% with the microscope.

Gilles and Reader⁵⁵ found that the mean distance of MB2 orifice from MB1 was 2.31 mm (range 0.7 to 3.75 mm). Kulild and Peters⁶¹ found that the distance between MB1 and MB2 was on average 1.82 mm and the orifice was to the lingual of MB1. However, the MB2 orifice can sometimes be found close to or even in the palatal canal orifice (Figure 18). While two mesiobuccal orifices are most common, three can also be present (Figure 19).

The mesiobuccal canals have two separate apical foramina or, more commonly, join to exit at one foramen (Figure 20). In contrast, the distobuccal root is conical and usually straight but may have a slight curvature to the mesial. Although far more infrequent than the mesiobuccal root, the distobuccal root can also have a second canal that almost invariably joins the main (DB) canal to a common apex. It can be found lingually to the main canal and usually in a visible fin connecting the DB canal to the palatal canal. The incidence of two DB canals ranges from 2% to 9%.

The access preparation for the DB canals does not have to be extended as far toward its line angle as the mesial canals. The distal canal is distally inclined and so the file projects out of the orifice to the mesial naturally. Therefore, the transverse ridge can usually be preserved (see Figure 15).

The palatal root is broad mesiodistally and its canal mirrors it. Therefore the access should be extended mesiodistally. The extent to which it has to be extended palatally can be deceiving as the orifice coronally projects palatally naturally and therefore the file does not seem to contact the palatal wall toward the orifice. However, the apical third often curves to the buccal, and to reach the apex with large files, one needs to extend the palatal wall slot palatally and flare the coronal mid thirds of the canal. Again, a file is inserted and only that area of the dentin that contacts the file is removed to achieve SLA. This can also be accomplished using an ultrasonic tip.

Figure 18 The MB2 canal can be located anywhere along the fin between the MB1 and palatal canals. **A**, Second mesiobuccal orifice was found in the entrance (arrowhead) to the palatal canal and shows how the customary extension was inadequate. **B**, Obturation and the distance between MB1 and MB2. **C**, Proximity of MB2 to the palatal orifice.

Figure 19 Clinical examples of maxillary molars with three mesiobuccal canal orifices.

Figure 20 Radiographs illustrating possible variations in the anatomy of mesiobuccal root canal system of maxillary first molars. **A**, Two canals joining in the coronal root canal third. **B**, Widely separated canals but joining to a common apex. **C**, Separate apical foramina.

Also the palatal canal can split into two, and therefore the access preparation needs be extended mesiodistally (Figure 21). In such oval-shaped canals,⁸ simple instrumentation with round cross-section files will not suffice for complete débridement of the canals (see Figure 14A).

Maxillary Second Molars

ANATOMY AND MORPHOLOGY

Maxillary second molars are very similar in form and function to the maxillary first molars with some variations (Table 5). The mesiobuccal and mesiolingual cusps are larger but the distobuccal and distolingual cusps are smaller. The cusp of Carabelli is usually absent. The

buccolingual diameter of the crown is about equal to the first, but the mesiodistal diameter is approximately 1 mm less. There are two types of maxillary second molars when viewed from the occlusal aspect:

- (1) *Rhomboidal*: four-cusp outline similar to the first molars but more rounded. This is the more common form.
- (2) *Triangular*: three-cusp form more similar to the third molar form where the distolingual cusp is poorly developed.

The roots are usually closer together than the first molar's and can also have two or three fused roots. The canal system can vary from one large canal, two canals, or three or four canals. The palatal root can

Figure 21 Radiographs illustrating variations in the palatal root canal anatomy. **A**, First molar showing one wide canal. **B**, Two canals in another first maxillary molar. **C**, Apical bifurcations in the palatal root.

also have two separate roots with separate canals within each. The occlusal table is smaller.

CLINICAL

Access is more complicated due to the tooth being further back in the arch and more difficult to reach. Shorter length burs may sometimes be needed. Gilles and Reader⁵⁵ found that the mean diameter of the MB2 orifice in the second molars was 0.42 mm with a range of 0.15 to 1.00 mm. The mean distance from MB1 orifice to MB2 orifice was 2.6 mm (range 0.9 to 3.9 mm). The distobuccal canal can sometimes be hidden under a large shelf of dentin. The orifice appears on the same line joining the mesio-buccal and palatal canals. However, during cleaning and shaping, the shelf must be carefully removed so that the furcal surface is not encroached upon.

The palatal root usually has one canal, as described in vitro (see Table 6–18). Peikoff et al.⁷² found in vivo

that only 1.4% of maxillary second molars had two palatal roots and two palatal canals.

Maxillary Third Molars

ANATOMY AND MORPHOLOGY

From an occlusal viewpoint, this tooth usually presents with a heart-shaped triangular outline similar to the second molar. The distolingual cusp is typically small and often completely absent. Unlike the mandibular third molars, these teeth tend to have underdeveloped crowns. The roots are often fused forming one large root.

CLINICAL

Alavi et al.⁶⁴ found that 50.9% of third maxillary molars had three separate roots of which 45.5% had two

or more canals in the mesiobuccal root. About 45.7% had fused roots, 2% had C-shaped canals, and 2% had four separate roots. Therefore, modifications must be made in accessing these teeth compared to first and second molars to accommodate these anatomical variations.

Mandibular Central and Lateral Incisors

ANATOMY AND MORPHOLOGY

The mandibular central incisor is usually the smallest tooth in the mouth, having a little more than half the mesiodistal diameter of the maxillary central incisor; however, the labiolingual diameter is only about 1 mm less (Table 6, Figure 22). Bilateral symmetry is usually evident with central incisors.³³ There are slight differences between central and lateral incisors, but the most important with regard to access is that the crowns of lateral incisors are not as symmetrical as central incisors from the incisal view as they curve distally to accommodate the curvature of the arch and correspondingly the cingulum is displaced slightly to the distal. Lateral incisors are also slightly larger than the centrals; this is the reverse relationship found in the maxillary incisors.³³

The incisal edge relative to the long axis of the root in the proximal view is lingually placed—this is clinically corroborated by LaTurno and Zillich's study.¹⁸ However, this should have little bearing on the access preparation, and the two teeth can be approached with the same criteria. It is important to note that often the most bulbous or the broadest lingual aspect of the tooth is below the free gingival margin. Therefore, using the free gingival margin to determine the extent of lingual extension of the access cavity can leave it underextended. One has to use a probe to palpate the contour of the crown below the free gingival margin.

CLINICAL

According to LaTurno and Zillich,¹⁸ incisors do not have SLA projections entirely on the lingual; all involved the incisal edge and/or the facial surface (6% projected completely onto the buccal) (see Figure 8). Mauger et al.⁸¹ in a similar study found that an ideal SLA was at the incisal edge in 72.4% and in 27.6% was facial of the incisal edge. They also found that as the

wear of the incisal edge increased, the ideal access moved from the facial toward the incisal. Similarly, Sonntag et al.⁶ showed that a shift toward the incisal edge resulted in more adequate preparation and in fact less loss of hard tissue.

The entry point for access should be just above the cingulum with the bur angled perpendicularly to the surface of the entry point. As these teeth are narrow mesiodistally, the main concern is the width of the preparation. No more than a #1/2 round bur or a long thin cylindrical diamond is used to initiate the access, followed by a cylindrical diamond bur to extend only as a slot in a labiolingual dimension. The main point being that unnecessary extension toward the mesiodistal surface is avoided. Even the thinnest bur will provide an adequate width once collateral hand movement is taken into account. The disadvantage is of course that visibility is restricted and therefore the use of microscopes becomes paramount.

Once the chamber or the canal is found, the access can be precisely widened for each individual tooth according to its SLA projection. The other point is that 40% of mandibular incisors have two canals—buccal and lingual with only 2 to 3% having separate apical foramina (Figure 23). The lingual is by far the harder to locate because the angulation of these teeth in the jaws is proclined (see Figure 2). It is natural for the hand to angle the bur toward the buccal (thereby running the risk of gouging the labial wall). The lingual canal lies 1 to 3 mm away from the buccal, directly under the cingulum. Even when two canals are present, there is often a fin or a groove with pulp tissue between them (see Figure 23).

In summary, finding extra canals requires conviction that they are there and extending the access to look for them. Although the two canals seldom exit as separate apices, bacterial by-products from the necrotic tissue in the unfilled canal can communicate with the periodontal ligament via lateral canals or through a poor apical seal.

Mandibular Canines

ANATOMY AND MORPHOLOGY

These teeth are very similar to their maxillary counterparts and can be described in relation to them

Figure 22 **A**, Example of a mandibular incisor showing labial, mesial, and incisal views. **B**, The access preparation can be assessed from a more incisal view and a lingual view. Note how the lingual extension of the access preparation extends well into the cingulum.

Figure 23 Radiographs illustrating variations of lower incisors with two canals. **A**, Although usually both canals exit from a common apex, they can, **B**, have two separate or a figure eight-shaped foramen.

(see Figure 18A). Mandibular canines are usually narrower than maxillary canines (approximately 1 mm) and shorter in root length by 1 to 2 mm (Figure 24). The mesial edge is almost straight and therefore the access cavity can be prepared more to the mesial of the center point of the lingual surface. Also the cusp tip is inclined more to the lingual, similar to the incisors.³³ According to LaTurno and Zillich,¹⁸ none have SLA projections entirely to the lingual; 90% involved the incisal edge or incisal edge and buccal surface with 4% entirely on the buccal. Canine crowns are asymmetrical with a larger

distal half. Therefore, the access preparation can be started just slightly to the mesial of the mid-point mesio-distally, and checked that it corresponds to the center point at the CEJ. Similar to their maxillary counterparts, mandibular canines extend buccolingually, albeit to a smaller extent.

Heling et al.⁸² reported a mandibular canine with two roots and three canals but did not state whether two or three apical foramina were present. Orguneser and Kartal⁸³ reported a case of a three-canal mandibular canine with two apical foramina.

Figure 24 **A**, Example of a mandibular canine showing labial, mesial, and incisal views. **B**, The access preparation can be assessed from a more incisal view and a lingual view. Note that the access is extended lingually to look for a second, usually lingually located canal.

CLINICAL

The shape of the preparation ranges from an oval to a rounded slot depending on the size of the pulp chamber inside. As canines have large roots, the MAF (Box 1) is also large (size #40 to #60). Therefore, after creating a tapered preparation via step-back or rotary files, the

coronal orifice will be larger than for incisors mesiodistally (Figure 25).

Mandibular First Premolars

ANATOMY AND MORPHOLOGY

The mandibular first premolars have characteristics of a small canine because of a sharp buccal cusp (only occluding cusp) and a small lingual cusp that sometimes resemble a cingulum (Table 7, Figure 26). There is a characteristic mesiolingual developmental groove that makes the tooth asymmetrical.

From the occlusal view, the outline is diamond-shaped and similar to the mandibular canine. These teeth have a variable root anatomy. The crown is lingually inclined that makes searching for a lingual canal difficult. Therefore, the access has to be extended further to the lingual to search for it. This feels counterintuitive, as the lingual cusp is very small.

Nallapati⁸⁸ reported a case where both first and second premolars had type V anatomy, that is, three canals with separate apices, while Baisden et al.⁸⁵ reported the possibility of C-shaped canal anatomy in mandibular premolars.

Table 7 Summary of Studies Detailing Root and Root Canal Anatomy of Mandibular First Premolars

Figure 26 **A**, Example of a mandibular first premolar showing buccal, mesial, and occlusal views. **B**, The access preparation can be assessed from an occlusal view.

CLINICAL

The entry point is in the middle of the central groove, and the bur is directed to the buccal. Again, the access shape is an oval slot. As the crown is lingually inclined, the access cavity will result in the removal of more of the buccal cusp than the lingual (Figure 27).

Mandibular Second Premolar

ANATOMY AND MORPHOLOGY

Unlike the maxillary premolars, the mandibular second premolar is quite distinct from its neighboring first premolar (Figure 28). It resembles the first only from the buccal aspect but is otherwise larger. The tooth has two forms from the occlusal aspect, the more common three-cusp type and the two-cusp

type. With the three-cusp type, the buccal cusp is the largest followed by the mesiolingual cusp and then the distolingual. The occlusal outline is square. The two-cusp form is more rounded and has a smaller occlusal table. Case reports detailing four⁸⁹⁻⁹¹ and five⁹² coronal canals but only one showing four apical foramina have also been reported.⁸⁹

CLINICAL

Access is similar to first mandibular premolars, taking overall dimensions into account.

Mandibular First Molars

ANATOMY AND MORPHOLOGY

The occlusal surface of mandibular first molars has one major (or central) and two minor (mesial and distal)

Figure 27 *A, B*, Two examples of lower first premolars with two canals. *C*, Photographs of an extracted tooth demonstrate a C-shaped root cross section and suggest the impossibility of adequately cleaning and shaping the entire canal system.

triangular fossae (Tables 8 and 9, Figure 29). These teeth usually have two distinct buccal and two lingual cusps and one distal cusp. The buccal cusp tips are located more to the midline on the occlusal table compared to the lingual cusp tips that are almost directly over the outer surface at the “neck” of the tooth. Therefore, access preparations often encroach on the buccal cusp tip (mesiobuccal) but rarely onto the lingual.

Mandibular molars are known to have complex anatomy and like their upper counterparts can be deceptively difficult to treat, as the radiographic canal anatomy can appear simple in two dimensions.

There are usually four canals but three and five canals are well documented and one, two, and six canals have been reported. It is important to note that there is almost always a concavity on the furcal side of both the mesial and distal roots; therefore care must be taken during cleaning and shaping to avoid strip perforation. The roots start to bifurcate 3 mm below the CEJ. This gives a sense of the depth at which furcal perforation is possible. As the access cavity determines cleaning and shaping, the access cavity has to be designed to allow for protection of the furcal surfaces during instrumentation.

Figure 28 **A**, Example of a mandibular second premolar showing buccal, mesial, and occlusal views. **B**, The access preparation can be assessed from an occlusal view.

millimeters. Only four of the 17 roots had an isthmus that was continuous from its coronal beginning to its apical end, the other 13 had sections with and without the isthmus. The third section from the apex had the highest incidence of isthmuses (50%). Two distal roots can occur but are rare—however, reported to be more prevalent in the South East Asian population.

CLINICAL

The important point to note with the mandibular molars is the degree to which they are lingually and mesially inclined.¹⁹ To prevent unnecessary gouging of the axial walls of the access preparation, the bur should mimic this angulation of the tooth in the mandible.

The entry point is just mesial to the central pit. Initially, the access preparation should not be extended further distally as the distal canals project mesially toward the occlusal table. Once the angle of the canals has been determined with files, the decision can then be made to extend the access distally if needed. However, the access will be located largely in the mesial half of the tooth, as SLA for the mesial canals will dictate. Sometimes it is necessary to encroach on the mesiobuccal cusp tip to achieve SLA (Figure 30).

The groove between the mesiobuccal/mesiolingual and distobuccal/distolingual canals must always be troughed with a bur and/or ultrasonics and checked with files to search for mesial canals (Figure 31)—this can be best accomplished with a microscope.

Figure 30 **A**, Access preparation in a mandibular molar with moderate/severe root curvature. **B**, Hand files can be placed to length in all three mesial canals after adequate access and canal preparation. **C**, However, the access preparation requires an extreme extension for the mesiobuccal and mesiolingual canals due to the root curvature.

Figure 31 Anatomical variations in lower first molars and the potential for a negative clinical outcome. **A**, Tooth diagnosed with a failing root canal treatment that had had an apicoectomy completed 8 months earlier. The postoperative buccal and distal views show three mesial canals with separate portals of exit, probably causing the persistent infection. **B**, Mandibular third molar with preoperative view as well as straight and distal postoperative views. This tooth presented with three mesial canals; typically the middle mesial canal joins either the mesiobuccal or the mesiolingual canal early and is a more common form than the one in **A**. **C**, Tooth diagnosed with radix entomolaris. The distolingual root often has a significant curvature in the buccolingual plane and can therefore be deceptively difficult to treat.

The distal canal is ovoid or figure eight-shaped buccolingually if only one canal is present, and a microscope should be used to confirm this. There can be a second distal canal that bifurcates in the apical third—to minimize chances of missing these; the walls of the preparation should be divergent, and the clinician should be able to see the entire surface of the buccal and distal walls of the canal to the apex with a microscope. It is advisable to “feel” the wall of the canal with precurved files for areas in the middle and apical thirds of the canal where the instruments may stick.

It is easy to assume that the canals curve only to the mesial or the distal, but because these roots are so broad, they always have a curvature in the buccolingual dimension that cannot be assessed radiographically. Cunningham and Senia¹⁴ showed that of the 100 mesial roots of mandibular molars, all demonstrated curvature in mesiobuccal and mesiolingual canals in both buccal and proximal view radiographs. They reported a reduction of canal curvature after coronal flaring. It is important to remember that the flaring will have to occur in both the mesial and buccal planes for mesiobuccal canals as well as in mesial and lingual planes for mesiolingual canals. Similar planes need to be addressed respectively for the distobuccal and distolingual canals. Fabra-Campos¹⁰¹ found that 4 molars out of 145 had five canals that were confirmed radiographically—the extra canal was the middle mesial canal in the mesial root.

The presence and impact of furcation canals has been widely discussed. Vertucci and Williams,¹⁰² using decalcification and staining, found that of the 100 mandibular first molars, 46% had furcation canals and 13% had a single lateral canal from the floor to the interradicular region. Of these, 57.1% extended from the center of the pulp floor, 28.5% arose from the mesial aspect of the floor, and 14.4% extended from the distal aspect. In 23%, lateral canals were found originating in the coronal third (distal root 80%, mesial 20%). Finally, in 10% of the cases, both lateral and furcation canals were found. Vertucci and Anthony¹⁰³ used scanning electron microscope (SEM) and found 32% of mandibular first molars and 24% of mandibular second molars, a total of 56% with accessory canals. Although relatively uncommon, mandibular first molars can also have C-shaped canals.^{104,105} In a study on Burmese subjects, about 10.1% of observed teeth had an extra distal root on the lingual aspect (*radix entomolaris*).¹⁰⁶ Gulabivala et al.⁹³ found an additional distolingual root with one canal and one apical foramen 12.7% of the time (see Figure 31C).

Mandibular Second Molars

ANATOMY AND MORPHOLOGY

Generally, mandibular second molars differ from the first molars in their capacity for variation (Figure 32). Usually the crowns and roots of second molars are smaller than the first molars by less than a millimeter in all dimensions. The occlusal table is more symmetrical and rectangular with four equally apportioned cusps; a fifth cusp is not present. The roots of the second molars are inclined more distally, in relation to the occlusal table, than the first molars, but less than the third molars. Therefore, the access cavity may have to be extended more toward the mesial marginal ridge than for first molars. The roots, and therefore canals, are usually closer together and can be fused to a single conical root with varying internal anatomy or often C-shaped canal systems. Cooke and Cox¹⁰⁷ were the first to report C-shaped configurations in mandibular molars. Weine et al.¹⁰⁸ evaluated 811 endodontically treated second molars and reported 7.6% had C-shaped canal systems.

CLINICAL

The entry point of the access cavity should be mesial to the central pit similar to the first molars, but may not require the same degree of mesial extension if the roots are closer together. Otherwise, a similar preparation as for the first molar can be made. Cleaning C-shaped canals is unpredictable as there are many different types with several subtypes. The access cavity will follow the curvature of the canals.

According to Melton,¹⁰⁹ C-shaped canals can be divided into three categories:

- Category I:* The continuous C-shaped canal is any C-canal outline without any separation.
- Category II:* The “semicolon”-shaped canal—referred to canal configurations in which dentin separates one distinct canal from a buccal or a lingual C-shaped canal in the same section.
- Category III:* Simply with two or more discrete and separate canals.

Mandibular Third Molars

ANATOMY AND MORPHOLOGY

Third molars have significant variations and anomalies. They are usually less developed, with oversized crowns and undersized roots. Due to the lack of space in the jaws, they are often impacted and may have

Figure 32 Variations in mandibular second molar anatomy. **A**, Common anatomy. **B**, Apical bifurcation. **C**, Dilacerated roots. **D**, Four separate apical foramina. **E, F**, C-shaped configuration.

very curved roots. They may have four or five cusps. Usually, when in good alignment and occlusion, the crown is likely to have four cusps and is similar to the second molar. Usually third molars have two roots—a mesial and a distal root that can be bifurcated or fused. When fully erupted and in functional occlusion, third molars provide excellent protection for the first and second molars by spreading the occlusal load. In such situations, keeping these teeth is beneficial and therefore knowledge of their anatomy and morphology is important.

CLINICAL

Similar to mandibular first molars, anatomical variations will require modifications compared to accessing first and second molars.

Procedural Mishaps

Successful endodontic treatment originates from a well-designed and executed access preparation. The opposite is also true; errors during root canal

treatment can often be traced back to a problem originating from an inadequate access preparation. Errors generally stem from two access cavity characteristics: underextension and overextension.

UNDEREXTENSION

Not opening up the access cavity across the width of the root sufficiently can result in the operator missing canals. They can often be buried under calcified dentin. However, if the canal is found but the cavity is not extended away from the furcation sufficiently, the file will preferentially cut the furcal dentin causing a strip perforation. Another possibility, of not extending the access far enough, is that the coronal canal curvature is not removed. This will increase chances of instrument separation as the file tries to go around more than one curve, or transportation at the apex as the coronal canal curvature renders the file tip uncontrollable. Underextension of the access preparation also limits the final diameter of the apical preparation size. In anterior teeth, if the pulp horns are not adequately exposed and cleaned, the remaining pulpal tissue will cause coronal discoloration.

OVEREXTENSION

Generally, overextension will cause unnecessary removal of tooth structure that weakens the remaining crown and ultimately decreases the long-term prognosis of restoration, and therefore the tooth. With the acceptance of implants that have good long-term prognosis, remaining tooth structure will be the critical determinant between these two treatment choices.

Effect of Access Cavity Preparation on Structural Integrity

There is little debate that endodontic treatment weakens teeth resulting in an increased susceptibility to fracture (Figure 33).¹¹⁰ But it has been widely stated that this may be due to endodontic treatment resulting in increased brittleness of the dentin.^{111–114} However, it does not seem that root canal treatment changes the quality of the dentin, except some moisture loss,¹¹⁵ and it is thought that weakening of the tooth is more a result of tooth structure loss.

Using strain gauges in extracted premolars, Reeh et al.¹¹⁶ showed that endodontic procedures reduced the relative cuspal stiffness by only 5%. This was in contrast to an occlusal cavity preparation (20%), an

MO/DO cavity (46%), and an MOD cavity preparation (63%). Howe and McKendry¹¹⁷ examined 40 freshly extracted noncarious, unrestored human mandibular first and second molars, prepared endodontic access preparations and/or MOD amalgam cavities, and then subjected them to increasing occlusal load until fracture. They found that an endodontic access cavity, or a conservative MOD cavity, fractured at the same load (225.5 and 222.4 kg, respectively). On the other hand, an access cavity with both marginal ridges breached fractured with significantly less load (121.7 kg). Intact teeth fractured at significantly more force (341.4 kg) than all other groups. They suggested that when access cavities are kept conservative and proximal tooth structure remains intact, simple restoration of access cavities might suffice.

Sedgley and Messer¹¹⁸ studied whether loss of pulp vitality resulted in changes in tooth structure as measured by biomechanical properties (punch shear strength, toughness, load to fracture, and microhardness). Twenty-three matched pairs of teeth were obtained where one tooth in each pair had endodontic treatment while the other was vital. Teeth were extracted and for comparison, data were collected immediately after extraction and after 3 months. The authors found no significant differences in punch shear strength, toughness, and load to fracture between groups. Vital dentin was 3.5% harder than the endodontically treated matched pair. They suggested that the dentin does not change in character but rather it is the cumulative loss of tooth structure from caries, restorative, and endodontic procedures that increases the susceptibility to fracture. Another possibility is that loss of pressoreception or an elevated pain threshold may allow larger loads without triggering a protective response.

In a study similar to experiments by Reeh et al.,¹¹⁶ Panitvisai and Messer¹¹⁹ measured actual cuspal deflection (rather than relative cuspal stiffness) and used more extensive cavity preparations (no tooth structure between access cavity and box preparation) to simulate clinical situations more closely. They used 13 extracted human mandibular molars and used a ramped load of 100 N to the mesial cusps. Increasingly extensive MO or MOD cavities were prepared, tested, and finally followed by an access preparation. They found that cuspal deflection increased with increasing cavity size, with the greatest deflection after access preparation when cuspal deflections of more than 10 μm were observed. They reiterated the importance of cuspal coverage to minimize marginal leakage and cuspal fracture.

Radicular Preparations

OBJECTIVES

Upon the completion of the coronal access cavity and the identification of root canal orifices, preparation of the root canal system is initiated. Root canal preparation serves two main objectives: mechanical and chemical elimination of intracanal tissue and pathogens, aided by antimicrobial substances and by optimized root canal fillings.¹²⁰⁻¹²²

A well-executed root canal preparation is a prerequisite for success (Figure 34).

Using anaerobic culturing, a reduction of intracanal bacteria after canal preparation has been demonstrated to a level of 10 to 100 CFU/mL,^{9,123-127} but

it is highly unlikely that any root canal is rendered sterile in a clinical setting. Both clinically successful and failing cases illustrate the presence of bacteria and immune cells.¹²⁸⁻¹³⁰ However, in using stringent criteria for assessing healing of apical periodontitis, that is, the reconstitution of a lamina dura around the entire root perimeter¹³¹ as well as the absence of inflammatory cells, only 6% of endodontically treated teeth were deemed successful.¹²⁸ The fate of bacteria initially remaining in inaccessible canal areas, regardless of the clinical technique,¹³² has been a matter of speculation: do they die from starvation,¹³³ are they killed by sealer components¹³⁴ or can they survive and cause posttreatment disease?¹³⁵ On the other hand, a comparison of histological and clinical material

Figure 34 Examples of root canal-treated first maxillary and mandibular molars in which cleaning and shaping was done adhering to the principles laid out in this chapter. Radiographs represent situation immediately after root canal filling.

Figure 35 Healing is commonly detected by clinical and radiographic appearances and only occasionally it is possible to assess the outcome of root canal treatment histologically. Both cases shown here had preoperative diagnoses of chronic periapical periodontitis and were extracted for nonendodontic reasons. **A**, During the 13-year follow-up period of this case, the mesial root apex of this mandibular molar did not present complete healing of the original radiolucency, despite the absence of symptoms. The obvious reason was the presence of bacteria, as shown in the histological images. **B**, In this mandibular molar, the periapical region of the distal root exhibited radiographic healing, contrary to the mesial root, where a vertical fracture was the ultimate reason for extraction. Radiographic features of healing were confirmed by the histological picture, showing fibrous uninfamed tissue in the apical part of the root canal and calcified tissue. The latter did not completely obturate the lumen, as shown by serial sections. Images courtesy of Dr. Domenico Ricucci.

presented in Figure 35 demonstrates that histological success is present only if microbial contamination is absent.¹³⁶

Furthermore, it was recently shown that well-filled and presumably well-shaped canals may still be asso-

ciated with failing root canal treatments, mainly due to the fact that microorganisms remain in inaccessible areas of the root canal system.^{137,138} Consequently, rather than “sterilizing” root canal systems, intracanal procedures are tailored to reduce microbial burden,

Figure 36 Proposed relationships between preparation size and elimination of bacteria as well as prepared canal surface. **A**, Based on bacterial sampling with a detection threshold of about 10 colony forming units (CFU), this threshold, essentially a canal with negative culture, may be reached on various pathways (colored lines in graph). **B**, Based on microcomputed tomography and analysis of cross sections, complete preparation of canal surface is unlikely. Again, values between 40 and 60% treated surface may be obtained with various canal shapes and apical sizes.

so that it becomes compatible with success, by creating conditions prohibiting regrowth and persistent infection.

Apparently, a threshold may be reached with different disinfection and preparation paradigms (Figure 36) that depend on numbers, virulence, and location of surviving microorganisms. The objective of root canal preparation, therefore, is to provide an environment in which periapical disease is prevented or the body's immune system achieves healing periapical disease.

A futuristic vision of ideal endodontic treatment is to replace necrotic or irreversibly inflamed pulp tissue

with new healthy pulp tissue. Revascularization of empty pulp spaces in juvenile teeth may occur, but it is an ongoing topic of investigation and many open questions are yet to be solved.^{139,140}

Because this ultimate goal is not yet obtainable, clinicians still have to deal with contaminated and inflamed pulp tissue. Rendering or keeping root canals bacteria-free during endodontic treatment is one of the most important goals to achieve successful healing or to maintain periapical health.¹⁴¹ To reiterate, the prime condition under which medical professionals work, *nihil nocere* or “do not harm,” should prevail in root canal treatments and canal preparation in particular, since obvious iatrogenic errors are likely to decrease the prognosis of a case.

EVIDENCE AND STRATEGIES FOR SHAPING THE ROOT CANAL SYSTEM

The first objective, elimination of tissue and pathogens, is achieved by skillful instrumentation including copious irrigation and, if deemed necessary, interappointment medication. Mechanical instrumentation alone is effective in reducing bacterial load,^{142,143} but should be complimented with irrigation to further eliminate microorganisms.^{144,145} Some authors have differentiated between the mere flushing action of saline^{142,146,147} and the added antimicrobial effect of the most widely used irrigant, sodium hypochlorite (NaOCl).^{148,149} Both of those actions are dependent on canal size and shape,^{10,150} but the latter depends also on factors such as NaOCl turnover, the amount of available chlorine, and contact time (for a more detailed review of endodontic irrigants, see Chapter 28, Irrigants and Intracanal Medicaments).

The accessibility of the contaminated root canal areas is key to disinfecting efficacy. Thus, overall canal anatomy and in particular canal dimensions (reviewed in detail in Chapter 6, Morphology of teeth and their root canal systems) play an integral role in radicular shaping (Figure 37). Two basic numerical concepts govern root canal shaping procedures (see Box 1): WL and apical size, recently also described as working width.¹⁵¹

Clinical experience has shown periapical bony lesions to heal predictably if the offending tooth is extracted, thus removing all intracanal and adhering microorganisms. This observation supports the notion that extraradicular bacteria play a minor role in supporting periapical disease, insofar as they colonize the periapical lesion.¹⁵² Therefore, procedures

confined to the root canal space^{153–155} seem to be able to address most of the cases of endodontic treatment needs.

Figure 38 Examples of two cases in which incomplete shaping and short fills did not result in periapical pathosis. Patients indicated root canal treatments were performed **A**, 10 years and **B**, 27 years earlier.

Varying concepts have been proposed regarding WL,¹⁵⁵ partially depending on preoperative diagnoses. Clinical experience suggests that *vital cases* will be clinically successful despite apparent short fills (Figure 38). This may be explained by the absence of microorganisms in these cases, and a vital pulp stump may be beneficial for periapical health.^{156,157} However, with existing periapical lesions and contaminated canal systems, WL definitions closer to the apex must be adopted. Classic studies suggest that a WL between 0 and 2 mm from the radiographic apex

results more often in success (healing of periapical lesions) than shorter or longer fills (Figure 39).

One school of thought recommends the use of a patency file, a small, that is, size #10, K-file that is gently just pushed through an apical foramen without actually enlarging it. The purported benefit is to “clean” a foramen and to avoid apical blockage; however, a clinical benefit of this approach has not been demonstrated so far. In fact, the patency technique is controversial and is not uniformly accepted or taught in all US dental schools.¹⁵⁸

On the other hand, a deleterious effect that could have been brought about by mechanically injuring periapical tissues or by inoculating microorganisms¹⁵⁹ may be suspected but was not conclusively demonstrated.¹⁶⁰ This may be due to the fact that a contaminated file that passes through canal spaces filled with NaOCl is unlikely to carry any significant numbers of microorganisms past the foramen.¹⁶¹ However, the extrusion of debris is more likely if the apical foramen is patent.^{162,163} Certainly, cleaning the foramen, in the sense that the foramen is enlarged and

debris is mechanically removed with a small file, is unlikely.¹⁶⁴

It should be stressed that the use of a patency file is distinct from “apical clearing,” which is defined as a technique to remove loose debris from the apical extent, and involves sequentially rotating files two to four sizes larger than the initial apical file at WL; the largest apical file is then again rotated after a final irrigation and drying.¹⁶⁵ This technique may be useful after hand instrumentation¹⁶⁶ but no effect has been shown after rotary instrumentation.

It is commonly held that the use of a patency file during preparation would minimize the blocking of canal space with dentin mud and thus improving shapes. However, Goldberg and Massone¹⁶⁷ showed canal transportation in more than half of their specimens shaped with stainless steel or NiTi K-files used as patency files. Confining shaping procedures to the canal space was already recommended by Schilder; he in fact stressed that the apical foramen should remain in its position and not be enlarged.³

The question then is where does the root canal end (Figure 40) and how close to that point can clinicians estimate their WL. Histological studies indicated the presence of the transition of the pulp to the periapical tissue as well as dentin and cementum in the area of constriction (Figure 41).¹⁶⁸ However, a constriction in the classic sense may be absent.¹⁶⁹ In fact, high-resolution tomographic studies suggest more complicated apical canal configurations than previously shown (Figure 42). Therefore, radiographic interpretation alone may not give the clinician a good estimate for WL determination.^{170–172} Indeed, shaping to the radiographic apex, or even slightly short of it, will lead to frequent overinstrumentation.^{171,173}

DETERMINATION OF WORKING LENGTH

The term “WL” (Figure 43 and Box 1) is defined in the Glossary of Endodontic Terms as “the distance from a coronal reference point to the point at which canal preparation and obturation should terminate.”¹⁷⁴ The anatomical apex is the tip or the end of the root determined morphologically, whereas the radiographic apex is the tip or the end of the root determined radiographically.¹⁷⁴ It is well established that root morphology and radiographic distortion may cause the location of the radiographic apex to vary from the anatomical apex. The apical foramen is the main apical opening of the root canal. It is often eccentrically located away from the anatomical or the radiographic apex.^{168,169,175,176} Kuttler’s¹⁶⁸ investigation showed that this deviation occurred in 68 to 80%

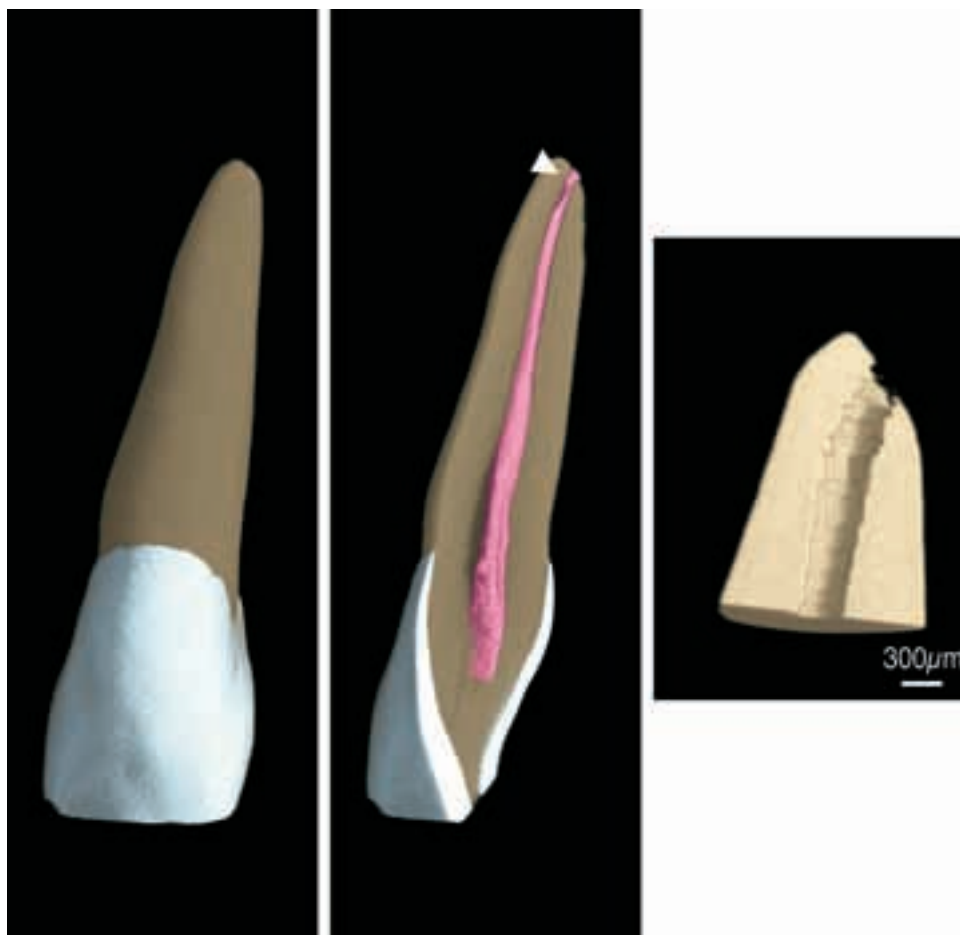

Figure 40 Microcomputed tomography reconstructions demonstrating external and internal anatomy of a maxillary anterior. The insert is a magnified view of an apical segment of 2 mm length showing no appreciable constriction (see arrowhead in larger image) and a cross-sectional diameter of the root canal of approximately 300 μm .

of teeth under investigation. An accessory foramen is an orifice on the surface of the root communicating with a lateral or an accessory canal.¹⁷⁴ They may be found as a single foramen or as multiple foramina. The apical constriction (minor apical diameter) (see Figures 40 and 43) is the apical portion of the root canal with the narrowest diameter. This position may vary but is often 0.5 to 1.0 mm short of the center of the apical foramen.^{168,169} The constriction widens apically to the foramen (major diameter) and assumes a funnel shape.

Probably owing to its importance as a clinical entity, the apical third of the root canal and the foramen location have been the topic of numerous investigations.^{7,168,169,175–183} Dummer et al.¹⁶⁹ reported four basic variations in the apical canal area that included about 50% of cases where a constriction was present. They also reported 6% of their cases where the constriction was

probably blocked by cementum.¹⁶⁹ The cementodentinal junction is the region where the dentin and the cementum are united; this is the point at which the cemental surface terminates at or near the apex of a tooth.¹⁷⁴ Of course the cementodentinal junction is a histological landmark that cannot be located clinically or radiographically. Langeland¹⁸⁴ reported that the cementodentinal junction does not always coincide with the apical constriction. The location of the cementinodentinal junction also ranges from 0.5 to 3.0 mm short of the anatomical apex.^{168,169,175,176} Therefore, it is generally accepted that the apical constriction is most frequently located 0.5 to 1.0 mm short of the radiographic apex. It has been pointed out by Ricucci¹⁵³ that significant anatomical variation makes difficult the direct clinical use of these average values as end points of canal preparation. Further problems exist in locating apical landmarks and in interpreting their positions on radiographs.

METHODOLOGICAL CONSIDERATIONS

Before determining a definitive WL, the coronal access to the pulp chamber must provide a straight-line pathway into the canal orifice. Modifications in access preparation may be required to permit the instrument to penetrate, unimpeded, into the apical constriction. Similarly, a crown-down preparation, including WL determination after initial shaping, will alleviate this problem. The loss of WL during cleaning and shaping can be a frustrating procedural error. Once the apical preparation is accomplished, it is useful to reassess the

WL since the WL may shorten as a curved canal is straightened.^{185–187} WL may also be lost owing to ledge formation or blockage of the canal.

As stated above, most dentists agree that the desired end point is the apical constriction. Failure to accurately determine and maintain WL may result in the length being too long and may lead to perforation through the apical constriction. Enlargement of the apical narrowing may lead to overfilling or overextension and subsequently to increased incidence of post-operative pain. In addition, one might expect a

prolonged healing period and lower success rate.^{153,155,188–190} Failure to determine and maintain WL accurately may also lead to shaping and cleaning

short of the apical constriction. Incomplete cleaning and underfilling may cause persistent discomfort, may support the continued existence of viable bacteria,

and thus contribute to a continued periapical lesion and ultimately a lowered rate of success.

In this era of improved illumination and magnification, WL determination should be to the nearest one-half millimeter, which is the maximum resolution of the naked eye in working distance. The measurement should be made from a secure reference point on the crown in close proximity to the straight-line path of the instrument, a point that can be identified and monitored accurately. The length adjustment of the stop attachments should be made against the edge

of a sterile metric ruler or a gauge made specifically for endodontics (Figure 44). The requirements of an ideal clinical method for determining WL include rapid location of the apical constriction in all pulpal conditions and all canal contents; easy measurement, even when the relationship between the apical constriction and the radiographic apex is unusual; rapid periodic monitoring and confirmation; patient and clinician comfort; minimal radiation to the patient; ease of use in special patients such as those with severe gag reflex, reduced mouth opening, pregnancy; and

Figure 44 Sequence of steps in working length (WL) determination. **A**, Initial measurement. Tooth is measured on an orthogonal and diagnostic preoperative radiograph. In this case the tooth seems to be about 23 mm long. **B**, Tentative WL, as a safety measure during coronal pre-enlargement and crown-down, subtract 1 mm from tooth length and allow instruments to go to two-thirds of this length. **C**, After the coronal two-thirds of the canal have been prepared, advance the hand file to tentative full WL, using the electronic foramen locator, and expose the radiograph. **D**, Final radiograph after root canal filling and removal of rubber dam.

cost effectiveness.^{172,191,192} To achieve the highest degree of accuracy in WL determination, a combination of several methods should be used. This is most important in canals for which WL determination is difficult.¹⁹³ The most common methods are radiographic methods, digital tactile sense, patients' response to a file introduced into the canal, or a point to which a paper point can be placed and removed dry.¹⁹⁴ However, current electrical foramen locators (see Chapter 26D, Electronic Apex Locators) greatly aid in determining the narrowest cross-sectional diameter and width and therefore in approximating WL.¹⁹⁵

CLINICAL DETERMINATION OF WORKING LENGTH

Methods requiring formulas to determine WL have been largely abandoned. Bramante and Berbert¹⁹⁶ reported great variability in formulaic determination of WL, with only a small percentage of successful

measurements. The following items are essential to perform radiographic WL estimation:

1. Good, undistorted, preoperative radiographs showing the total length and all roots of the involved tooth.
2. Adequate coronal access to all canals.
3. An endodontic millimeter ruler.
4. Working knowledge of the average length of all of the teeth.
5. A definite, repeatable plane of reference to an anatomical landmark on the tooth, a fact that should be noted on the patient's record.

To secure reproducible reference points, cusps severely weakened by caries or restoration may be reduced to a flattened surface, supported by dentin. Failure to do so may result in cusps or weak enamel walls being fractured between appointments (Figure 45). Thus the original site of reference is lost. If this fracture is not accounted for, then there is the

Figure 45 Example of a root canal-treated tooth that presented with a fracture prior to placement of the planned definitive restoration. In this case, the palatal root was preserved and crown was restored after placement of a post and core. **A**, Clinical sequence from temporized access to status after surgical extraction of the two buccal roots. **B**, Radiographs immediately after endodontic treatment, after surgery and at 1-year follow-up. Images courtesy of Dr. Craig Noblett.

probability of overinstrumentation and overfilling. To establish the length of the tooth, a K-file with an instrument stop on the shaft is needed. The exploring instrument size must be small enough to negotiate the total length of the canal but large enough not to be loose in the canal. A loose instrument may move in or out of the canal after the radiograph and may also cause errors in determining tooth lengths. Moreover, tips of fine instruments (size #08 and #10) are often difficult to see in a radiograph,¹⁹⁷ as are NiTi instruments.

Clinically, it is advisable to estimate canal lengths from a preoperative radiograph (see Figure 44). About 1.0 mm “safety allowance” for possible image distortion is deducted,^{198,199} the endodontic ruler is set to this tentative WL, and the stop on the instrument adjusted at this level (see Figure 44). The instrument is placed in the canal until the stop is at the plane of reference unless pain is felt, in which case the instrument is left at this level and the rubber stop readjusted. An electric foramen locator (see Chapter 26D, Apex Locator) should be used to verify and potentially further adjust the rubber stop. A radiograph is exposed and the difference between the end of the instrument and the end of the root is determined.

Current apex locators are sufficiently precise²⁰⁰ to allow WL determination, thus reducing the frequency of overinstrumentation when only radiographs are used.^{173,201} Even in cases of apical resorption and wide-open apices after root-end resection, these apex locators are shown to be accurate.^{202,203} Therefore, it seems warranted to focus on the electronically determined WL and to use the radiograph merely to avoid gross errors in case the apex locator does not appear to work correctly. This strategy eliminates approximation strategies such as shortening WL, as suggested by Weine,²⁰⁴ to allow for apical resorption. Independent of the strategy, the final WL and the coronal point of reference are recorded on the patient’s chart. When two canals located in the buccolingual plane appear to be superimposed, much confusion and time may be saved by several simple means. Occasionally, it is advantageous to take individual radiographs of each canal with its length-of-tooth instrument in place. A preferable method is to expose the radiograph from a mesial–horizontal angle. This causes the lingual canal to always be the more mesial one in the image (MLM, also known as Clark’s rule). For any mesial- or distal-angulated radiographs, the SLOB (“same lingual, opposite buccal”) rule, or the Ingle MBD Rule (“Shoot” from the Mesial and the Buccal root will be Distal), may be applied to locate instruments.

Radiographic WL determination, using conventional films alone, is accurate less than 90% of the time,^{176,205,206} and it is unclear if digital radiography is currently an improvement over conventional films regarding WL determination accuracy.²⁰⁷ In fact, inferior²⁰⁸ as well as superior^{209,210} results were reported for phosphor plate systems. Sensor-based radiovisiography performed similar to films regarding accuracy in some studies^{211–213} but was recently shown to be superior.²¹⁴

Electronic foramen locators sometimes do not function accurately, for example, in cases where current may flow into the marginal gingiva or into metal restorations causing erroneous readings. Therefore, additional methods such as tactile assessment and detection of moisture on the tip of a paper point were recommended.¹⁷⁶ If the coronal portion of the canal is not constricted, an experienced clinician may also detect an increase in resistance as the file approaches the apical 2 to 3 mm. This detection is by tactile sense. In the apical region, the canal frequently features a constriction or a smaller diameter before exiting the root. There is also a tendency for the canal to deviate from the radiographic apex in this region,^{7,168,175} and both these geometric features may be perceived by a clinician. However, Seidberg et al.¹⁹⁴ reported an accuracy in WL determination of just 64% using digital tactile sense. If the canals were preflared, it was possible for an expert to detect the apical constriction in about 75% of the cases.²¹⁵ If the canals were not preflared, determination of the apical constriction by tactile sensation was possible in only about one-third of the cases.²¹⁶ Preflaring and subsequently determining WL also reduce the amount and incidence of WL changes during the course of canal shaping procedures.¹⁸⁶

All clinicians should be aware that this method, by itself, is often inexact. It is ineffective in root canals with an immature apex and is highly inaccurate if the canal is constricted throughout its entire length or if the canal has excessive curvature. Therefore, tactile detection should be considered as a supplementary to high-quality, carefully aligned, parallel WL radiographs and/or an apex locator. Consequently, a survey found that few general practice dentists and no endodontists trust the digital tactile sense method of determining WL by itself.²¹⁷ Even the most experienced specialist would be prudent to use two or more methods to determine accurate WLs in every canal.

In a root canal with an immature (i.e., wide open) apex, a relatively reliable means of determining WL is by gently passing the blunt end of a paper point into the canal after profound anesthesia has been achieved.

The moisture or blood on the portion of the paper point that passes beyond the apex may be an estimation of WL or the junction between the root apex and the bone. In cases in which the apical constriction has been lost owing to resorption or perforation, and in which there is no free bleeding or suppuration into the canal, the moisture or blood on the paper point is an estimate of the amount the preparation overextended. This paper point measurement method is also a supplementary one. As stated earlier, nonsurgical endodontic procedures should best be confined to the root canal. This is true for files also, or paper points, in the process of WL determination. WL determination should be painless. Advancing an instrument into a canal toward inflamed tissue may cause moderate to severe instantaneous pain. At the onset of the pain, the instrument tip may still be several millimeters short of the apical constriction. When pain is inflicted in this manner, little useful information can be gained and considerable damage is done to the patient's trust. When the canal contents are necrotic, however, the passage of an instrument into the canal and past the apical constriction may evoke only a mild awareness or possibly no reaction at all.

On the other hand, Langeland et al.^{184,218} reported that vital pulp tissue with nerves and vessels may remain in the most apical part of the main canal even in the presence of a large periapical lesion. Finally, passing a file through necrotic canal contents may inoculate bacteria-contaminated dentin shavings into periapical tissues, thus supporting or causing apical periodontitis.^{219,220} However, Izu et al.¹⁶¹ showed that small files used as patency files are unlikely to carry bacteria past a reservoir of NaOCl.

CLINICAL DETERMINATION OF WORKING WIDTH

The second factor to be considered is apical width or preparation size. It is a matter of debate as to which apical enlargement and more specifically which shape would lead to an optimal reduction of the intracanal microbial load.²²¹ Baumgartner's group^{10,150} has recently attempted to address this question in vitro, and they concluded that an apical preparation size #20 would be inferior to sizes #30 and #40 regarding canal débridement but that a larger taper (e.g., 0.10) may potentially compensate for smaller sizes. This notion is supported by an in vitro study on the efficacy of ultrasonically activated irrigation that demonstrated

better débridement with 0.10 taper preparation.²²² Similarly, Mickel et al.,¹² based on microbiological assays, as well as Khademi et al.,²²³ using SEM, found that apical preparation to size #30 is required to effectively clean root canals. Moreover, recent elegant analyses, using a thermal imaging system, revealed detailed relationships between MAF size, needle diameter, and insertion depth.²²⁴ Taken together, these results indicate that sufficient apical preparation size and the use of a small-caliber irrigation needle are desirable to promote irrigation and hence antimicrobial efficacy.

In situ, however, even larger apical preparation sizes were favored by results from Trope's group,^{9,125,127} in particular, when an interappointment dressing of calcium hydroxide was used. Interestingly, larger apical sizes (#40, taper 0.04 compared to #20, taper 0.10) facilitated the application of calcium hydroxide medication in vitro.²²⁵

Most clinical outcome studies incorporate the factor "apical preparation size" with often insufficient statistical power and with conflicting results.^{226–228} A review of the technical aspects of root canal treatments²²⁹ found that apical periodontitis was more frequent with inadequate root canal fillings; however, they did not find evidence that canal instrumentation methods, and in particular apical sizes, had any measurable effect on outcomes. Conversely, one result of the Toronto study²³⁰ on endodontic outcomes seemed to favor smaller preparations in conjunction with tapered shapes and vertically compacted gutta-percha over step-back preparation to larger apical shapes (90% and 80% success, respectively). Again in contrast, using Periapical Index (PAI) scores determined from radiographs, Ørstavik et al.²³¹ did not find any significant impact of preparation size on outcomes.

It is not possible to determine canal diameters from radiographs;¹⁵¹ however, μ CT scans may be able to give more detailed information regarding root canal anatomy in vivo (Figure 46). The resolution of current systems is in the range of 100 μ m, corresponding to a size #10 K-file, and hence not sufficient to determine canal diameters with precision. Clinically, canal width may be determined by passing a series of K-files to WL to gauge, as suggested by Ruddle.²³² This process may depend on the file type and the amount of preflaring.^{8,233,234} Clearly, the first instrument that gives the clinician a sense of binding does not correspond to any canal diameter. Wu et al.⁸ demonstrated that the diameter of the "binding" instrument was smaller than the canals' diameter in 90% of the cases with a difference of up to 0.19 mm. Unexpectedly,

Figure 46 Potential of a clinically used high-resolution computed tomography to show root canal anatomy. Scans were done in vivo using an Accuitomo cone beam machine (Morita, Tokyo, Japan). **A**, Reconstructed jaw segment with three teeth is shown after apicoectomy and retrograde fill of mesial root of lower left first molar in clinical. **B**, Distally angled projection. Two teeth were segmented free from bone and are shown independently. Note incomplete fill of mesial root and two merging canals in the distal root of the molar.

LightSpeed (LS) instruments (Discus Dental, Culver City, CA) that possess a fine noncutting shaft did not perform better than K-files with 0.02 taper. Therefore, they concluded that it is uncertain that circumferential removal of dentin occurs based on the criterion that one should prepare three sizes larger than the first binding file;⁸ this and also the criterion “clean dentin shavings” are not considered adequate to indicate sufficient apical preparation.²³⁵

It seems that preflaring, prior to any attempt at assessing canal diameter, is essential^{233,234} since it allows the probing file to approach the apical area with less interferences. Tan and Messer²³³ indeed found that K-files and LS instruments determined apical sizes about one ISO size larger after preflaring.

In their study, LS instruments that were felt to bind at the apex were almost two ISO sizes larger than K-files.

After preoperative canal size is estimated, working width determination may be done. Jou et al.¹⁵¹ suggested definitions based on variations in cross-sectional canal shape. Their goal was to allow clinicians to obtain a more complete shape regarding instrumented surface area; this strategy is in line with current guidelines.^{236,237} However, this goal may be unattainable with current instrumentation techniques.¹²⁰ In conclusion, there may be no practical way to objectively determine a final file size that predictably allows complete instrumentation of canal walls. Consequently, all potential mechanisms to increase irrigation efficacy should be explored.

Table 10 presents an overview of anatomical studies detailing physiological foramen diameters. There is an apparent variation in these measurements, probably due to variation in experimental conditions. Consequently, there is also a great deal of variation in recommended apical sizes, as shown in the left segment of Table 10.

For example, apical sizes ranging from sizes #20 to #100 for maxillary molar roots have been recommended. Figure 47A illustrates apical dimensions before and after shaping with two rotary instrumentation paradigms.

A third as yet incompletely understood aspect of canal shape is taper. Some have expressed concerns that the importance of root canal taper should be seen only in conjunction with root canal filling techniques, most notably vertical compaction.²⁴⁴ However, as stated before, there are some experimental

evidences that taper may be connected to the ability to clean the root canal system by improving irrigant action.^{10,150,222} Limited microbiological data are conflicting regarding the potential of smaller apical preparations with larger taper to disinfect root canal system.^{13,127} Using the amount of instrumented canal area as a surrogate outcome for disinfecting capacity, no significant differences were found overall, comparing shapes with GT 20 0.10 taper to apical size #40 with smaller tapers.²⁴⁵ However, there were significant differences when the apical canal segment was evaluated for instrumented canal surface area (Paque F, unpublished data).

Schilder³ described five *design objectives* for cases to be filled with gutta-percha, which are as follows:

- The shape should be a continuously tapering funnel from the apex to the access cavity.

Figure 47 Pre- and postoperative canal diameters after shaping with common instrument types. Measurements are from microcomputed tomography reconstructions. **A**, Original data from 12 mesiobuccal canals shaped to an apical size #40 with FlexMaster (left panel, VDW) and ProTaper (right panel, Dentsply Maillefer). **B**, Dimension of selected rotary instruments for comparison.

- Cross-sectional diameters should be narrower at every point apically.
- The root canal preparation should flow with the shape of the original canal.
- The apical foramen should remain in its original position.
- The apical opening should be kept as small as practical.

There were also four important biological objectives that are as follows:

- Procedures should be confined to the roots themselves.
- Necrotic debris should not be forced beyond the foramina.
- All tissues should be removed from the root canal space.
- Sufficient space for intracanal medicaments and irrigation should be created.

These objectives form the basis for today's quality criteria^{236,237} and also for the development of operational techniques that will be described below in detail. All of these techniques rely on the adaptation of geometric forms, of either handheld or engine-

driven instruments to root canal anatomy, by way of particular instrumentation sequences and usage parameters. However, an experimental, noninstrumentation system for root canal cleaning has been tested *in vitro* and *in vivo*,^{246,247} since neither this system nor potential alternatives are currently available for the clinic, mechanical preparation will be utilized to clean and shape root canals for the foreseeable future.

In conclusion, the current strategy in radicular preparation calls for the enlargement of root canals to a size sufficient to allow disinfection and subsequent root canal filling.¹²⁰ Available evidence to support a particular shape in direct connection with any given root canal filling technique is limited to Allison et al.,²⁴⁸ who found a better seal when spreaders used for lateral compaction could penetrate close to WL. Consequently, efforts continue to determine the best possible root canal shape for management of intracanal infection by mechanical action, irrigant delivery, and placement of interappointment medicaments.

MEANS FOR RADICULAR SHAPING

Historically, painful teeth were opened and symptomatic pulps were treated with caustic substances or

cauterized with heat.²⁴⁹ Some of these procedures as early as 1728 by Pierre Fauchard are said to have included root canal fillings with lead or gold.²⁵⁰ Root canal systems have been shaped with mechanical instruments for more than 200 years.^{250–252} According to Lilley²⁵¹ at the end of the eighteenth century “... only primitive hand instruments and excavators, some iron cautery instruments and only very few thin and flexible instruments for endodontic treatment had been available...”.

The development of the first endodontic hand instruments by Edwin Maynard involved notching a round wire (e.g., watch springs, piano wires) to create fine needles for pulp tissue extirpation and potentially shaping.²⁵³ In 1852, Arthur used small files to enlarge and shape root canals.²⁵⁴ Subsequently, textbooks in the middle of the nineteenth century recommended that root canals should be enlarged with broaches: “But the best method of forming these canals is with a three- or four-sided broach, tapering to a sharp point, and its inclination corresponding as far as possible with that of the fang. This instrument is employed to enlarge the canal and give it a regular shape”.^{122,252} In 1885, the GG drill and in 1904 the K-file were introduced, both of which are still in use to date. Standardization of instruments had been proposed by Trebitsch in 1929 and again by Ingle in 1958¹²² but remains an issue today with NiTi rotary instruments.²⁵⁵ For a detailed description of various instrument types and alloys, the reader is referred to Chapters 26B, “Introduction of Nickel-titanium Alloy to Endodontics” and Chapter 26C, “Instruments for Cleaning and Shaping”.

Instrument Movements While Shaping

WATCH-WINDING

The least aggressive instrument action is most desirable in the early phases of root canal instrumentation. Many clinicians^{232,256,257} recommend a “watch-winding” movement with rotations of a quarter turn using small (size #08 or #10) K-files to reach WL or to explore the canal prior to coronal flaring (see below). Importantly, copious irrigation and constant cleansing of the instrument with sterile gauze are necessary to clear the flutes and to prevent packing debris at or through the apical foramen.

REAMING

Reamers are instruments designed to enlarge or taper preexisting spaces. Traditionally, endodontic reamers

were thought to cut by being inserted into the canal, twisted clockwise one-quarter to one-half turn to engage their blades into the dentin, and then withdrawn, that is, penetration, rotation, and retraction.²⁵⁸ The cut is made during retraction. The process is then repeated, penetrating deeper and deeper into the canal. When WL is reached, the next size instrument is used, and so on. Reaming is a method that produces a round, tapered preparation, and this is used only in perfectly straight canals. In such a situation, reamers can be rotated one-half turn before retracting. In a slightly curved canal, a reamer should be rotated only one-quarter turn.

FILING

The tighter spiral of a file establishes a rake angle that achieves its primary cutting action on withdrawal, although it will cut in the push motion as well. The cutting action of the file can be effected in either a filing or a reaming motion. In a filing motion, the instrument is placed into the canal at the desired length, pressure is exerted against the canal wall, and while this pressure is maintained, the rake of the flutes rasps the wall as the instrument is withdrawn without turning. The file need not contact all walls simultaneously. For example, the entire length and circumference of large-diameter canals can be filed by inserting the instrument to the desired working distance and filing circumferentially around all of the walls. When using a file in a reaming action, the motion is obviously the same as for a reamer.²⁵⁸ Withdrawing the file then cuts the engaged dentin. Filing is very efficiently done with Hedström files while K-files are the most popular instruments.²⁵⁹ One the other hand, the often advocated technique of circumferential filing²⁶⁰ has been shown to leave significant canal areas unprepared.²⁶¹ Finally, hand versions of current NiTi rotary instruments, such as ProSystem GT (Dentsply Tulsa Dental, Tulsa, OK) and ProTaper (Dentsply Maillefer), may be used in filing and reaming action.

ROTARY MOVEMENTS

Until the advent of NiTi alloy, continuous rotary movement was thought undesirable for shaping curved canals due to the danger of instrument fractures. Nevertheless, it has been recommended to use stainless steel GG drills into the apical third of straight root canals,^{3,262} which have the potential of undesirable canal shapes (Figure 48) and instrument fracture. Furthermore, strip perforations may occur with indiscriminate use of GG or Peeso drills.^{263,264} However, it has been clearly established that continuous rotary

Figure 48 Clinical examples of root canal filled teeth that do not follow principles for an optimized shape. **A**, Very narrow shape that is not conducive to cleaning and irrigant access. **B**, Overenlargement that may predispose to vertical root fracture (arrowhead). **C**, The so-called “coke bottle” shape produced by overzealous action of Gates Glidden drills.

movement with NiTi instruments with noncutting tips creates shapes with little or no incidence of preparation errors.¹²⁰

POTENTIAL SHAPES

Figure 49 illustrates basic requirements for a radicular shape, with adequate WL and working width as well as a homogenous taper that attempts to recreate the original main canal shape in an enlarged form. Cases present clinicians with a variety of anatomical and other challenges but the principles for root canal shaping remain the same for straight and curved canals (see Figure 49). However, specific cases, such as wide apices found in incompletely formed roots or after apical root resorption, call for modified approaches due to thin dentin walls and difficulties in controlling the apical extent of the fill. Special procedures such as apexogenesis and apexification may be required to provide adequate obturation (see Chapter 30, Obturation of the Radicular Space).

Variations in apical shape have received special attention and varying recommendations. Names were given for the desired configuration (lower panel in Figure 49): “apical stop,”²⁶⁵ “apical box,”²⁴² “apical capture or control zone.”^{266,267} The intent of all the described techniques is two-fold: (1) allow irrigant access to the apical root canal system and (2) prevent filling material from being extruded into the periapical space. As stated earlier, no conclusive evidence favors one apical shape over another regarding clinical outcomes; however, Kast’akova et al.²⁶⁸ demonstrated that an apical stop, prepared to follow the recommendation to prepare three sizes larger than the first file to bind at WL, did not prevent sealer or gutta-percha extrusion.

Finally, the argument has been made that a tapered apical preparation would reduce the incidence of overpreparation that may occur following a length determination error and an apical stop preparation.²⁶⁹ This idea derived its attraction from the well-supported notion that preparation errors should be avoided as they are associated with inferior outcomes.^{270–275} Preparation errors and their development are discussed further below.

Several systems to prepare canal with hand or engine-driven instruments have been described, beginning with Ingle’s standardized technique²⁷⁶ (Table 11). There are two principally different approaches: the “apex first” and the “coronal first” techniques. The former approach advocates that WL is reached and the apical area is prepared first with increasingly larger instrument

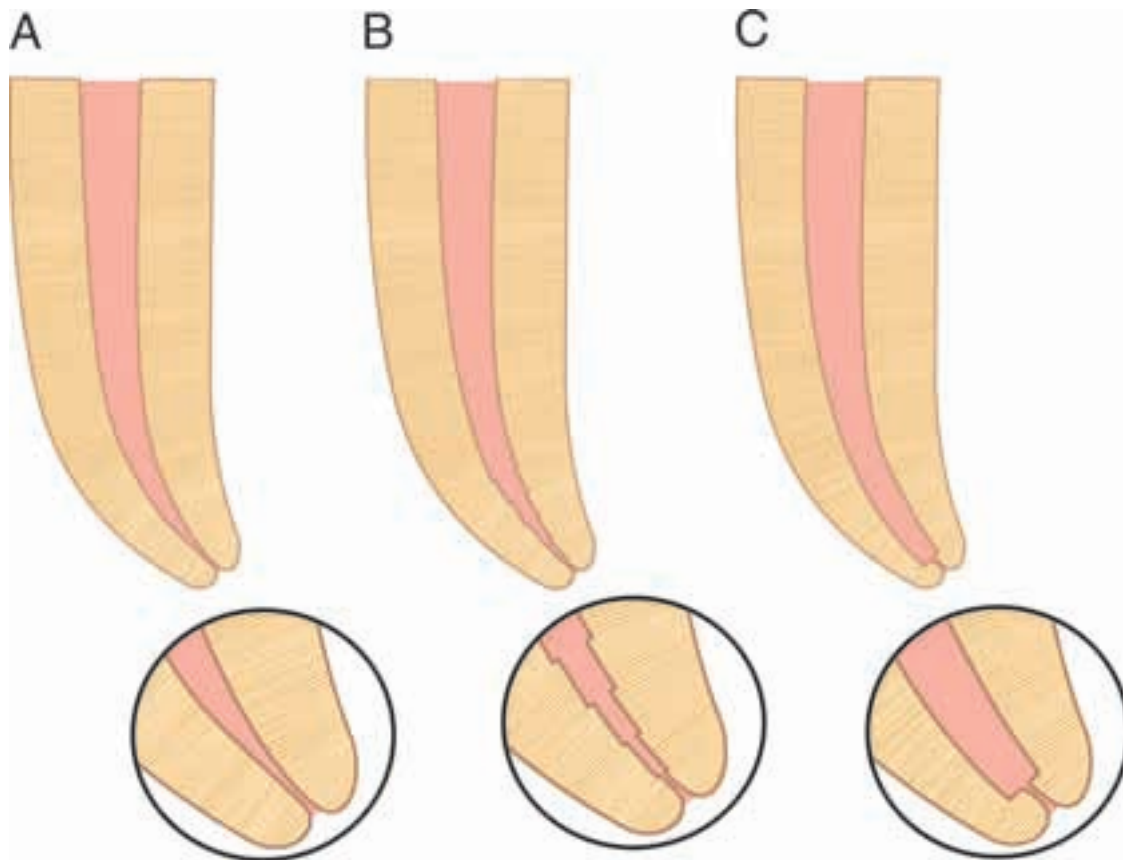

Figure 49 Schematic diagrams of potential root canal shapes after preparation. Depending on the instrument and the sequence used, the canal is enlarged into a tapered shape (**A**, for example, rotary instrumentation), a taper with incremental size increase (**B**, step-back preparation), or a slight taper with defined apical stop **C**. The bottom panel shows magnified apical shapes produced.

sizes, whereas the latter uses descending instrument sizes to prepare coronal canal areas first and apical ones last. The following section will describe the basic techniques and some subspects of them in more detail. As these

techniques are generally independent of the instruments with which they are performed, the reader is referred to Chapter 26C, “Instruments for Cleaning and Shaping” for a detailed review of design and properties of handheld and engine-driven endodontic instruments. However, it needs to be kept in mind that the literature is replete with references to the superiority of one instrument or one method of preparation over all others.^{288–290} The following statement may put expectations on any particular file type into perspective: “Regardless of the instrument type, none was able to reproduce ideal results; however, clinically acceptable results could be obtained with all of them.”²⁹¹

Preparation Techniques

STANDARDIZED

The standardized technique uses the same WL definition for all instruments introduced into a root canal

Table 11 Summary of Preparation Techniques Suggested for Hand and Rotary Instruments

Reference	Year	Technique
Ingle ²⁷⁶	1961	Standardized instrumentation
Clem ²⁷⁷ , Weine ²⁷⁸	1969–1974	Step-back, serial preparation
Schilder ³		
Abou-Rass ²⁷⁹	1980	Anticurvature filing
Marshall ^{280,281}	1980	Crown-down pressureless
Goerig ²⁶²	1982	Step-down
Fava ^{282,283}	1983/1992	Double flare, with modifications
Roane ²⁸⁴	1985	Balanced force
Torabinejad ^{285,286}	1994	Passive step back
Siqueira ²⁸⁷	2002	Alternate rotary motion

and therefore relies on the inherent shape of the instruments to impart the final shape to the canal. It can therefore also be called a “single-length technique,” an approach that has recently gained popularity with the ProTaper (Dentsply Maillefer) and MTwo (Sweden and Martina, Padova, Italy) NiTi rotary instruments.

Negotiation of fine canals is initiated with fine files that are then advanced to WL and worked until a next larger instrument may be used. Conceptually, the final shape is predicted by the last-used instrument (also named MAF, see Box 1). A single matching gutta-percha point may then be used for root canal filling. In reality, this concept suffers from two factors of variation: first, canals (in particular those with curvatures), shaped with the standardized technique, end up wider than the instrument size would suggest,^{292,293} and second, production quality is insufficient, both for instruments and for gutta-percha cones, leading to size variations.^{294,295}

STEP-BACK

Realizing the importance of a shape larger than that produced with the standardized approach, Clem²⁷⁷ and Weine²⁷⁸ introduced the step-back technique, sometimes also called telescopic technique.²⁹⁶ This paradigm relies on stepwise reduction of WL for larger files, typically in 1- or 0.5-mm steps, resulting in flared shapes with 0.05 and 0.10 taper, respectively. Incrementally reducing WL for larger and stiffer instruments in turn lessened the forces associated with aberrant preparations, in particular in curved canals (Figure 50).

Clem²⁷⁷ originally described the step-back technique for curved canals in teeth of adolescents, as the creation of a single step, at the transition from the straight to the curved portion of the root. The resulting shape is somewhat similar to the “coke bottle” configurations that occur when inflexible engine-driven instruments such as GG or Peeso drills are advanced past the middle root canal third (see Figure 48). Taking GG and Peeso drills deep into canals carries the risk of fracture as they are not very resistant to fatigue occurring in curved canals.²⁹⁷ Furthermore, overpreparation and subsequent strip perforations may occur,^{263,264,298} and therefore these shapes are generally not desirable.

Subsequently, Schilder³ suggested a “serial preparation” that included enlarging to a file size #30 or #35 and then serially reducing WL for the following instruments. Initially, he did not advocate a metrically defined step but rather a tactile feedback and cutting of dentin when initial wall contact was made. Thus,

Figure 50 Principles of radicular dentin removal. In a curved canal, apical pressure leads to transportation toward the outer curvature. At the same time, the reactionary force builds up in the straightening instrument against the dentin coronal of the curvature and leads to transportation toward the inner curvature (e.g., furcation).

larger instruments would be used with decreasing WL and finally a smoothly tapered canal shape would result. The developed shape, however, may be very similar to what had been described as the outcome of a step-back procedure and in fact later, Schilder-type preparation was illustrated as involving regular predetermined steps.²⁵⁸ Coffae and Brilliant,²⁹⁹ for example, described a serial procedure that entailed the use of a #35 file to WL, stepwise reduction of WL for subsequent files up to size #60, and then the use of GG drills Nos. 2 and 3 approximately 16 and 14, respectively, into the canal (Figure 51). They describe superior débridement with serial preparation compared to standardized shapes.²⁹⁹ Walton et al.³⁰⁰ corroborated these results by histological evaluations. Clearly, coronal enlargement (flaring) appeared beneficial for cleaning and obturation.²⁴⁸ However, there

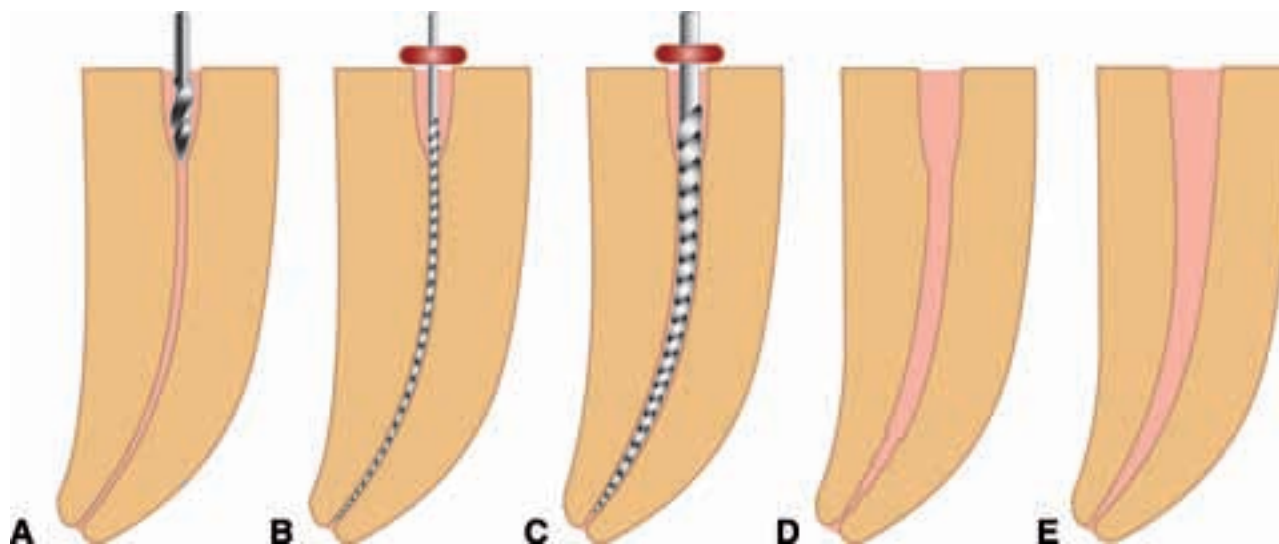

Figure 51 Sequence of instruments in the step-back procedure. After coronal preenlargement with Gates Glidden burs **A**, apical preparation to the desired master apical file (MAF) size commences with K-Files to determine working length (WL) **B** and then files of ascending size to the desired apical dimension (also called Phase I, **C**). Then, the WL is progressively decreased ("stepped-back") by 1 or 0.5 mm to create a more tapered shape (Phase IIa, **D**). Recapitulation with a small K-file is done to smooth canal walls and to ensure that the canal lumen is not blocked (Phase IIb, **E**). Frequent irrigation promotes disinfection and removal of soft tissue.

was concern about the potential for overinstrumentation and potential perforation. Development continued to modify shaping procedures.

Mullaney³⁰¹ described the step-back technique as particularly effective in fine canals. He divided the step-back preparation into two phases. Phase I is the apical preparation starting at the apical constriction. Phase II is the preparation of the remainder of the canal, gradually stepping back while increasing the instrument size. The completion of the preparation is the Refining Phase IIa and IIb to produce the continuing taper from the apex to the cervical (see Figure 51). To start Phase I instrumentation, the canal should have been explored with a fine instrument and the WL established. It is important that a lubricant is used at this point since fibrous pulp stumps may be compacted against the apical constriction and cause apical blockage.³⁰² In very fine canals, the irrigant that will reach this area may be insufficient to dissolve tissue. Lubrication is believed to emulsify tissue, allowing instrument tips to macerate and remove this tissue. It is only later, in canal filing, that dentin chips pack apically blocking the constriction. When the MAF size has been used to full WL, Phase I is considered complete and the 1.0- to 2.0-mm space back from the apical constriction should be clean of debris.

It must be emphasized here that irrigation between each instrument use as well as recapitulation with the previous smaller instrument carried to full depth is

crucial. Then the step-back process (Phase II) begins with a file one size larger than the MAF. Its WL is set 1 mm short of the full WL, and it is carried down the canal to the new shortened depth. The same process is repeated with subsequent instruments again shortened by 1.0 or 0.5 mm from the MAF. Thus, the preparation steps back up the canal with either 1 or 0.5 mm and one larger instrument at a time. It has been recommended to end this step-back phase at size #60³ or when the instrument has reached the wider straight portion of the root canal. In any case, frequent turnover of the irrigant and recapitulation with the MAF are necessary to promote canal disinfection and prevent blockage. The most coronal canal portion may then be carefully flared with GG drills or Hedström files. The refining Phase IIb is a return to the MAF, smoothing all around the walls to perfect the taper from the apical constriction to the cervical canal orifice, which would then be a larger replica of the original canal.³⁰³

Although the step-back technique was primarily designed to avoid preparation errors in curved canals, it applies to straight canal preparation as well. In fact, all root canals have some curvature.^{14,304,305} Apparently straight canals are usually curved to some degree and canals that appear to curve in one direction often curve in other directions as well.¹⁴ While it has been maintained that only curved instruments should be introduced into curved canals,³⁰² it seems in fact unlikely that one can successfully match canals' curvature with

a precurved file. Moreover, rotary instruments are straight and should be introduced only into canal areas that a straight hand instrument, size #15 or #20, has explored (“glide path,” see below).

A modification of the step-down approach using hand instruments has been described by Torabinejad.^{285,286} He advocated insertion of progressively larger hand instruments as deep as they would passively go in order to gain insight into the canal anatomy and to provide some enlargement prior to reaching the WL. Subsequent use of GG drills or Peeso reamers will provide additional coronal enlargement and improve tactile feedback from the apical region as well as better access for irrigants.^{306,307} The use of an ultrasonically activated size #15 K-file has been advocated to further blend canal irregularities.²⁸⁶ A second, probably even more important, benefit is the ultrasonic or sonic activation of the irrigant placed in the root canal for 1 to 2 minutes, and is turned over every 30 seconds.^{222,286}

ANTICURVATURE FILING

In this context, Abou Rass, Glick, and Frank³⁰⁸ described a method called “anticurvature filing” to prevent excessive removal of dentin from thinner root sections in curved canals. The underlying observation was that the furcation side (danger zone) of cross sections of mesial roots of mandibular molars has less dentin thickness than the mesial side (safety zone).^{34,309} The technique included the use of precurved hand files that were purposefully manipulated to file the canal away from the danger zone. It also incorporates coronal flaring with rotary instruments after the use of hand instruments, but it is stated that such instruments should not be introduced more than 3 mm into root canals.³⁰⁸ The final use of a manual instrument to blend the apical and coronal segments was advocated.

Kessler et al.³¹⁰ as well as Lim and Stock²⁶⁰ demonstrated that “anticurvature” filing in fact helped to reduce the risk of perforation. Later, Safety Hedström files (Kerr/Sybron, Romulus, MI) followed a similar concept, namely filing away from the danger zone. These files had cutting edges that were flattened and thus dulled at one side and were therefore believed to remove less material in one direction.³¹¹ However, subsequent research showed that Safety Hedström files when used as engine-driven versions are in fact not safe but tend to create preparation errors.³¹²

STEP-DOWN

A different approach was taken by Goerig et al.,²⁶² who advocated shaping the coronal aspect of a root canal first before apical instrumentation commenced. The authors

list the following advantages: the technique permits straighter access to the apical region, it eliminates coronal interferences, it removes the bulk of tissue and microorganisms before apical shaping, it allows deeper penetration of irrigants, and the WL is less likely to change. Subsequently, several of these claims were investigated; it was found that shaping was subjectively easier but had no measurable effect on canal transportation.³¹³ Furthermore, there was a small but significant beneficial effect on WL retention.^{186,314} The removal of coronal obstructions does allow a better determination of apical canal sizes;^{233,234} however, it is not clear if better irrigant penetration occurs and if that has clinically measurable benefits.

Another primary purpose of this technique is to minimize or eliminate the amount of necrotic debris that could be extruded through the apical foramen during instrumentation. This would help prevent post-treatment discomfort, incomplete cleansing, and difficulty in achieving a biocompatible seal at the apical constriction.²⁸⁰ One of the major advantages of step-down preparation is the freedom from the constraint of the apical enlarging instruments. By first flaring the coronal two-thirds of the canal, the final apical instruments are unimpeded through most of their length. This increased access allows greater control and less chance of zipping near the apical constriction.³¹⁵ In addition, it “provides a coronal escape way that reduces the piston in a cylinder effect”²⁰⁴ responsible for debris extrusion from the apex. This is one possible reason for the finding that coronal preflaring reduced the amount of apically extruded debris.³¹⁶

The procedure itself involves the preparation of two coronal root canal thirds using Hedström files of size #15, #20, and #25 to 16 to 18 mm or where they bind. Thereafter, GG drills Nos. 2 and 3, and then potentially No. 4, are used sequentially shorter, thus flaring the coronal segment of the main root canal. Then, apical instrumentation is initiated; it consists of negotiating the remainder of the canal with a small K-file, shaping an apical “seat,” and combining the two parts, step-down and apical shape, by stepwise decreasing of WL of incrementally larger files. Frequent recapitulation with a #25 K-file to WL is advised to prevent blockage.

Numerous modifications of the original step-down technique have been used clinically but most include the use of a small initial penetrating instrument, mostly a stainless steel K-file exploring the apical constriction and establishing the WL. To ensure this penetration, one may have to enlarge the coronal third of the canal with progressively smaller GG drills or with other rotary instruments. At this point, and in the presence of NaOCl,

step-down cleaning and shaping may begin with a variety of instruments. For example, starting with a size #50 K-file and working down the canal, the instruments are used until the apical constriction (or WL) is reached. When resistance is met for further penetration, the next smallest size is used. Irrigation should follow the use of each instrument and recapitulation after every other instrument. To properly enlarge the apical third and to round out ovoid shape and lateral canal orifices, a reverse order of instruments may be used starting with a size #20 (for example) and enlarging this region to a size #40 or #50 (for example). The tapered shape can be improved by stepping back up the canal with larger instruments, bearing in mind all the time the importance of irrigation and recapitulation.

BALANCED FORCE

After many years of experimentation, Roane et al.²⁸⁴ introduced the “Balanced Force” concept of canal preparation in 1985. The concept came to fruition, they claimed, with the development and introduction of a new K-type file design, the Flex-R File^{284,317} (originally manufactured by Moyco Union Broach, now Miltex, York, PA). The technique can be described as “positioning and preloading

an instrument through a clockwise rotation and then shaping the canal with a counterclockwise rotation.”²⁸⁴ The authors evaluated the damaged instruments produced by the use of this technique and discovered that a greater risk of instrument damage was associated with clockwise movement.³¹⁸ For the best results with the “Balanced Force” technique, preparation is completed in a step-down approach. The coronal and mid-thirds of a canal are flared with GG drills, beginning with small sizes, and then shaping with hand instrument is carried out in the apical areas. Similar to techniques described above, increasing the diameter of the coronal and mid-thirds of a canal removes most of the contamination and provides access for a more passive movement of hand instruments into the apical third. Shaping becomes less difficult: the radius of curvature is increased as the arc is decreased. In other words, the canal becomes straighter and the apex is accessible with less flexing of the shaping instruments (see Figure 50).

After mechanical shaping with GG drills, Balanced Force hand instrumentation begins with the typical triad of movements: placing, cutting, and removing instruments using only rotary motions (Figure 52).

Figure 52 Principles of the Balanced Force technique. Instruments with a symmetrical triangular cross section and pilot tips (e.g., Flex-R files, Moyco Union Broach, Montgomeryville, PA) were originally suggested to be used in three steps in a rotational movement. A file may be advanced into the canal with a one-quarter clockwise rotation. The second movement involves adequate apical pressure to keep the instrument at this level of the canal while rotate counterclockwise for a half- to three-quarter turn. Currently, it is recommended to use the first two movements repeatedly, progressing more apically. Then the third movement pulls the instrument gently out of the canal with clockwise rotation.

Insertion is done by a quarter-turn clockwise rotation while slight or no apical pressure is applied. Cutting is then accomplished by counterclockwise rotation applying sufficient apical pressure to the instrument.

The amount of apical pressure must be adjusted to match the file size (i.e., very light for fine instruments to fairly heavy for large instruments).²⁸⁴ Pressure should maintain the instrument at or near its clockwise insertion depth. Then counterclockwise rotation and apical pressure act together to enlarge and shape the canal to the diameter of the instrument. Counterclockwise motion should be 120° or greater. It must rotate the instrument sufficiently to move the next larger cutting edge into the location of the blade that preceded it in order to shape the full circumference of a canal. A greater degree of rotation is preferred and will more completely shape the canal to provide a diameter equal to or greater than that established by the counterclockwise instrument twisting during its manufacture. It is important to understand that clockwise rotation allows the instrument to engage dentin, and this motion should not exceed 90°. If excess clockwise rotation is used, the instrument tip can become locked into place and the file may unwind.²⁸⁴ If continued, when twisted counterclockwise, the file may fail unexpectedly. The process is repeated (clockwise insertion and counterclockwise cutting) as the instrument is advanced toward the apex in shallow steps. After the working depth is obtained, the instrument is freed by one or more counterclockwise rotations made, while the depth is held constant. The file is then removed from the canal by a slow clockwise rotation that loads debris into the flutes and elevates it away from the apical foramen.²⁸⁴ A more or less flared final shape may be obtained by stepping back in 0.5 or 1 mm increments.

Generous irrigation follows each shaping instrument, since residual debris will cause transportation of the shape. Debris applies supplemental pressures against the next shaping instrument and tends to cause straightening of the curvature. By repeating the previously described steps, the clinician gradually enlarges the apical third of the canal by advancing to larger and larger instruments. Working depths are changed between instruments to produce an apical taper. The working loads can and should be kept very light by limiting the clockwise motion and thereby reducing the amount of tooth structure removed by each counterclockwise shaping movement. This technique can and should be used with minimal force.

The Balanced Force technique may be used with any file with symmetrical cross section;³¹⁹ however,

shaping and transportation control are considered optimal when a Flex-R file is used.³²⁰ The Flex-R file design removes the transition angles inherent to the tip of standard K-files (see Chapter 26C, Instruments for Cleaning and Shaping). These angles may cut a ledge into the canal wall.^{321–324} The specific tip design prevents Flex-R files from transporting the canal into the external wall of a curve.³²⁵

Balanced Force instrumentation initiated from the belief that the apical area should be shaped to sizes larger than were generally practiced (see Table 10). The original Balanced Force concept then refers to apical control zones by, for example, first using sizes #15 and #20 files to the periodontal ligament (i.e., through the apical foramen) and then reducing the working depth by 0.5 mm for subsequent sizes #25, #30, and #35. The apical shape is then completed 1 mm short using sizes #40 and #45 under continuing irrigation with NaOCl. Single-appointment preparation and obturation played an important role in the formation of these shaping concepts.

The success of this shaping technique and enlarging scheme has been closely evaluated in both clinical practice and student clinics, and it can be said that files used in “Balanced Force” motion generally lead to comparatively little canal transportation. However, subsequent research has indicated that the underlying mechanisms are different from what was originally envisaged.^{326,327} Specifically, there is evidence that the force required to hold the instrument close to the position during counterclockwise rotation closely matches the amount of force required to bend an instrument into a curve similar to the main curve of the canal that is prepared.³²⁶ Nevertheless, *in vitro* reports indicate that shapes created with the Balanced Force technique are of excellent quality³²⁸ and are comparable to those with NiTi rotary instruments.^{245,329,330} Furthermore, extrusion of material was less than with other techniques, such as the step-back filing technique and the CaviEndo ultrasonic method.³³¹ More recently, Siqueira et al.²⁸⁷ tested a modification of the Balanced Forces technique they had earlier called alternated rotary movements. This approach did not recommend withdrawal of the instrument after each set of rotations but emphasized incremental apically directed movement and withdrawal only when the file, for example, a size #25 NitiFlex (Dentsply Maillefer) has reached the WL. Canals shaped to an apical size #40 had *in vitro* bacterial reduction similar to canals prepared with GT rotaries to size #20 0.12 taper.²⁸⁷

CROWN-DOWN PRESSURELESS

The first description of a crown-down preparation, in which larger files are first used in the coronal two-thirds of the canals and then progressively smaller files

are used more apically, can be found in a Master's Thesis by John Pappin³³² and the endodontic technique manual of the Oregon Health & Science University.²⁸¹ They described the approach as follows (Figure 53):

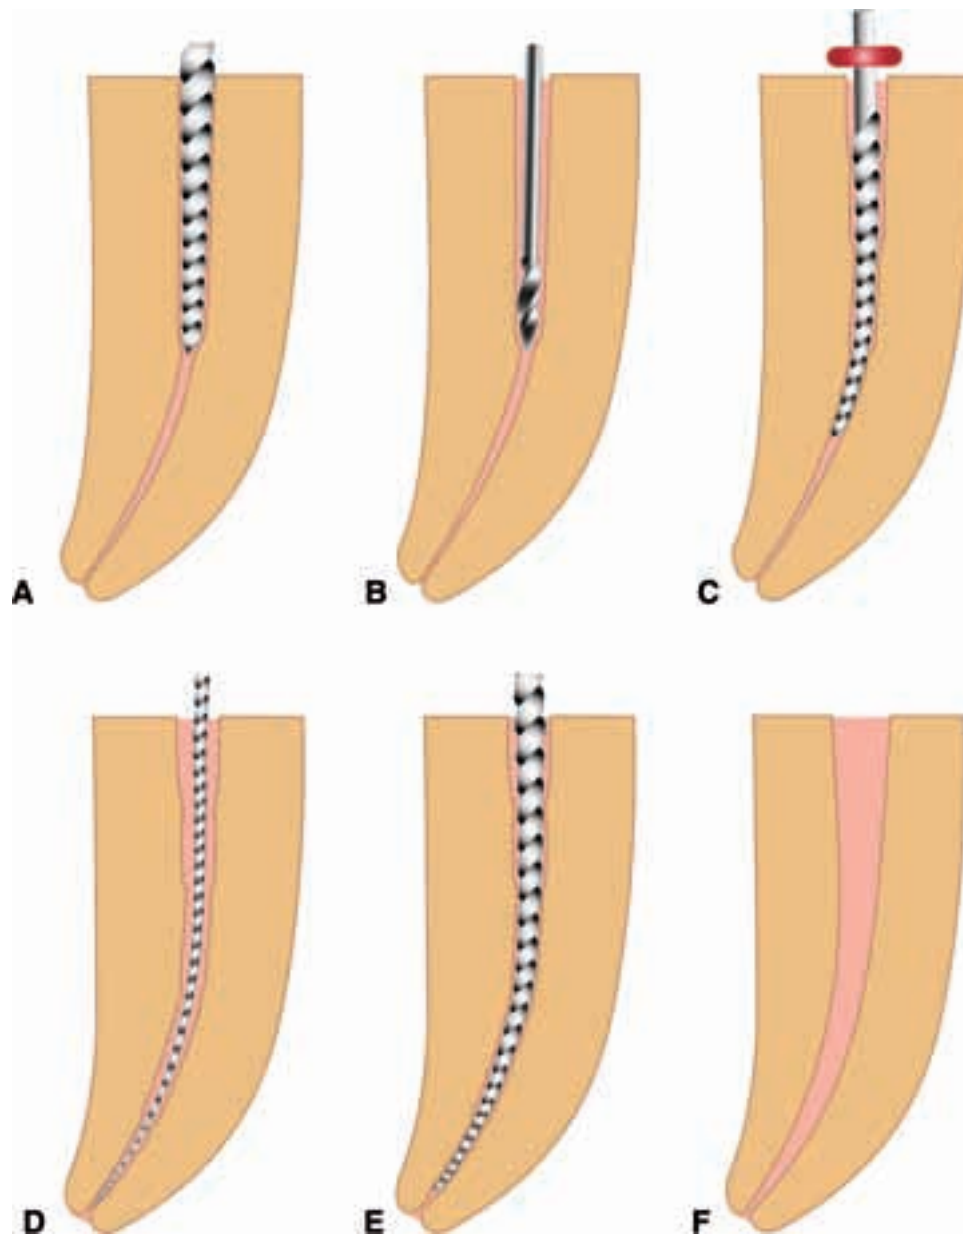

Figure 53 Sequence of instruments in the crown-down approach. Coronal preenlargement was originally suggested to commence after determination of a provisional working length (WL) with a size #35 hand file **A**. Then, Gates Glidden burs were used **B**, followed by hand files starting with a large file (e.g., size #60) and progressing apically with smaller sizes **C**. The definitive WL was determined as soon as the progress was made beyond the provisional WL **D**. Apical enlargement **E**, and recapitulation **F**, created a homogenous shape that may be similar to the one created with the step-back approach, provided that both techniques were performed with little or no procedural errors. Both step-back and crown-down techniques may be used in conjunction with hand and rotary instruments but in vitro evidence suggests that a crown-down approach is preferred for tapered rotary instruments.³³⁵

After completion of coronal access, a provisional WL is determined and a size #35 K-file is introduced into the root canal with no apically directed pressure. Then, a GG No. 2 is used, short of or to the length explored by the size #35 file. The GG No. 2 flares the coronal root canal and is followed by GG Nos. 3 and 4 with progressively shorter WLs. The next step is the core of what is now known as crown-down technique: a size #60 hand file is used with no apical force, and reaming is employed to enlarge the canal, followed by incrementally smaller instruments progressing deeper into the canal. A radiograph is taken when an instrument penetrates deeper than the provisional WL; after that, the apically directed procedure continues until an instrument reached the definitive WL.

The final step is to enlarge the apical area to three sizes larger than the first file that bound at WL. This is accomplished by going through the sequence of descending instrument sizes starting with a file one size larger than the starting size in the preceding series. Copious irrigation and recapitulation at the end of the procedure is advocated. Marshall in 1984 and 1987 amended the manual to include “Balanced Force” movements (Tinkle J, personal communication).

Morgan and Montgomery³³³ described a slightly different method where both GG Nos. 2 and 3 were introduced to a straight portion of the canal and the “crown-down” process was started with a size #30 K-file. They showed superior ratings by experts judging canal shapes, but similar occurrence of preparation errors, compared to the step-back preparation.³³³ However, a subsequent study found no differences in canal transportation when comparing “crown-down,” “step-back,” sonic instrumentation, and a NiTi rotary system.³³⁴ Nevertheless, a crown-down approach is currently advocated for the majority of engine-driven rotary systems due to reduced contact areas and forces on the instruments.³³⁵

DOUBLE FLARE

Fava²⁸² presented a preparation technique that consisted of an exploratory action with a small file, a crown-down portion with K-files of descending sizes, and an apical enlargement to size #40 or similar. He recommended stepping back in 1 mm increments with ascending files sizes and frequent recapitulations with the MAF. Copious irrigation is considered mandatory. It is further emphasized that significant wall contact should be avoided in the crown-down phase to reduce hydrostatic pressure and the possibility of blockage. At this time, the double-flare technique was felt to be indicated for straight canals treated in one visit.²⁸² Later studies demonstrated better prepara-

tions in teeth with curved root canals shaped with a modified double-flare technique and Flex-R files compared to shapes prepared with K-files and step-back technique. A double-flare technique was also suggested for ProFile rotary instruments.³³⁶

Rotary Instrumentation

The introduction of NiTi alloy³³⁷ for manufacturing hand files,³³⁸ and later engine-driven instruments,³³⁹ has altered canal shaping procedures drastically over the past two decades.³⁴⁰ The endodontic literature is replete with accounts of shaping outcomes in vitro and descriptions of forces to which NiTi instruments are subjected (for review see references 120 and 122). NiTi rotary instruments and their design specifics are described in detail in Chapter 26B, “Introduction of Nickel-titanium Alloy to Endodontics” and Chapter 26C, “Instruments for Cleaning and Shaping”. The following section is dedicated to their clinical use.

A major benefit of NiTi rotaries is their potential to avoid preparation errors.³⁴¹ This in turn may result in better clinical outcomes.^{228,273} Moreover, through changes in instrument geometries, the creation of optimized canal shapes has been simplified. There is an ongoing debate over which shape is the most useful. In any event, shapes that are apically narrow and have a smooth taper can be safely prepared to become more parallel and apically larger. In achieving these designs, most manufacturers of rotary files recommend a strict crown-down sequence, with the exception of the LS instrument.³⁴² Several strategies have been recommended for this instrument, most of which represent a double-flare technique. Recently, other instruments (ProTaper, MTwo) have appeared on the market that are to be used in a single-length technique, somewhat similar to the standardized technique for hand instruments.

A main reason for recommending a crown-down approach is to avoid overloading rotating instruments with large frictional wall contact; this is believed to reduce the incidence of file fracture, in particular torsional fracture (Box 2).^{343,344} One possible

Box 2 Fracture Mechanisms for Endodontic Instruments and Possible Mechanisms

Torsional failure	Forcing the instrument into a narrow canal space and rotating it
Fatigue failure	Overusing an instrument by prolonged rotation in a curved canal
Corrosive failure	Combination of torsional and fatigue failure of an instrument with signs of corrosion

Figure 54 Rotary instruments may be subject to taper lock as soon as the canal taper approaches their dimension. Then, a large proportion of the instrument surface engages the canal wall (indicated by red bars), frictional resistance and hence torque increases, with a high risk of instrument fracture. This risk may be minimized by sequentially **A** to **C** using instruments with smaller tip sizes or taper, thus reducing contact areas and torque.³³⁶

mechanism for this type of fracture is an event known as “taper lock,” illustrated in Figure 54.^{345,346} Taper lock occurs when the shape of the tapered root canal being prepared becomes similar to the instrument in use. Instruments may then become locked into the canal, and the tip may fracture.³⁴³ In a crown-down pattern, the next smaller instrument should be selected before taper lock can occur. Blum et al.³³⁵ were convinced that ProFiles used this way experienced much less torque than when a step-back pattern was followed. This finding can be extended to most of the other rotaries that have a similar longitudinal design, for example, K3 (SybronEndo), EndoSequence (BrasselerUSA), HERO 642 (MicroMega, Besançon, France), and several others.

The distinctive design of LightSpeed instruments (Discus Dental) maximizes flexibility and allows larger apical preparations without unnecessary removal of dentin. The LightSpeed (LSX) has a noncutting shaft and a very short blade. After making SLA to about the mid-root, the coronal third is flared with the instrument of choice (not with the LSX). After flaring, at least #15 K-file is used to obtain patency to WL. A #20 LSX and sequentially larger sizes are used to prepare the apical third. The Final Apical instrument Size (FAS) is the blade size that encounters

4 mm or more of cutting resistance apically. A 4-mm step back with the next larger instrument (than the FAS) is then cleaned and tapered with the next two or three sequentially larger LSX sizes, blending mid-root instrumentation with the previously prepared coronal third. Recapitulation is usually necessary only once, with the FAS, at the end of canal preparation. The new LSX is to be used at 2500 rpm, and irrigation is required throughout the procedure.

Apical enlargement is sometimes done after crown-down has been accomplished. At this stage, different strategies are possible, that is, switching tapers or tip sizes, changing to different instruments. Torsional stresses that files are subjected to depend on the sequence employed.³⁴⁷ Little is known of the incidence of fractures with single-length techniques,³⁴⁸ particularly when the recommendations of the manufacturers are followed. In addition, it is not certain how important overall NiTi instrument fractures are for clinical outcomes.³⁴⁹ Nevertheless, strict monitoring of instrument use should be instituted so that NiTi files can be periodically disposed of prior to failure.^{350,351} In fact, single use in severely curved or calcified canals may be preferable due to problems of decontamination^{352–355} and corrosion^{356–358}

in addition to the greater amount of stress that the instruments are subjected to in such situations.

Three different main handling paradigms have been described for the use of rotary instruments. Buchanan³⁵⁹ recommends feeding the rotating file into a root canal with very slight apical force, until the instrument stalls, and then to immediately withdraw the file. At this point the file has done its cutting action and the flutes are loaded with debris that must be removed. The file is then reinserted. A similar movement has been recommended for RaCe files (FKG, La Chaux-de-Fonds, Switzerland), designed to avoid threading into the canal.

In contrast, the second recommendation for most other instruments is to use them in an up-and-down movement^{342,360} with a very light touch to avoid taper lock and to distribute forces throughout the canal. This movement is continued until a certain resistance is met or WL is reached. Rotation in a curved canal leads to accumulation of cyclic fatigue, another potential reason for instrument fracture (see Box 2).^{343,361–363} Fatigue occurs through cyclic compression and elongation of metal. The compounded amount of strain leads to fracture after a typical lifespan of up to 1,500 rotations in the most commonly used experimental configuration.^{364,365} While the lifespan, calculated as rotations to fracture, is independent of the rotational speed,³⁶⁶ the instrument undergoing fatigue will fracture in a shorter time period with higher rotations per minute.

Regarding hand movements, there is mixed evidence regarding the protective effect of up-and-down movements on the accumulation of cyclic fatigue,^{360,363} but it does not appear to be harmful for the instrument brands tested.

The third instrument usage recommendation is specifically for ProTaper instruments and is termed “brushing”.³⁶⁷ Instead of feeding the file axially into the root canal, it is moved distinctly laterally in order to avoid threading in. Such lateral cutting occurs most effectively with a positive rake angle and a stiffer instrument. Regarding operational safety, it was recently established for MTwo instruments that the “brushing” motion extended fatigue life for larger size instruments.³⁶⁸ This finding may be extended to other instruments using lateral cutting (Peters OA, Paque F, Boessler C, unpublished data). However, GG drills, used in this manner in the coronal third of the canal,^{308,310} occasionally separate through fatigue. In this case, the GG shaft may be readily removed since fracture usually occurs on the transition from shaft to shank.

A guideline emphasized for ProTaper³⁶⁷ that may be extended to other currently available instruments

suggests determination of a “glide path.” Specifically, prior to the use of any rotary instrument, root canals should be explored with #10, #15, or even #20 K-files to avoid overloading NiTi instrument tips with unexpected canal curves or excessive wall contact.³⁶⁹ Special pathfinding files with specially designed geometry are available for this task (e.g., ProFinder, Dentsply Maillefer). Regardless of the design, it is important to use straight, not precurved, files to allow the subsequent rotary files to reach the same depth, without encountering acute bends or very narrow canal areas.

Finally, it has been recommended by manufacturers to use gel-based lubricants in conjunction with NiTi rotary files, or to fill the access cavity with NaOCl prior to instrument insertion.^{232,359} The use of gel-based lubricants could potentially reduce frictional resistance and hence torsional load.³⁷⁰ However, experimental evidence, using a dentin disk model, suggests otherwise.³⁷¹ In fact, the use of ethylenediaminetetraacetic acid (EDTA)-containing gels such as RC-Prep (Premier Dental Products, Norristown, PA) or Glyde (Dentsply Maillefer) may be detrimental, due to increased torque scores^{371,372} and, more importantly, due to chemical interaction with its EDTA moiety and NaOCl action.³⁷³

Therefore, and despite reports of its corrosive potential,^{374,375} frequently replenishing a reservoir of NaOCl³⁷⁶ is presently advocated, providing lubrication and disinfection during canal shaping. After rotary instrumentation is complete, irrigation with EDTA and/or NaOCl may be done³⁷⁷, with and without ultrasonic activation.^{147,222,378}

The following ten principles apply to the successful use of currently available NiTi rotary files:

1. As with any type of instrument, poor access preparation will lead to procedural errors. While generally important in root canal preparation, it is crucial for the use of NiTi rotaries.
2. Files should never be forced, as NiTi instruments require a passive technique. If resistance is encountered, stop immediately and before continuing, increase the coronal taper and verify the “glide path” using small stainless steel hand files.
3. Canals representing difficult anatomy should be detected, analyzed, and carefully instrumented following specific rules (Figure 55, see below for more details).
4. Files should not be overused. Once only is the safest number but the actual stress level depends upon the case. Hence files may be used for more than one canal, but may have to be replaced when shaping a particularly difficult canal.

Figure 55 Example of a sequence of instruments to safely enlarge and shape the coronal part of the root canal system. This enables a complete shape of the apical third also. Shown are magnified buccal views into the access cavity of a maxillary molar and respective radiographs. After pathfinding with a lubricated (arrowhead) K-file, straight-line access (SLA) is created with ultrasonically powered and rotary instruments. This is often difficult but equally important in the second mesiobuccal canal (shown accessed here). Then working lengths (WLs) in all four canals are determined; subsequently canals are enlarged and filled.

5. Instrument breakage occurs more often during the initial stages of the learning curve. The clinician changing from stainless steel to NiTi should take

continuing education courses with experienced clinicians and educators, followed by in vitro practice on plastic blocks and extracted teeth.

6. NiTi rotaries should not be used to bypass ledges. Confirmation of a glide path with a straight K-file is required prior to the use of any NiTi rotary.
7. Cutting with the entire length of the file blade should be avoided. This total or frictional fit of the file in the canal will cause the instrument to lock.
8. Sudden changes in the direction of an instrument caused by the operator (i.e., stopping and starting while inside the canal) must be avoided. A smooth gentle reaming or rotary motion is most efficient.
9. Inspection of instruments, particularly used instruments, by staff and doctor is essential. It should be remembered that NiTi has an excellent memory. The file should be straight. If any bend is present, the instrument is fatigued and should be replaced.
10. WL should be well established and controlled, as should the actual length of the file. If a file breaks without the clinician taking notice, a very sharp tipped instrument, upon the next insertion, will create procedural errors.

It is extremely important, for successful root canal preparation with rotary instruments, to carefully review the specific anatomy of each case (see earlier in this chapter and Chapter 6, Morphology of teeth and their root canal systems). Straight access into the root canal middle third should be created, with extended access cavities and early coronal flaring. When using rotary instruments, canals that curve, recurve, dilacerate, divide, or merge should be approached with extra care.²³² Figure 56 illustrates other problematic canal configurations. For example, very long narrow canals do not allow early coronal enlargement to the same extent as regular canals. The consequence is an increased frictional contact area and the potential for torsional overloading. There is no ideal solution to this problem except for extra careful flaring and potentially using hand instruments.

Acute bends, that is, those with a small radius of curvature, more coronally (see Figure 56B), puts a larger instrument cross section under cyclic fatigue and may cause breakage.³⁶² Here coronal flaring to the point of curvature and the use of rotary files with less taper to the WL are indicated. Ovoid canals that are wide buccolingually, such as distal canals of mandibular molars or some premolars, present a different problem. Instrument fracture is not very likely, but they can rarely be prepared to be round; hence débridement may be incomplete. It may be appropriate to approach these cases as if two canals existed buccally and lingually, and then merge the preparations by

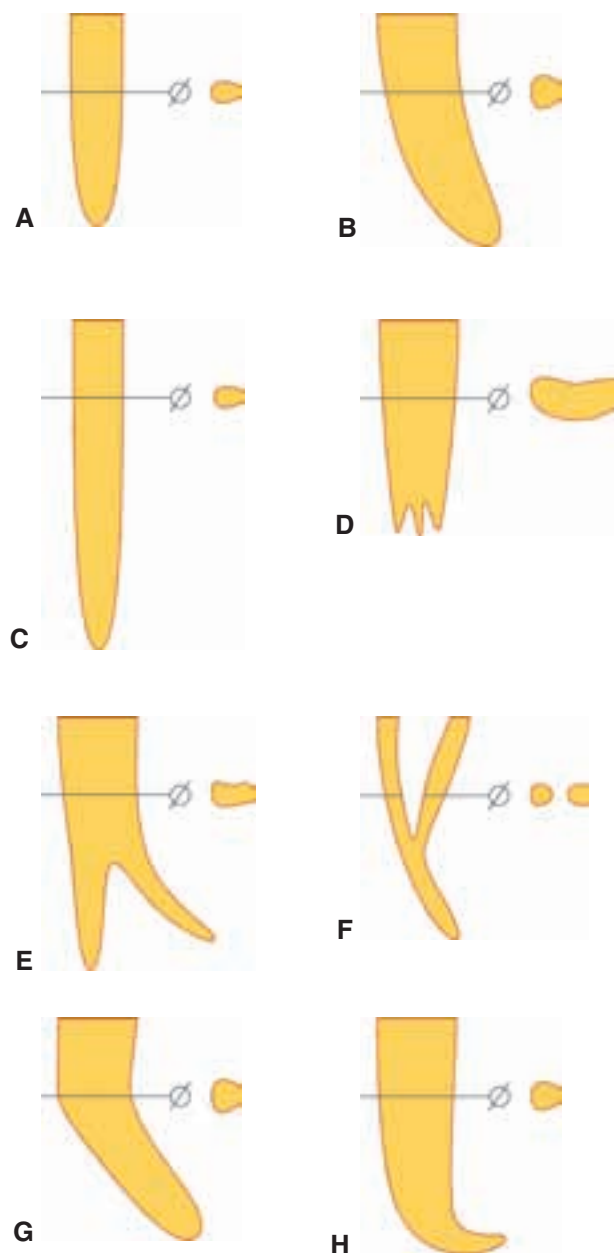

Figure 56 Schematic diagram of typical root canal anatomy with increasing degrees of difficulty for root canal preparation. Shown are basic canal shapes and cross sections at the middle root canal third (see text for more details). **A**, Short straight canal. **B**, Longer canal with moderate curvature. **C**, Very long canal. **D**, Canal that is wide buccolingually and may have multiple apical ramifications. **E**, Canal that splits apically in two main canals. **F**, Canals merging at the transition of middle and apical thirds. **G**, Acute curvature in coronal root canal third. **H**, Extreme curve in the apical 2 to 3 mm.

filing action with ultrasonic files or hand files. For merging canals, it is suggested to prepare the straighter canal to WL and the other canal to the merging

point. This avoids forcing a rotary instrument through a sharp S-curve. Many procedures have been suggested for very acute curves and narrow canals (see Figure 56C), although none is certain to be universally successful.

By extending the strategies detailed earlier in this chapter, the following recommendations represent current thinking³⁷⁹ for such a procedure. In part,

these are different from earlier descriptions for hand instruments.^{256,257} Coronal enlargement and creation of SLA are important to allow rotary instrument to work without undue stress. Moreover, this procedure reduces the danger of ledging and blocking. Figure 57 illustrates how this may be accomplished for a curved canal in a maxillary molar.

Figure 57 Example of a clinical sequence of instruments to safely enlarge and shape the apical two-thirds of curved root canal systems (palatal canal in **A**) using hand and rotary instruments. After pathfinding with small hand instruments **B**, and coronal pre-enlargement **C**, working length (WL) is determined. For a safe use of rotary instruments, a glide path is established with a series of hand instruments **D**, which rotary instruments can then follow **E**. Sufficient apical enlargement **F**, allows small irrigation needles to be passively inserted deep into the main canal **G**, and facilitates fitting of master cones **H**.

Calcifications occur nearest to the irritant to which the pulp is reacting. Since most irritants are in the coronal region of the pulp, the farther apical one goes into the canal, the more unlikely it is to be calcified. When files bind in these canals, it may be from small constrictions in the coronal part of the canal.

Obviously, before the canals can be entered, their orifices must be found. Knowledge of pulp anatomy is of first importance. Perseverance is the second requirement, followed by a calm determination not to become desperate and decimate the internal tooth when the expected orifice does not appear. The endodontic explorer is the greatest aid in finding a minute canal entrance (see Figures 18 and 55), feeling along the walls and into the floor of the chamber in the area where the orifices are expected to be.

A valuable aid in finding and enlarging canal orifices, particularly with magnification, is the Micro-Opener (Dentsply Maillefer) or the EndoHandle (Logan Dental, Logan, UT), with K-type flutes in 0.04 and 0.06 tapers.

Radiographs are indispensable in determining where and in which direction canals enter into the pulp chamber. The initial radiograph is one of the most important aids available to the clinician; a bite-wing radiograph is helpful in providing an undistorted and metrically accurate view of the pulp chamber. The handpiece and the bur may be held up to the radiograph to estimate the correct depth of penetration and direction to the orifices. Color is another important aid in finding a canal orifice. The floor of the pulp chamber and the continuous anatomical line that connects the orifices (the so-called molar triangle) are dark gray or sometimes brown in contrast to the white or light yellow of the walls of the chamber (see Figure 55). Various ultrasonically powered tips

are very helpful in relocating and enlarging orifices once their position has been determined (see Figure 55).

Current rotary instruments have noncutting tips and, with correct handling, pose relatively little risk of ledging the canal, certainly not in the coronal two-thirds. Provided that copious irrigation is used, apically directed transport of debris is less than with hand instruments and filing actions.^{162,380,381} Verifying a glide path, as illustrated earlier, is particularly important when shaping narrow canals. This may be accomplished with a small (size #6, #8, or #10) K- or C-file (Dentsply Maillefer), lubricated and used in a watch-winding motion (see Figures 55 and 57).

An argument against using a straight instrument is that it tends to engage the wall at the curve or the pivot on a catch on the wall. Rotary instruments, however, are also straight. Therefore, the presence of a glide path has to be verified with a straight hand file. When the presence of sharp curves, debris, or very narrow canal areas is expected, precurving an exploratory file is indeed indicated (Figure 58). Most often, the pathfinding file can be advanced to WL with adequate hand movements, in particular gentle watch-winding. If this cannot be accomplished, coronal interferences must be removed by increasing the taper of the already explored coronal canal segment (see Figure 55).

When tentative WL is reached with a pathfinder file, the clinician may determine the direction of a major curvature by noting the direction of the tip of the file when it is withdrawn. This is a valuable clue, since the clinician understands the direction in which the canal curves and may guide the instrument accordingly. Valuable time may be saved when exploration is eliminated each time the instrument is

Figure 58 Flexible endodontic files may be used straight **A**, to initially scout and pathfind a root canal, since a subsequent rotary instrument can more safely be used in a canal area that a straight hand file negotiated ("glide path"). If an intracanal obstruction is encountered, an adequately precurved manual instrument should be used to conform more to overall canal anatomy **B**. A more acutely curved instrument can be utilized to bypass ledges or blockages **C**. Inset shows bacterial growth on blood agar after a K-file was bent using "clean" gloved fingertips.

placed in the canal. A pointed silicone stop will clearly show the direction of the file curvature. The WL may then be confirmed with a radiograph using a size #15 K-file. After determining the WL, a curved pathfinding file should be used if additional canals are suspected, for example, in mandibular incisors, mandibular premolars, the distal root of mandibular molars, or the mesiobuccal root of maxillary molars.

While ultrasonically powered inserts are routinely used under magnification to explore and refine access into canals, rarely do they need to be used into middle and even apical third of canals. However, when severe calcification is present, there is the option to locate a canal cross section that needs further shaping with hand or rotary files to WL (Figure 59).

Others have recommended the use of EDTA buffered to a pH of 7.3 to “dissolve” a pathway for exploring instruments.^{382,383} When the mineral salts have been removed from the obstructing dentin by chelation, only the softened matrix remains.³⁸⁴ However, this action has been disputed by others, since chelation does not readily occur in narrow parts of the canal, although softening can occur in the cervical and middle portions.^{385,386} EDTA must be concentrated enough in an area to be effective.

Like in many other situations in root canal therapy, it is the obligation of an astute clinician to execute a cost-benefit evaluation, in order to determine if further progress without clear evidence of a canal cross section is indicated. Magnification and

Figure 59 Occasionally, calcification may occur more apically than usual. In this case, ultrasonic instruments were used to remove the obstruction (arrowhead in **A**); both mesial and distal canals were shaped and filled to the desired working length (WL). **A**, View through the operating microscope before using ultrasonic tips and preoperative radiographs. **B**, Canal lumen exposed as seen in the operating microscope and postoperative radiograph. illumination are keys to this task and experience will help to guide the clinician here more than textbooks.

In conclusion, it needs to be emphasized that the suggested methods are by no means the only way to approach difficult root canals. Again, it is in the hands of an artful clinician to master all aspects of such a case.

Devices for Powered Canal Preparation

Engine-driven instruments have been used in root canal preparation for more than 100 years beginning with GG drills in 1885. These drills were mostly used in handpieces connected to belt drives and were pedal-powered, even though the first electric dental handpiece had been patented in 1875. Subsequently, many modifications, and specifically handpieces with various oscillating movements, were brought to the market, none of which provided superior preparation quality.¹²² Currently, the newest major energy sources for root canal preparation are again electric motors for continuous rotary motion and ultrasonic/sonic units for vibration.

MOTORS FOR ROTARY INSTRUMENTATION

Engine-driven instruments can be used in three types of contra-angle handpieces: a full rotary handpiece, mostly latch grip, a reciprocating/quarter-turn handpiece, or a special handpiece that imparts a vertical stroke but with an added reciprocating quarter turn that “cuts in” when the instrument is stressed. These all are powered by electric or air-driven motors. While electric motors are more popular in Europe, air-powered motors are in much use in the United States. It is not clear if there are relevant differences between these two motor types regarding file breakage.³⁸⁷ In addition to these two motors, there are battery-powered, slow-speed handpieces that may be

combined with an apex locator, designed to simplify WL-control as well as torque-control motors (Figure 60).

As stated above, traditional handpieces with non-continuous movement such as the Giromatic (Micro-Mega) and M4 Safety handpiece (Kerr/Sybron) (see reference 122 for review) have been shown to lead to aberrant canal preparations. Some reports for these systems were favorable^{388–390} while most others demonstrated problems, most notably a high incidence of preparation errors.^{391–397} Consequently, these handpieces have lost popularity in the last years with the increased market share of NiTi rotaries.

An exception may be the Canal Finder system developed by Levy (currently marketed by SET, Olching, Germany) that uses a handpiece, either air-powered or electrically driven, that delivers a vertical stroke ranging from 0.3 to 1 mm. The more freely the instrument moves in the canal, the longer is the stroke. The handpiece also has a quarter-turn reciprocating motion that starts along with the vertical stroke when the canal instrument is under bind in a tight canal. If it is too tight, the motion ceases and the clinician switches to a smaller file.

More recently another handpiece with oscillating action was introduced (EndoEZE AET, Ultradent, South Jordan, UT) to more adequately prepare canals with oval cross sections. Unfortunately, this technique in its original configuration did not perform well in curved canals,³⁹⁸ but with updates, in file type and alloy as well as instrument sequence, it may serve as an adjunct to address cases not suitable for rotary preparation alone.³⁹⁹

Recommended speeds for currently available NiTi rotaries are in the range of 150 to 600 rpm, with the exception of LS that works predominantly above 1,500 rpm. This range of speeds is typically reached with reduction gear handpieces (1:8 or 1:10). Higher speed is occasionally advocated for better efficacy and safety,⁴⁰⁰ but the majority of authors maintain that lower speeds are beneficial, offering a better

Figure 60 Selection of cable-bound **A**, and cordless **B**, motors intended for use with nickel–titanium (NiTi) rotary instruments.

compromise regarding fatigue lifespan^{387,401,402} and occurrence of taper lock.^{345,346,403,404}

For continuous rotary movement, electric motors offer several benefits over air-powered ones, such as stable preset rotations per minute. However, the most attention has been focused on the potential to pre-select maximum torque in order to protect instrument tips from fracturing.⁴⁰⁵ This is accomplished by setting a maximum current (DC motors) except for the so-called stepper motor that is software-controlled (EndoStepper, SET). There is some evidence that the use of a torque-limiting motor reduces the

overall load on NiTi files and hence increases their fatigue lifespan.^{406,407} Moreover, these motors are seen as useful for beginners, to avoid forcing an instrument.⁴⁰⁴ Various settings are possible for some torque-limited motors; for example, the motor can stop, go into reverse or into oscillations.

On the other hand, electronics inside motors and hence their torque limits are not very precise;^{408–410} wear and friction inside the handpiece must also be further taken into account. Moreover, these motors depend on correct presets for the expected fracture limit. The limits are determined according to the

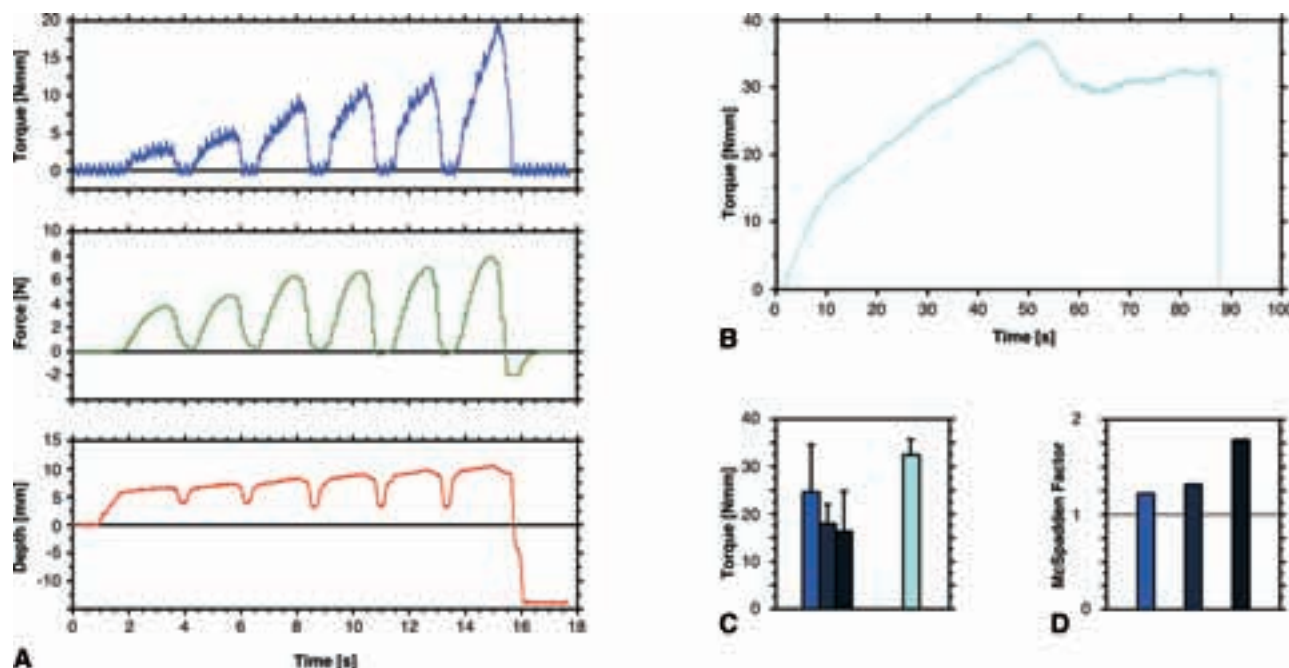

Figure 61 Relationship of torque during canal preparation and fracture load: The McSpadden Factor. **A**, Working torque (in blue), apically directed force (in green), and insertion depth (in red) into an extracted tooth simultaneously recorded during preparation with a ProFile 0.04 60 rotary using a testing platform. Note that total length of the instrument use was about 16 seconds. **B**, Determination of fracture load according to ISO 3630-1 at 2 rpm, determined at D3. **C**, Mean working torques (means SD, $n = 10$ each) in straight and curved plastic blocks or in extracted teeth (indicated by various shades of dark blue) and static fracture load (bright blue bar, $n = 8$). Modified with permission from Peters OA and Barbakow F.³⁶³ **D**, Values of the McSpadden factors for ProFile 0.04 60 are above 1 in all tested conditions, indicating a very fracture-resistant instrument (bar shades correspond to panel C).

pertinent norms at D3, 3 mm from the tip of the file.⁴¹¹ Hence, a short and less resistant segment of the file can still break even when the presets are correct.

A minimum torque is required for a rotary instrument to work against friction to prepare a canal (Figure 61). This torque level depends on instrument cross sections and hand movements employed. The relationship between fracture load at D3 and working torque has been referred to by J.T. McSpadden as the “safety quotient”; it is calculated by dividing fracture load by working torque.

If working torque is high and the fracture limit is a small torque value, the instrument’s safety quotient is below 1. This indicates that the instruments may operate with imminent danger of fracturing. In contrast, if there is very little working torque and a high torque is required to fracture the instrument, the quotient is well above 1, and hence safety is considered high (see Figure 61). However, Blum et al.⁴¹² have correctly pointed out that the quotient should refer to a specific instrument cross section rather than D3 alone to be more meaningful.

ULTRASONIC CANAL INSTRUMENTATION

The use of ultrasonic in endodontics is based on sound as an energy source (at 20 to 25 kHz) that activates an endodontic file. As a result, three-dimensional file movement in the surrounding medium of root canals may be enlarged.⁴¹³ The main débride-ment action of ultrasonics was initially thought to be by cavitation, a process by which bubbles formed from the action of the file become unstable, collapse, and cause an implosion. A combined shock, shear, and vacuum action resulted.⁴¹³ Ultrasonic handpieces typically use K-files as instruments for canal shaping. Before a size #15 file can fully function, however, the canal must be enlarged with hand instruments to at least a size #20 to allow the file to oscillate without constraint. Although Richman must be credited with the first report (1957) of the use of ultrasonics in endodontics,⁴¹⁴ Martin and Cunningham^{415–420} were the first to develop a device, test it, and see it marketed in 1976. It was named the Cavitron Endodontic System by Dentsply Caulk and was followed by many other devices on the market. These instruments all deliver an irrigant/coolant, usually NaOCl, into the

canal space while canal preparation is carried out by a vibrating K-file. The canal shapes and surfaces achieved, by preparation with ultrasonic units, have ranged from outstanding^{419–424} to disappointing,^{166,425–428} in particular regarding canal shapes,^{289,429,430} and the use of ultrasonics to shape canals has fallen into disregard over the last decade.

Research into the potential mechanisms of ultrasonic action has continued and has revealed that it is not cavitation, but a different physical phenomenon, acoustic streaming, that is responsible for the débridement.^{431–433} Clearly, acoustic streaming depends on the free displacement amplitude of the file, and if the vibrating file is at least partially constrained and damped in its action, it will become ineffective.⁴³⁴

SONIC CANAL INSTRUMENTATION

Sonic endodontic handpieces attach to the regular airline at a pressure of 0.4 MPa. Air pressure may be varied with an adjustable ring on the handpiece to give an oscillatory range of 1.5 to 3 kHz. Tap water irrigant/coolant is delivered into the preparation from the handpiece. Walmsley et al.^{434,435} studied the oscillatory pattern of sonically powered files. They found that out in the air, the sonic file oscillated in a large elliptical motion at the tip. However, when loaded, as in a canal, they found that the oscillatory motion changed to a longitudinal motion, up and down, "... a particularly efficient form of vibration for the preparation of root canals..."⁴³⁵

Similar to ultrasonic instrumentation, there is currently little support for the use of sonic vibration to prepare root canals, with the only exception of retrograde canal preparation during endodontic surgery (see Chapter 32, Endodontic treatment outcome: the potential for healing and retained function).

Today ultrasonically activated instruments are used for final canal débridement rather than canal preparation.⁴³⁶ Passive sonic and ultrasonic irrigation is distinct from active irrigation; in the former, irrigant deposited in the canal is activated, whereas in the latter, a stream of solution is continuously delivered from the ultrasonic or sonic unit. Passive irrigation

(after smear layer removal) with a size #15 file for 3 minutes in the presence of 5.25% NaOCl produced cleaner canals when compared to hand instrumentation alone.⁴³⁷ Improvement in irrigation efficacy was also reported by authors using 5.25% NaOCl for 30 to 60 seconds,⁴³⁸ 2% NaOCl for 3 minutes,²²² or 2% chlorhexidine for 1 minute.⁴³⁹

There has been concern that cutting instruments would in fact negatively impact canal surface and shape and therefore blunt noncutting inserts have been advocated. Figure 62 shows canal segments after passive ultrasonic irrigation, demonstrating no damage with either cutting or noncutting instruments.^{378,440} It has also been of interest to see if NaOCl may be extruded out of the apical foramen from ultrasonic filing and cause harmful effects. Alacam⁴⁴¹ intentionally overinstrumented beyond the apex in a monkey study and then evaluated the tissue response when NaOCl was used with conventional filing versus ultrasonic filing/irrigation. He did not find any difference between the two methods and noted a low to moderate inflammatory response periapically.

Ultrasonically and sonically activated passive irrigation exerts its effects via acoustic streaming and increase in temperature^{442,443} (Figure 63) rather than cavitations as previously thought. Using both mechanisms, 3 minutes of ultrasonic instrumentation with a size #15 file and 5.25% NaOCl improved canal cleanliness.⁴⁴⁴ It is presently not clear which combination of file size and canal shape produces the best results. In one study, smaller files generated greater acoustic streaming and hence much cleaner canals.⁴³² As it had been shown that constraint of the activated insert in the apical canal third was an important factor,^{434,445} a freely oscillating size #15 K-file was used for 5 minutes with a free flow of 1% NaOCl. The same authors found that root canals had to be enlarged to the size of a size #40 file to permit enough clearance for the free vibration of the size #15 file at full amplitude.⁴⁴⁶ Others have also recommended a size #15 file;^{378,427,447} however, van der Sluis et al.⁴⁴⁰ recently speculated that the shape of the insert in

Figure 62 Varying effect of ultrasonic activation of deposited irrigation solution on apical canal wall morphology. In this experiment, both 5.25% sodium hypochlorite (NaOCl) and 17% ethylenediaminetetraacetic acid (EDTA) irrigation were activated with either K-file-type or prototype noncutting inserts after enlargement of single-rooted teeth to an apical size #45. **A**, Scanning electron micrographs of ultrasonic inserts, black bars are 300 μm . **B**, Canal surface with smear layer without the use of EDTA (control). **C**, Apical segments after irrigation with NaOCl and EDTA with ultrasonic activation, demonstrating thin continuous (left) or no smear layer with open dentinal tubules (right, white bars are 50 μm).

relation to the canal shape may play a role for its efficacy. Indeed, temperature changes during activation of irrigants vary with the geometry and the material of the insert, indicative of energy transfer (Paque F and Peters OA, unpublished data) (see Figure 63). While the majority of in vitro studies support improved débridement with the use of passive ultrasonic irrigation, potential clinical benefit is as yet unproven. In fact, ultrasonic inserts may fracture, representing an iatrogenic problem during canal shaping (Figure 64).

Evaluation of Canal Preparation Techniques

A variety of techniques have been used over the years to assess preparation quality (see references 120, 122 for review), and most of these investigations were done in vitro. Previously, two main parameters were addressed, mostly from a mechanistic viewpoint: canal shapes and appearance of canal surfaces, the latter also termed cleanliness.

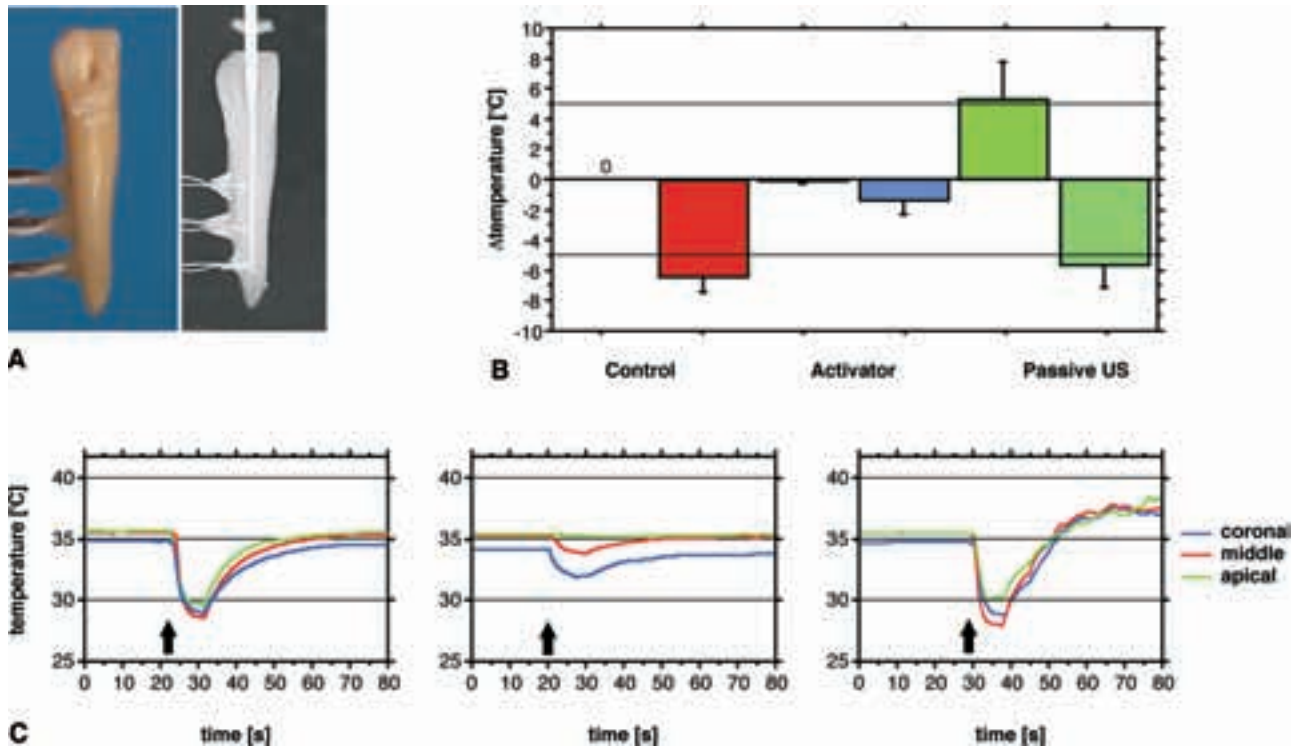

Figure 63 Effect of ultrasonic activation on intracanal temperature in vitro. Thermocouples were attached to single-rooted teeth and the assembly was placed in a water bath at 37°C. Irrigation solution was either added and activated or continuously deposited concurrent with ultrasonic activation using various inserts. **A**, Three thermocouples fitted into holes drilled in radicular dentin close to the intracanal surface. **B**, Bar diagrams showing maximum and minimum temperatures at the coronal, middle, and apical levels. Measurement duration 2.5 minutes, $n=15$. **C**, Original records of temperature over time with no ultrasonic activation (control, left), using an agitator at sonic frequency (prototype, middle) and a blunt nickel–titanium (NiTi) wire for passive ultrasonic agitation (right, EndoSoft, EMS, Nyon, Switzerland). Beginning of irrigation indicated by arrows.

The ability of an instrument or a technique to allow the prepared canal to stay centered in root cross sections is seen as beneficial (Figure 65). Conversely, canal transportation, or any deviation from the original canal path, is seen as negative and in particular the end points of transportation, namely preparation

errors (Figure 66). The term “zip” was coined by Weine,²⁷⁸ who described the appearance of a “zipped” apex when viewed directly in vitro. The formation of preparation errors is believed to be due to the interaction of canal curvature, file design, and file handling (see Figure 50). The tendency of a file to straighten

Figure 64 Use of activated irrigation in the clinical setting. A size #15 K-file was attached to an ultrasonic unit (middle power setting) and activated for 30 s. During cone fit, it was noted that a segment of the instrument had fractured. The fragment was removed and the root canal system filled with thermoplasticized gutta-percha.

itself cannot be completely overcome by precurving and leads to uneven distribution of forces and hence material removal.^{284,448}

Moreover, the cutting action of instruments in the apical region, particularly when extended beyond the canal space, may create an apical zip with perforation.⁴⁴⁹ The occurrence of such apical preparation errors has previously been linked to hand and rotary instruments with sharp tips.^{450–452} Zip-and-elbow formation and other well-described preparation outcomes such as ledges, strip perforations, or excessive thinning of canal walls⁴⁵³ may have clinical consequences such as incomplete débridement, problems with root canal fill-

ing, or eventual vertical root fracture (Figure 67). Preparation errors may decrease outcomes, most likely via reduced antimicrobial efficacy, but their clinical consequences are still a matter of debate.^{270–274,454,455}

Generally, apical canal areas tend to be overprepared toward the outer curve or the convexity of the canal, while more coronal areas are transported toward the concavity or the furcation in multirooted teeth (see Figure 50). This results in an uneven preparation demonstrated in canal cross sections with large areas left unprepared.^{456–460} This finding was validated by three-dimensional analyses (see Figure 66) using micro-computed tomography.^{245,263,461–464} While the amount

Figure 65 Canal cross sections before and after preparation can be assessed using a specially designed mold that allows sectioning of root, removal, and precise reposition of the resulting root disks **A**, Photographs can be taken and the effect of canal preparation numerically determined, for example, in the coronal, middle, and apical root thirds before **B**, and after preparation **C**, In this case shown, rotary preparation (left canals) resulted in round and centered shapes, while hand instrumentation produced canal transportation and thinning of root structure (arrowhead, **C**). Gradation of bar is 0.5 mm.

of prepared canal surface seems to be independent of the instrument type, it was significantly affected by preoperative canal anatomy.^{245,463,464} Sequential mechanical enlargement, as shown in Figure 68, may be indicated in order to increase prepared surface

areas, in particular to remove tenacious biofilms present in retreatment cases.⁴⁶⁵

While the use of microcomputed tomography represents the latest available technology, there are numerous other ways to evaluate canal shapes, for

Figure 66 Root canal preparation errors develop more readily with increasing instrument size and hence stiffness. This panel of micro-computed tomography data shows canal straightening and perforation after shaping to size #25 in an experiment where quarter-turn pull motion was employed with stainless steel hand files. **A**, Unprepared root canal system of a maxillary molar. **B**, Accessed and coronal scouting with a size #15 file. **C**, Enlargement to size #15 (buccal canals) and #25 (palatal canal) to working length (WL), note fractured instrument in second mesiobuccal canal (arrowhead). **D**, Enlargement to size #30 (buccal canals) and #35 (palatal canal), note perforation in main mesiobuccal canal. **E**, Enlargement to size #50 and #55 in buccal and palatal canals, respectively. **F**, Enlargement to size #60 and #70 in buccal and palatal canals, respectively.

example, superimposing radiographs before and after shaping.^{334,466–468} Bramante et al.⁴⁶⁹ and later others^{470–474} embedded teeth with their roots in a

Figure 67 Relationship between vertical root fracture location, clinical, and radiographic appearance. A buccal swelling but not appreciable probing was present in this case. Only after the removal of the crown and the buildup material, a fracture line extending to the mesial was apparent (arrowhead in **A**). A periodontal defect (probing depth 11 mm) was detected that corresponded to radiographically visible bone destruction **B**. Images courtesy of Dr. Tri Huynh.

muffle system (see Figure 65). They were then cut and the cross sections evaluated before and after canal preparation. Center points of the canals were determined and movements of the canals' centers calculated.^{472,474–480} Numerous studies evaluated shaping capabilities of specific instruments using canals of varying geometry in plastic blocks and extracted teeth. Various factors for canal transportation have been

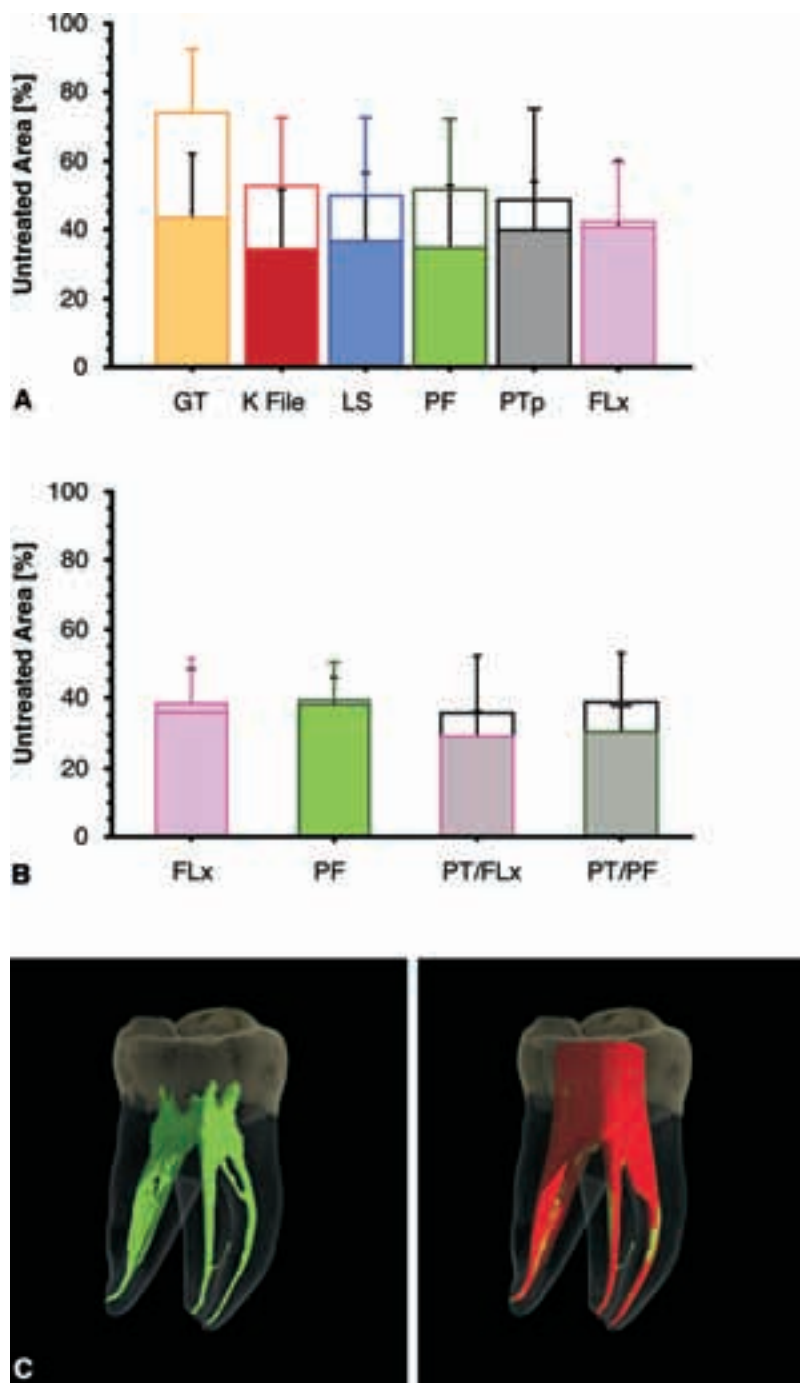

Figure 68 Dependence of instrumented canal surface on file geometry and usage. **A**, Bar diagram showing overall and apical fractions of instrumented canal surface. Data recalculated from Peters OA, et al.²⁴⁵ **B**, Bar diagram showing increase of instrumented surface with increased apical sizes (Paque F, Peters OA, unpublished data). **C**, Microcomputed tomography reconstructions of canals shaped with cutting and noncutting instruments used subsequently.

identified, such as canal anatomy, instrument type, cross-sectional and tip design, instrument taper, sequence, operator experience, rpm, and the use of irrigants or lubricants.¹²⁰

The effect of canal anatomy on shaping outcome is well documented for LS, ProFile 0.4 and 0.06, Quantec LX and SC (Analytic Endodontics, Glendora, CA, USA), and HERO 642, in particular by experiments from Dummer's group^{452,481-488} using plastic blocks. Taken together, these studies demonstrated an impact of canal geometry on outcome: the more severe the angle and radius of the curve, the more severe the canal transportation. On the other hand, there was no significant effect of canal shape on preparation times.

Furthermore, file design was crucial to avoid preparation errors: actively cutting tips such as with Quantec SC and LX^{452,488} produced more aberrations than instruments with noncutting tips.^{450,451,488-492}

The direction of apical canal transportation varied, but occurred mainly outward in relation to the canals' curve; the total amount of canal transportation varied significantly, again in relation to canal geometry, and ranged in most cases between 0.01 and 0.150 mm.^{452,481-488}

Compared to stainless steel hand files, NiTi instruments were superior in their shaping ability.^{493,494} Schäfer et al. reported that HERO 642,⁴⁹⁵ FlexMaster (VDW, Munich, Germany),⁴⁹⁶ and K3 instruments⁴⁹⁷ maintained the original canal path in curved plastic blocks better compared to stainless steel hand instruments. They found little incidence of canal aberrations and material removal in excess of 0.15 mm in less than 50% of the levels analyzed for HERO, FlexMaster, and K3,⁴⁹⁵⁻⁴⁹⁷ while hand instrumentation resulted in significantly greater material removal (up to 0.69 mm).⁴⁹⁷

ProTaper instruments prepared curved canals in plastic blocks in less time and with no definite canal aberrations, but with a larger amount of material removed, compared to GT Rotary, Quantec, and ProFile 0.04 and 0.06 instruments.⁴⁹⁸ In a study using another brand of plastic blocks, Hata et al. found overly long preparation times (>250s) for ProFile 0.04 and 0.06, GT Rotary, and in particular for "Balanced Force" instrumentation.³³⁰

Instrument shaft design did not significantly modify shapes of similar apical sizes in one series of studies,^{461,462} while it is generally held that a thin flexible shaft will allow larger apical shapes with less aberrations.^{9,472} In contrast, ProFile 0.04 instruments alone removed more material compared to a combination of ProFile 0.04 and 0.06.³³⁰

Cutting blade design was modified lately from passive, so-called U-file designs to more actively cutting triangular ones in instruments such as ProTaper, FlexMaster, K3, HERO 642, and RaCe. However, while there is only limited evidence for each individual file,^{462-464,495,496,499,500} the introduction of actively cutting cross sections does not appear to negatively affect centering abilities.

K-files used in most techniques, with the exception of "Balance forces," performed inferior to NiTi rotary in vitro.^{290,292,501-503} Clearly, reaming produced rounder canal shapes in cross section,⁵⁰⁴⁻⁵⁰⁶ which may be desirable as long as a canal may be reasonably prepared round.

Handpieces with noncontinuous rotation have also been extensively tested, and some are better in cutting efficiency, some in following narrow curved canals, some in producing smooth canals, and some in allowing irrigation and smear layer removal.^{398,423,507-514} While all of the automated devices may be occasionally useful, none has proved to be outstanding; currently NiTi rotary instrumentation is widely believed to be a better choice for root canal preparation.

As stated earlier, rotary instrumentation is potentially associated with an increased risk of instrument breakage.^{349,515-518} Substantial work has been done in vitro to elucidate the fracture mechanisms involved (see Box 2); however, the clinical impact of instrument fractures is less well documented and does not lend itself to assessment in prospective clinical studies.

Currently available evidence for outcome studies regarding the impact of file breakage, as recently reviewed by Parashos and Messer,³⁴⁹ relates mainly to the pre-NiTi era, with few exceptions.^{518,519} For example, Strindberg¹³¹ using very stringent criteria in his comprehensive outcome study found a 19% higher incidence of failure when a file fragment was retained. He speculated that infection of the root canal apically of the retained fragment would render the prognosis poorer. On the other hand, a retrospective analysis by Crump and Natkin⁴⁵⁴ of the outcomes of root canal treatments done by dental students revealed instrument fractures in 178 out of approximately 8,500 cases. Matched control cases of the same cohort without instrument fracture had statistically similar outcomes when cases were evaluated as "success," "failure," or "uncertain," based on clinical and radiographic criteria. In fact, the success rate was slightly higher in the cases with retained fragments (81.2% versus 73.6%, $p>0.05$).

In a retrospective assessment of 66 cases with broken instruments, Grossman⁵²⁰ found over a recall

period of up to 5 years, that out of cases without pre-existing apical periodontitis (47/66) about 90% stayed healthy and only 2 showed signs of a lesion. Of the 19 cases with a diagnosis of apical periodontitis, however, healing occurred only in 9 cases. Similar results were reported by Fox et al.⁵²¹ referring to 204 cases with accidentally broken files, out of which only 12 were scored as failures.

In a recent study on 8,460 cases, Spili et al.⁵¹⁸ found overall a 3.3% prevalence of instrument fractures but a prevalence of 5.1% after the introduction of NiTi rotaries (4.4% NiTi versus 0.7% stainless steel). However, success rates were similar for teeth with and without a retained instrument fragment (91.8% versus 94.5%). Moreover, if an instrument fractured in a tooth with existing apical periodontitis, the healing rate would be lower (86.7% versus 92.9%), but this difference was not significant. Similarly, Wolcott et al.⁵¹⁹ in an analysis of 4,652 cases found an overall fracture incidence of 2.4% using ProTaper instruments; however, they did not report on clinical outcomes of these cases.

From the described outcome studies, fractures that developed early compared to late during cleaning and shaping may be viewed differently, regarding the potential to remove microbes from the root canal space. Irrigant efficacy is affected by the amount of canal enlargement;^{9,10,222} therefore, a fragment lodged in the canal before sufficient enlargement has taken place may render canal disinfection ineffective. In case of corrosion^{356,358,522} of the retained fragment, changed ion concentrations in the microenvironment may inhibit microorganism growth.⁵²³ At least this partially explains acceptable outcomes, even in the presence of retained instrument fragments.³⁴⁹

Opinions vary over the risk and incidence of rotary instrument fractures, but even without solid clinical data it is generally thought that NiTi rotary fracture incidence is higher when compared to stainless steel hand instruments. The impact of these fractures on healing probabilities⁵²⁴ is not clear.³⁴⁹ In fact, consequences of a retained or removed instrument fragment are part of a complex array of impact factors governing the spectrum of clinical outcomes. Therefore, an immediate attempt to remove a fractured root canal instrument is mainly indicated if the coronal aspect of the fragment is visible, aided by magnification, and if there is microbial contamination apical to the fragment. A fragment position apical to a major curve significantly decreases the potential of successful removal.^{525,526}

In summary, available evidence from recall studies would suggest to take a conservative approach after a

fracture of a root canal instrument: (1) when a pre-operative diagnosis of irreversible pulpitis and hence a noncontaminated root canal system had been made; (2) if the instrument fractured very late in the procedure, after a sufficient attempt for canal disinfection had been done; and (3) if the instrument fractured apical to a significant curve. For a detailed account of techniques for instrument removal, the reader is referred to Chapter 31, "Retreatment of non-healing endodontic therapy and management of mishaps".

Nontraditional Techniques

Besides hand and rotary instruments, lasers have been proposed for root canal preparation for some time and is still contemplated by some authors today.⁵²⁷ On the other hand, if no enlargement of the root canal system was required for disinfection and root canal filling, no preparation errors could be made; this may be possible with the so-called noninstrumentation technique.⁵²⁸ Finally, ongoing research is aimed at changing the paradigm of root canal preparation for disinfection and filling altogether, with the potential of seeding stem cells or at least allowing local cell population to recolonize endodontic spaces.⁵²⁹

LASER-ASSISTED CANAL PREPARATION

Early studies of the effects of lasers on hard dental tissues were based simply on the empirical use of available lasers and an examination of the tissue modified by various techniques. Lasers emitting in the ultraviolet, visible (i.e., argon laser, wavelengths of 488 and 514 nm), and near infrared (i.e., neodymium:yttrium–aluminum–garnet laser, 1.064 μm) are weakly absorbed by dental hard tissues, such as enamel and dentin.^{530,531} Nd:YAG laser energy, on the other hand, interacts well with dark tissues and is transmitted by water. Excimer lasers (193, 248, and 308 nm) and erbium lasers ($\sim 3.0 \mu\text{m}$) are strongly absorbed by dental hard tissues.^{530,531} Studies have been conducted evaluating the effects of laser irradiation inside root canals. The authors have discussed laser endodontic therapy, some as supplementary and others as a purely laser-assisted method.⁵³²

Applications of lasers in endodontic therapy have been aggressively investigated over the last two decades, and this is discussed in more detail in Chapter 26E, "Lasers". Briefly, there are three main areas in endodontics for the use of lasers: (1) hard tissue, (2) root canal surface, and (3) the periapex. Obviously, laser light travels straight; therefore, specific light-

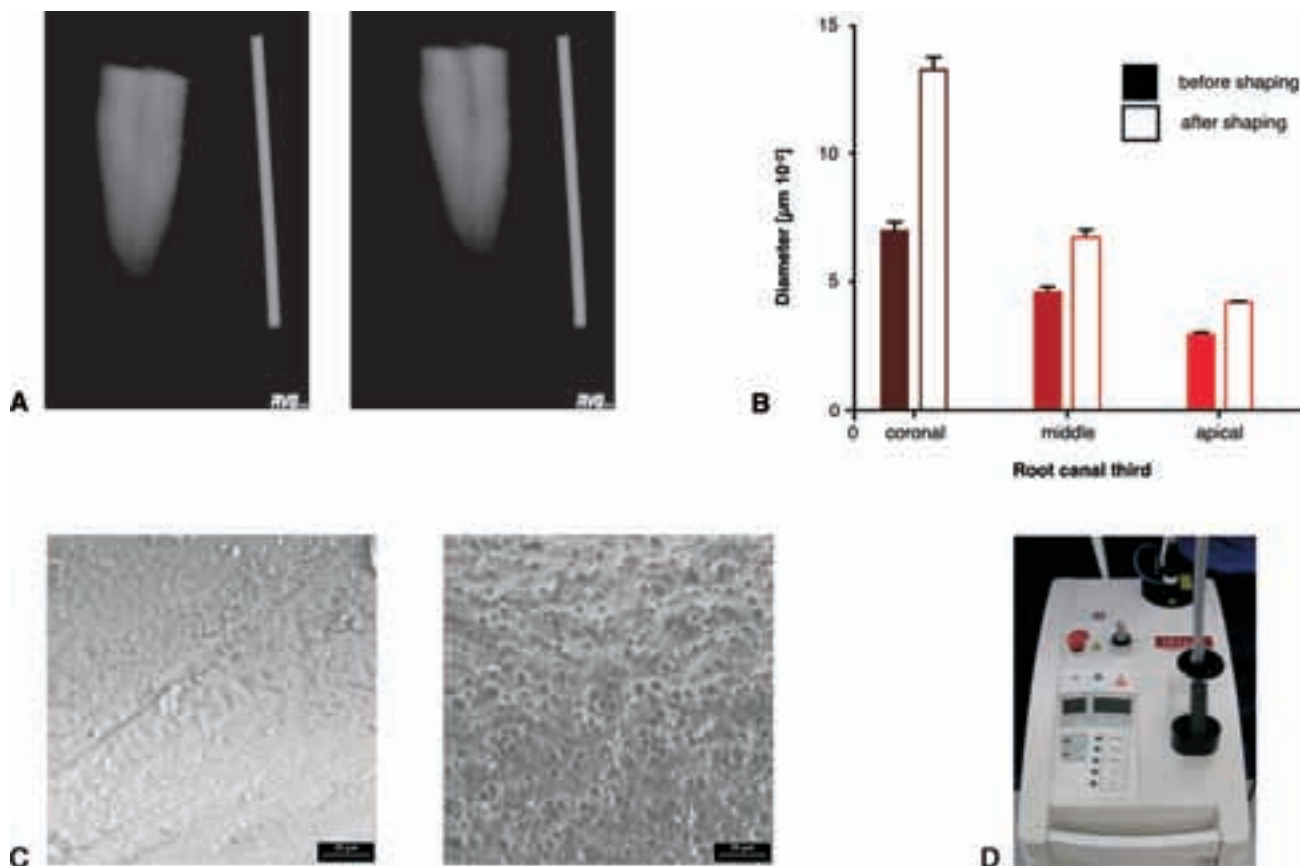

Figure 69 Shaping of single-rooted teeth in vitro using an Er:YAG laser. **A**, Canal diameters compared using standardized radiographs. **B**, Bar diagram showing mean (\pm SD) canal diameters before and after shaping. **C**, Scanning electron micrographs of lased apical canal surface (left) and control after rotary instrumentation (right). **D**, Er:YAG laser used in the study. Images courtesy of Dr. Mark Roper.

emitting probes have been developed to direct laser energy not only into straight but also into curved root canals. Enlargement and cleaning of straight canals with an Er:YAG laser was found to be effective and in fact faster than with step-back preparation with K-files.⁵²⁷ However, shaping curved root canals, independent of the probes used, has not been satisfactory (Figure 69).

Several authors have reported better removal of debris, for example, using an erbium:YAG laser,^{533,534} although areas covered by residual debris could be found where the laser light did not get into contact with the root canal surface.⁵³⁵ An erbium:YAG laser was more effective in debris removal (Figure 70), producing a cleaner surface with a greater number of open tubules when compared with a Nd:YAG laser and an unlased control without laser treatment.

Nd:YAG laser-irradiated samples presented not only with melted and recrystallized dentin and smear

layer removal but also with charring in light microscopic images.⁵³⁶ However, SEM evaluation showed specific patterns for erbium:YAG and Nd:YAG irradiation as a result of different mechanisms of laser--tissue interaction by these two wavelengths.^{533-535,537}

Dederich et al.⁵³² used a Nd:YAG laser to irradiate the root canal walls and showed melted, recrystallized, and glazed surfaces. The process of melting and recrystallizing root canal surfaces was hoped to create a clean and less penetrable canal.⁵³⁸ Laser energy transferred into canal surfaces, when sufficient to melt dentin, may overheat the periodontal ligament also. Bahcall et al.,⁵³⁹ for example, investigated the use of the pulsed Nd:YAG laser to clean root canals. Their results showed that the Nd:YAG laser may cause harm to the bone and periodontal tissues by overheating, which was also suggested by others.^{536,540,541} According to Hibst et al.,⁵⁴² the use of a highly absorbed laser light tends to localize heating to a thin layer at the sample surface, thus minimizing the absorption depth.

Figure 70 Intracanal dentin surfaces (apical third) under scanning electron microscope (SEM) (orig. mag. x1500) after laser treatment. **A**, Dentin treated with erbium:YAG laser (100 mJ, 15 Hz). Note effective debris removal. **B**, Control, unlasered dentin surface. **C**, Dentin surface treated with Nd:YAG laser (80 mJ, 10 Hz). Note melted and recrystallized dentin surface. Reproduced with permission from Cecchini SCM et al.⁵³⁷

Consequently, the risk of subsurface thermal damage may decrease since less energy is necessary to heat the surface.⁵⁴³

One of the limitations of the laser treatment was demonstrated in a study by Harashima et al.⁵⁴⁴ Where the (argon) laser optic fiber had not touched or reached the canal walls, areas with clean root canal surfaces were interspersed with areas covered by residual debris. Access into severely curved roots and the cost of the equipment are other limitations. Finally, operator and patient safety are of concern in the application of lasers in endodontics; safety precautions include safety glasses specific for each wavelength, warning signs, and high-volume evacuation close to the treated area.

NONINSTRUMENTATION TECHNIQUE

Based on the premise that optimal cleansing of the root canal system is a prime prerequisite for long-

term success in endodontics, Lussi et al.²⁴⁶ introduced a minimally invasive approach for removing canal contents and accomplishing disinfection that did not involve the use of a file (the noninstrumentation technique or NIT). This system consists of a pump, a hose, a special valve, and a connector that needs to be cemented into the access cavity (Figure 71). Cleaning action is then provided by oscillations of the irrigation solution (1% to 3% NaOCl) at a reduced pressure. Cavitation likely loosens the debris and NaOCl dissolves viable and necrotic tissue components that are then removed by suction from the low pressure. It needs to be stressed that this system is different from other recently proposed active irrigation systems,^{545–547} since the latter techniques still rely on mechanical shaping prior to the use of irrigation while a canal undergoing NIT is not enlarged.

The evolution of the technique over the years^{548,549} has resulted in good cleaning ability in vitro. However, clinical moisture control and filling

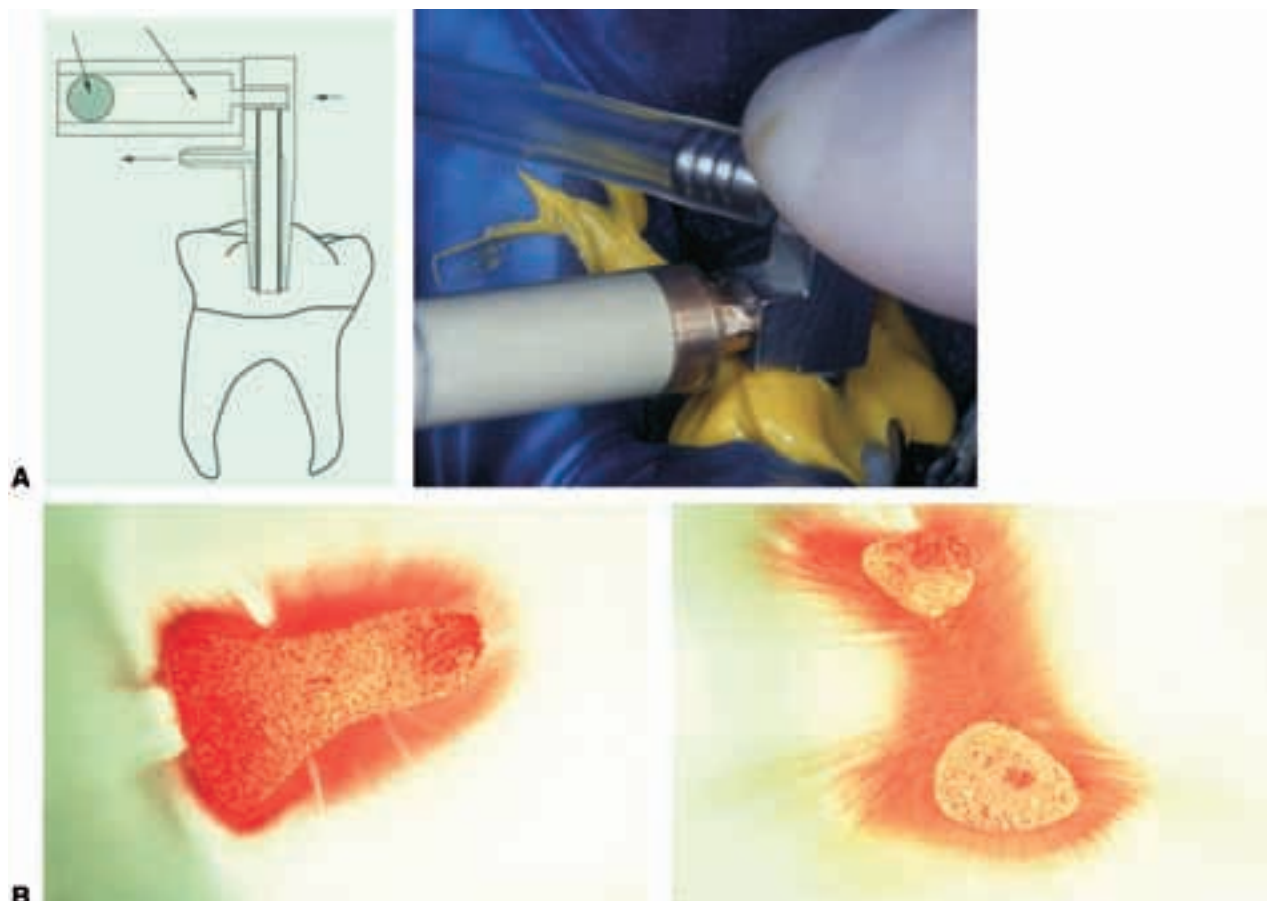

Figure 71 Application of the noninstrumentation technique for root canal cleaning and filling. **A**, Principle and clinical placement of the tubing system. The pump is connected to a tubing system and via a three-way valve to a cannula. This cannula is sealed into the access cavity with impression material to provide an air-tight system. **B**, After removal of the soft tissue with oscillating pressure waves of sodium hypochlorite (NaOCl), highly viscous sealer is delivered into the canal system at low pressure. Micrographs show adaptation of sealer at canal walls and also diffusion of sealer stained with red dye into the dentinal tubules. Images courtesy of Prof. Adrian Lussi.

root canal system, while possible,^{550,551} is not straightforward. Moreover, preliminary *in vivo* results are mixed and the technique is currently not commercially available.²⁴⁷

Canal Surface Modification

It has been established that mechanical canal preparation¹⁴² alone cannot predictably remove microbial canal contaminants and therefore irrigation with antimicrobial solutions is recommended. The effect of various irrigants and medicaments is described in Chapter 28, “Irrigants and Intracanal Medicaments” but some issues pertinent to canal preparation will be detailed below.

In addition to the removal of soft tissue and microorganisms, the canal surface is modified by irrigation

solutions.⁵⁵² Canal surface after shaping with mechanical instruments is characterized by an irregularly distributed layer of soft and hard tissue debris that is smeared onto dentin surfaces (Figure 72).^{553–555} This 1- to 5- μm -thin superficial structure consists of two separate layers: a loose superficial layer and an attached layer that also extends into dentinal tubules to form occluding plugs.⁴²¹ A smear layer consists of several components: dentin “mud,” remnants of odontoblastic processes, pulp tissue, and microorganisms.⁵⁵⁴ Its appearance and structure differs depending on the contacting instrument’s cutting action: more actively cutting blades shear off dentin leaving thinner smear layer, while U-blade designs tend to burnish a thicker smear layer deeper into dentinal tubuli.^{556,557}

The question as whether to leave the smear layer *in situ* on the canal walls or to remove it has been a

Figure 72 Appearance of root canal walls in a scanning electron micrograph. The smear layer was partially removed; there is a thin smear layer present in the area that was touched by an instrument (left half). Hard tissue debris and pre-dentin calcospherites (arrowhead) were present in the area that was not instrumented but had soft tissue removed by sodium hypochlorite (right half).

matter of debate for more than 50 years. For example, some authors reported that the presence of a smear layer delays but does not eliminate disinfection,⁵⁵⁸ it may also increase microleakage after canal obturation.⁵⁵⁴ In contrast, other researchers suggested that the presence of a smear layer, while acting as a barrier, might block irrigation solutions from entering the dentinal tubules.^{555,559} Others reported that a smear layer might act as a beneficial barrier preventing microorganisms from entering dentinal tubules when a root canal is contaminated between appointments. Their microbiological analyses of split root halves showed that the early removal of the smear layer may lead to significantly higher bacteria counts.⁵⁶⁰

Smear layer removal may be accomplished by various chemicals, as suggested over the last 50 years (Table 12), ranging from EDTA³⁸² to bisphosphonates.⁵⁵² Earlier studies had suggested a synergistic mechanism with EDTA removing the organic smear layer and then subsequently allowing NaOCl better access to deeper calcified layers;¹⁴⁵ recent work has demonstrated that EDTA and NaOCl show chemical interactions;³⁷³ similar interactions were demonstrated between citric acid and NaOCl.⁵⁵² These interactions greatly reduce NaOCl efficacy and suggest attention to irrigation sequencing. In fact, the often cited “bubbling” that occurs between EDTA and NaOCl suggests that the active component of NaOCl, chlorine, is released from the solution and hence does not actively kill microorganisms.

Salvizol is another root canal chelating irrigant that has a broad spectrum of bactericidal activity. This

gives the product a cleansing potency while being biologically compatible.⁵⁷⁰ Kaufman⁵⁶⁷ reported the success of several cases using bis-dequalinium acetate as a disinfectant and chemotherapeutic agent. He cited its low toxicity, lubrication action, disinfecting ability, and low surface tension, as well as its chelating properties and low incidence of posttreatment pain.

Table 12 Available and Potential Solutions and Pastes for Smear Layer Removal.

Reference	Year	Chemical
Baumgartner ⁵⁶¹	1984	Citric acid 10%
Wayman ⁵⁶²	1979	Citric acid 20%
Tidmarsh ⁵⁶³	1978	Citric acid 40%
Nygaard-Østby ³⁸²	1957	EDTA (15%, ethylenediamineacetate)
Fehr ³⁸³	1963	EDTAC (15% EDTA plus cetrimide)
Stewart ⁵⁶⁴	1969	RC Prep (Premier Dental, Philadelphia, PA) (10% urea peroxide, 15% EDTA) [†]
Koskinen ⁵⁶⁵	1975	Tubulicid (38% benzalkonium chloride, EDTA, 50% citric acid)
Koskinen ⁵⁶⁶	1980	Largal Ultra (Septodont, Paris, France), 15% EDTA, cetrimide, NaOH)
Kaufman ⁵⁶⁷	1981	Salvizol (Ravensberg, Konstanz, Germany), 5% aminoquinaldinium diacetate, propylene glycol
Berry ⁵⁶⁸	1987	40% polyacrylic acid
Torabinejad ⁵⁶⁹	2003	MTAD (Densply Tulsa Dental) (4.25% citric acid, 3% doxycycline, 0.5% Tween 80)
Zehnder ⁵⁵²	2005	HEBP (7% 1-hydroxyethylidene-1, 1-bisphosphonate)

[†]Other preparations are similar, for example, Glyde (Dentsply Maillefer), File Care (VDW), FileEze (Ultradent), except for the base that could be carbowax or glycerine.

Salvizol, as well as several EDTA formulations, contains surface-active substances that are supposed to increase wetting and hence chelating action. There are conflicting reports regarding the benefits of such surface-active components such as Tween 80.⁵⁷¹⁻⁵⁷⁴

MTAD, commercially available as BioPure (Dentsply Tulsa Dental), contains citric acid and doxycycline as decalcifying substances and has been shown to effectively remove the smear layer;^{569,575} moreover, it was shown to be effective against *Enterococcus faecalis*.^{576,577} However, others report that 1.3% NaOCl/MTAD is less effective than 5.25% NaOCl/15% EDTA;⁵⁷⁸ moreover, understanding of its effect on outcomes is limited at this point.⁵⁷⁹

Recently, substances such as bisphosphonates⁵⁸⁰ and sodium triphosphate⁵⁵² have been investigated as potential chelators. While no significant interaction between these substances and NaOCl activity was found, the potential of these experimental chelators to remove the smear layer, measured both as smear layer scores and amount of dissolved calcium, is lower than

that of EDTA and citric acid.⁵⁵² A gel-based formulation of a bisphosphonate, however, may offer advantages in the initial phase of root canal instrumentation with hand files.^{372,580} Finally, the organic component of dentin undergoes modifications in contact with NaOCl,^{581,582} while EDTA may lead to erosions.^{575,583} Taken together, these results suggest that chelators and concentrated NaOCl do have beneficial effects but should be used with a clear understanding of potential harmful effects to the substrate.⁵⁸⁴

IRRIGATION DYNAMICS

As stated earlier, the relationship between prepared canal shapes and irrigation needle size is important for apical irrigation (Figure 73).^{10,146,150,224} On the other hand, canal preparation itself produces dentin chips of various sizes⁵⁸⁵ that need to be removed. These chips are part of what is described as unclean canals when observed in a SEM and should be removed by irrigation.

Figure 73 Effect of different irrigation needle sizes and canal diameters on needle position. **A**, Light micrographs of irrigation needles of size 27 and 30 gauge (0.4 and 0.31 mm). **B**, Mandibular canine shaped with ProTaper instrument S2 and then F2, corresponding to apical diameters of size #17 and #25. Shown are the insertion depths of both needles without binding in the canal.

Irrigation is commonly applied by a syringe and a needle, with needle sizes varying typically between 27 and 30 gauge (see Figure 73), 0.635 and 0.305 mm, respectively. With such a system, irrigation solutions will not travel apically more than 1 mm beyond the tip of the needle.^{307,586} While it is therefore desirable to place the irrigation needle into the shaped root canals, the needle must not be locked in to avoid expressing the irrigation solution into periapical tissues. Serious incidents have been reported following NaOCl expressed into maxillary sinus or close to nerves.⁵⁸⁷⁻⁵⁹⁰

With careful use, the benefits of deep intracanal irrigation clearly seem to outweigh the risks.⁵⁹¹ In fact the proximity of the irrigation needle to the apex plays an important role in removing root canal debris.⁵⁹² Druttman and Stock⁵⁹³ found that irrigation performance varied with the size of the needle and the volume of the irrigant, while Walton and Torabinejad⁵⁹⁴ stated in their textbook that perhaps the most important factor is the delivery system and not the irrigating solution per se.

Canal size and shape are crucial to the penetration of the irrigant. The apical 5 mm are not flushed until they have been enlarged to size #30 and more often size #40 file.^{146,595-597} Small-diameter needles were found to be more effective in reaching adequate depth but were more prone to problems of possible breakage and difficulty in expressing the irrigant from the narrow needles.⁵⁹¹

Recently, Hsieh et al.²²⁴ compared a shaped root canal to a “wind tunnel” and evaluated the behavior of irrigation solutions deposited into various depths of flared canals from irrigation needles measuring from 23 to 27 gauge. They showed that an undisturbed laminar flow of irrigants occurred with a combination of sufficiently enlarged canals, deep needle insertion, and small needle diameter, for example, a 27-gauge needle placed 3 mm from the apex in a canal prepared to size #30. Similar observations had been made earlier in experiments using radiopaque irrigation solutions (Machtou P, personal communication).

Several methods have been devised to increase irrigant turnover and overall efficacy. As mentioned

earlier, the use of ultrasonic or sonic irrigation to remove dentin filings, debris, and bacteria from root canals has been well documented (Figure 62 and Figure 74).^{123,147,222,351,417,598,599}

However, there are doubts that passive ultrasonically or sonically assisted irrigation can in fact remove all contaminants.^{600,601} While the time frames and sequence of irrigation solutions is still a matter of debate,^{149,602} the cleanest canals were produced by irrigating with ultrasonics and NaOCl after the canal has been fully prepared. Ultrasonics was shown to be superior to syringe irrigation alone when the canal was prepared to 0.3 mm (size #30 instrument).⁶⁰³

Several novel strategies have been proposed to increase irrigation efficacy. Gutarts et al.⁵⁴⁶ evaluated the use of a 25-gauge irrigation needle, connected to an ultrasonic unit, through which 6% NaOCl was delivered for 1 minute at the conclusion of canal shaping. They reported significantly cleaner canals compared to a control group that did not receive ultrasonic irrigation.

Irrigation with positive pressure has also been tried, for example, with the system RinsEndo (Duerr, Bietigheim-Bissingen, Germany). However, reports for this particular device are sparse;⁶⁰⁴ moreover, there is a potential for apical extrusion of NaOCl, and the necessary precautions should be taken.

More recently, Fukumoto et al.⁵⁴⁷ described an experimental system that consisted of a washing needle, placed just into the root canal, and a 27-gauge aspiration needle, ground flat at the tip and placed deep into the shaped root canal. Irrigants, 14% EDTA and 6% NaOCl, were aspirated at ~20 kPa; their results showed superior smear layer removal compared to a control group that received conventional irrigation with a needle of the same diameter.

This system is similar to a patent submitted by Schoeffel⁵⁴⁵ with the exception that his system does not include a constantly operating washing line (Figure 75). Irrigant is deposited into the access cavity; then, two sequentially operated and specially designed aspiration needles are placed into the shaped root canal. Preliminary data suggest good cleaning

Figure 74 Canal surfaces as seen in scanning electron micrographs. **A**, Typical appearance after cleaning and shaping with wall areas that has instrument contact and some smear layer removal as well as uninstrumented areas with calcospherites as part of the mineralization front in predentin (arrow). **B**, Uninstrumented canal that was washed with 5.25% sodium hypochlorite (NaOCl). **C**, Canal wall segment presenting with all dentinal tubules open. **D**, Completely shaped canal wall area with a thin remaining smear layer. Bars are 30 μm .

capacity;⁶⁰⁵ however, currently no published results are available regarding clinical outcomes using these new irrigation techniques.

Currently, ultrasonically activated passive irrigation seems to be the standard until more experimental techniques are scientifically evaluated and brought to the market. However, as mentioned earlier, using an ultrasonically activated insert deep in a root canal

carries some risk (see Figure 63). Furthermore, more work is needed to clarify insert shapes and materials as well as activation times and power settings.

PHOTODYNAMIC THERAPY

While lasers are probably not a good alternative for mechanical root canal preparation, they have been

Figure 75 The EndoVac system (Discus Dental) for apical negative pressure irrigation. Recent in vitro results demonstrate better debridement compared to conventional syringe irrigation.⁶⁰⁵ **A**, Overview of the micro cannula demonstrating a closed rounded tip and an array of 12 openings in the apical end (inset, bar is 250 μm). **B**, Light microscopic images of canals irrigated with conventional syringe (left) and with the EndoVac system (right). Orig. mag. x100. Images courtesy of Dr. John Schoeffel.

shown to be effective for canal disinfection and canal surface modification, as reviewed in detail in Chapter 26E, “Lasers”. In this context, the use of lasers for photoactivated disinfection, also known as photodynamic therapy, has been promoted.^{606–608} This technique does not provide canal enlargement but assists in the eradication of intracanal microorganisms. Photodynamic therapy is well known as a treatment for cancer and other diseases⁶⁰⁹ and is based on the concept that a nontoxic photosensitizing agent can be preferentially localized in target tissues. The agent is then activated by light of appropriate wavelength to generate reactive molecules that in turn are toxic to cells of the target tissue.⁶⁰⁹ Visible light can also kill bacteria in root canal systems after treatment with an appropriate agent (Kishen A, personal communication).

Such photoactivated disinfection has only recently been explored to treat bacterial infections in humans.⁶⁰⁶ A wide range of oral bacteria could be killed by red light after sensitization with toluidine blue and methylene blue.⁶¹⁰ More than 400 photoactive substances are known that can be combined with lasers tailored to their specific wavelengths of absorption. Potentially one of these substances will be able to penetrate into the root canal system better than currently available irrigants. In fact, partial inactivation of *Streptococcus intermedius* biofilms in root canals of extracted teeth using toluidine blue and light applied at the orifice level has been recently reported.⁶¹¹

Clinically, the photoactivated agent is used as an irrigant after mechanical canal enlargement (Figure 76) and activation; root canal filling is accomplished

Figure 76 Use of photoactivated disinfection in a case of post-endodontic disease. The existing root canal filling was removed (Arrowhead) and the canals reshaped with ProFile instruments (upper panel). Then, toloum chloride (also known as toluidine blue O) was placed in the root canal system and irradiated with a diode laser (lower panel, also showing root canal filling after retreatment). Images courtesy of Prof. Paul Lambrechts.

conventionally. This technique is experimental and its impact on clinical outcomes needs to be evaluated.

Conclusion

The past decade has brought significant changes to root canal preparation, for example, the use of rotary

NiTi instruments and magnification. These techniques have allowed more complicated root canal treatment to be undertaken safely and successfully (Figure 77). The way educational content is delivered is also changing: private educational institutions are taking the lead in presenting information to clinicians. Moreover, electronic media and web-based content have gained more widespread acceptance. Using these

Figure 77 Routine cases of second maxillary and mandibular molars that had coronal and radicular preparation done adhering to the principles laid out in this chapter. Radiographs represent situation immediately after root canal filling.

avenues, evidence-based information will reach clinicians who at present have limited access to book, journals, or hands-on teaching.

Aseptic techniques are a prerequisite for successful endodontic therapy as they are in the goal of eradicating the causative microbial flora (Figure 78). Asked for any particular direction for development in the next decade, disinfection and systems to increase its efficacy are the most likely candidates. Seemingly exotic applications such as the use of ozone (e.g., Healozone, KaVo, Biberach, Germany) or high-frequency

current (Endox, Lysis, Nova Milanese, Italy)⁶¹² or photoactivated disinfection may be utilized more; however, it will be difficult to prove with statistical methods that any individual device will have significant and clinically relevant impact.

Regarding instrument and strategies, new materials may appear, such as more durable and flexible alloys or plastic materials, but the basic strategy will likely remain the same in the next decade: enlargement for subsequent disinfection and filling. The long-term goal is certainly to replace root canal therapy, as part

Figure 78 Aseptic techniques and disinfection of the root canal system. **A**, Swabbing of the operation site, for example, with sodium hypochlorite (arrow), while marginal imperfections of the rubber dam seal are corrected with a caulking material (e.g., Oraseal, Ultradent). **B**, Reservoir of sodium hypochlorite (NaOCl) is always present in the access cavity during hand and rotary instrumentation to promote disinfection and lubrication.

of current repair methods, with tissue-engineering strategies that provide healing in the sense of a *restitutio ad integrum*.

ACKNOWLEDGMENT

The authors would like to express their special gratitude to Vickie Leow, Master Graphic Designer at the UCSF School of Dentistry, as well as Anjan Lall for their expert help with the schematic drawings used in this chapter.

CHAPTER 28

IRRIGANTS AND INTRACANAL MEDICAMENTS

MARKUS HAAPASALO, WEI QIAN

Infection Control in the Human Body

Successful elimination of opportunistic infections in most parts of the human body usually requires only involvement of normal host defense mechanisms. Occasionally, a systemic antibiotic therapy or manipulative treatment (such as drainage of pus) is applied in addition in order to resolve the infection. Elimination of endodontic infection, however, follows a different pathway. Host measures that are sufficient to eliminate the infective microorganisms in other sites are unable to completely eliminate endodontic infections. Because of the special anatomical challenges, control of an endodontic infection must be built on a joint effort by a number of host and treatment factors.¹⁻³ Success in all parts of treatment will be needed for elimination of infection and healing of periapical pathosis. The sequence of events and procedures in the control of endodontic infections are host defense system, systemic antibiotic therapy (rarely used with specific indications only), instrumentation and irrigation (“cleaning and shaping”), intracanal medicaments used between appointments, permanent root filling, and coronal restoration.¹⁻³

Host defense is responsible for the prevention of spreading canal infections to the bone and to other parts of the body. The body defense is usually successful in stabilizing the lesion size and preventing its expansion after the initial growth period. However, because of the lack of circulation, host defense mechanisms cannot effectively reach the microbes residing inside the tooth in the necrotic root canal system. Mechanical instrumentation removes a portion of the microbes from the main root canal space, but its main purpose is to enhance irrigation and the placement of medication and the root filling. Irrigation supports mechanical instrumentation, by reducing friction and removing dead and living microbes from the root canal. In addition, many irrigating solutions have antimicrobial activity that effectively

kill residual microbes in the canal. Intracanal antimicrobial medicaments, on the other hand, are used in multi-appointment endodontic treatments to complete the work started by instrumentation and irrigation and, optimally, to render the root canal system bacteria-free.

The classical study by Sjögren and his colleagues⁴ and by others indicated that a bacteria-free canal at the time of filling is a prerequisite for high success rate and that calcium hydroxide [Ca(OH)₂] as an intracanal medicament will predictably help reach this goal.⁵⁻⁷ A number of other studies, however, have challenged these results, and at present, there is no clear consensus regarding the use of intracanal medicaments, or the microbiological and other advantages from their use.⁸⁻¹⁰

In this chapter, the focus is on the role of irrigation and intracanal medication in killing and reducing the number of bacteria in the root canal system. It is important, however, to understand that irrigation and local antibacterial dressings in the root canal are part of a concerted effort to control endodontic infections. Alone they cannot guarantee success if there are problems in quality of some other parts of the treatment.

Complete Elimination of Microbes in the Root Canal System

Pulpitis is caused by microbial antigens entering the pulp from a carious lesion or a leaking filling through dentinal tubules. As long as the pulp remains vital, the number of bacteria in the pulp is considered minimal and of no clinical significance. However, with proceeding infection, necrosis and apical periodontitis, the entire root canal system becomes invaded by bacteria. It has been shown beyond doubt that microorganisms are the etiological factor of apical periodontitis (Figure 1).¹¹⁻¹³ It has been suggested that, in a small

Figure 1 Bacteria are the etiological factor of apical periodontitis. Six-week-old biofilm on the main root canal wall created by a mixed culture of oral bacteria under anaerobic conditions. Notice that several cells have died (hollow cells) because of limited availability of nutrients.

number of cases, non-microbial factors are responsible for the persistence of the lesion after treatment.^{14,15} Nevertheless, there is general consensus that, in an optimal situation, the goal of endodontic treatment is to remove and kill all microorganisms in the root canal and to neutralize any antigens that may be left in the canal after killing the microbes. Reaching this goal is expected to guarantee healing of periapical lesions. It has become obvious that complete destruction of root canal microbes is a particularly difficult challenge. On the other hand, in a high number of cases, high quality treatment is followed by complete healing.¹⁶⁻¹⁸ It has also been shown that a majority of cases harboring living bacteria at the time of filling healed completely.⁴ It is clear, therefore, that although destroying 100% of the infective flora is the optimal goal, complete clinical and radiographic healing can also occur when the microbiological goal of treatment has not been fully realized. The situation may be compared to marginal periodontitis and gingivitis, where it is not possible to gain a totally bacteria-free environment in the gingival

crevice area. Periodontal treatment of good quality, however, results in healing of the periodontal disease.

The Goal of Endodontic Treatment

The goal, with the great majority of teeth requiring root canal treatment, is either the prevention or treatment of apical periodontitis.¹⁹ In other words, the goal is prevention or elimination of a microbial infection in the root canal system. In some special situations, such as resorptions and endodontic complications, there may be a variety of intermediate goals of a more “technical” nature. Even then, the final success is dependent on successful infection control. There is a widely accepted view that cleaning and shaping of the root canal system is the most important step toward a sterile canal free from a microbial presence.

Instrumentation of the Root Canal

The goal of hand and rotary instrumentation and irrigation is to remove all necrotic and vital organic tissue, as well as some hard tissue including dentin chips created by instrumentation, from the root canal system and give the canal system a shape that facilitates optimal irrigation, débridement and placement of local medicaments, and permanent root filling. From a biological point of view, the goal of instrumentation and irrigation is to remove and eradicate the microorganisms residing in the necrotic root canal system. Furthermore, the goal is to neutralize any residual antigenic material remaining in the canal after instrumentation and irrigation.

The Effect of Instrumentation on the Root Canal Microbes

Instrumentation has a key role in the cascade of treatment procedures to eradicate microbes in the root canal system. Instrumentation removes a great number of microbes from the accessible parts of the main root canal by direct mechanical cleaning action. Moreover, instrumentation shapes the root canal in such a way that effective irrigation becomes possible. In other words, instrumentation is a way of mechanically removing microbes from the root canal. In addition, it supports and facilitates mechanical removal and chemical eradication of the infection by irrigation during and following instrumentation.

The classical studies from Umeå, Sweden have greatly influenced our understanding of the effects of instrumentation and irrigation of the intracanal microflora.²⁰ In a series of studies on teeth with apical periodontitis, the authors demonstrated that thorough mechanical instrumentation with hand stainless steel instruments, together with irrigation with either physiological saline, ethylenediamine-tetra-acetic acid (EDTA), or EDTA and sodium hypochlorite (NaOCl), they were unable to predictably produce sterile root canals. Fifteen root canals were instrumented at five sequential appointments and sampled at the beginning and end of each appointment. The access cavity was sealed with a bacteria-tight temporary filling, but the canals were left empty between the appointments. This procedure resulted in a 100- to 1000-fold reduction in bacterial numbers, but it was difficult to obtain completely bacteria-free root canals. Corresponding results were also reported by Ørstavik et al.²¹ and Cvek et al.²² in teeth with closed and immature apices. The antibacterial effect of mechanical cleansing with sterile saline was reported to be very low and limited to the teeth with fully developed roots. NaOCl increased the antibacterial effect as compared with saline irrigation. Interestingly, no statistical difference was found in the antibacterial effect between 0.5% and 5.0% NaOCl solutions.²²

The effects of instrumentation and irrigation were investigated in an excellent series of studies by Dalton et al.²³ They measured reduction in microbial counts in 48 patients, on teeth instrumented with 0.04 taper nickel–titanium (NiTi) rotary instruments or with stainless steel K-files using the step back technique with saline for irrigation. Bacteriological samples were obtained before, during, and after instrumentation. All teeth with apical periodontitis yielded positive growth at the beginning, whereas control teeth with vital pulp and irreversible pulpitis were sterile. A reduction in bacterial counts was detected with progressive enlargement of the root canals with both techniques. However, only 28% of the teeth became bacteria-free following instrumentation.

Similar observations were reported by Siqueira et al.²⁴ when saline was used in irrigation. Interestingly, this study showed that increasing the size of apical preparation from #30 to #40 resulted in a significant reduction in microbial counts. Ex vivo studies by Pataky et al.,²⁵ using 40 human first maxillary premolars extracted for orthodontic reasons, also verified the difficulty of obtained sterility of the infected canal space by instrumentation and saline irrigation. Although a considerable reduction in bacterial counts

was detected after instrumentation, none of the teeth became bacteria-free. It should be mentioned, however, that the size of the master apical file in some of the studies was quite small, #25, and that may increase the possibility of positive cultures.²⁵ It can be concluded that instrumentation and irrigation with saline alone cannot predictably eliminate all bacteria from infected root canals. Therefore, it is not surprising that the focus of activity in root canal disinfection is placed on the development and use of irrigating solutions and other intracanal disinfecting agents with strong antibacterial activity. In addition, there is growing interest in the combined effect of ultrasonic energy and irrigating solutions as well as other new ways of mechanical irrigation.

Root Canal Disinfection by Chemical Means

THE CHALLENGES AND PITFALLS IN STUDYING THE ANTIMICROBIAL EFFECTIVENESS OF ENDODONTIC IRRIGATING SOLUTIONS AND INTRACANAL MEDICAMENTS

In Vitro Models

The testing of the antimicrobial activity of various chemical compounds may appear to be straightforward and simple procedure. In theory, this may be true—the microbes of interest are exposed to the antimicrobial agent to be examined. At certain time intervals, microbiological samples are collected and cultured on suitable media. The results are then expressed as the length of time required to kill all microbes. In reality, regarding endodontic disinfecting agents, it is, however, quite different. Research focusing on the antimicrobial effectiveness of irrigating solutions and temporarily used intracanal medicaments has in many occasions adopted techniques originally designed for some other context, for example, antibiotic susceptibility using agar plates. Testing of systemically used antibiotics is based on tens of years of international standardization.^{26–30} The chemical composition of both the antibiotic discs and the culture media used in testing are defined in detail in order to secure predictable diffusion of the active ingredient of the antibiotic and the absence of chemical reactions between the agar plate ingredients and the antibiotic. Zones of inhibition of growth around the antibiotic disc have been compared through clinical studies to the serum and tissue concentrations that

are possible to reach with safe dosages of low toxicity, as well as the clinical effectiveness of the antibiotics. In addition, reference strains from culture collections with known antibiotic susceptibilities are used as internal standards for quality testing of each new batch of plates. Most aerobic and facultative bacteria can be reliably tested using the disc diffusion method. However, despite years of extensive research, there is still no generally accepted standard for susceptibility testing anaerobic bacteria using the disc diffusion method.³¹

The use of agar diffusion method in endodontics, despite good intentions, is not based on any kind of standardization of the media or the tested materials. Chemical interactions between the media and the disinfecting agents are largely unknown. Furthermore, there are no true comparative studies helping to draw conclusions from the zones of inhibition to the performance of the disinfectants *in vivo*. The antimicrobial effect of some endodontic medicaments is based on the pH effect; therefore, the buffering capacity of the agar plate is in key position in determining the diameter of the growth inhibition zone. Another example is EDTA, that causes a zone of inhibition on an agar plate, but fails to reduce the number of viable microbes even after 24-hour incubation in a test tube. The growth inhibition on agar plates is based on removal of important ingredients from the media by EDTA, that makes the medium unsuitable for growth of many species. Such bacteria, even if alive, cannot multiply on the plate which has been nutritionally altered by EDTA. In conclusion, the information obtained from agar diffusion studies is at best of limited value and should not be used to compare and select disinfecting agents for clinical use.

Another matter of importance in susceptibility testing is understanding the difference between bacteriostatic and bactericidal activities. Bacteriostatic means prevention of growth of the microbial cells. However, they are not killed, unlike when the medicament has bactericidal activity. In endodontic studies, this difference is not always clearly addressed, and the results are often reported as “antibacterial activity.” The agar diffusion test, when properly used, is an example of measuring bacteriostatic activity. In endodontics, a bactericidal effect of a disinfecting agent is more important than a bacteriostatic effect. In the necrotic root canal system, a temporary prevention of bacterial growth (as long as the disinfecting agent remains in the canal) is of limited value, because the microbes may still grow in numbers afterwards causing a new challenge to the host defense.

Testing endodontic disinfecting agents *in vitro* can be done in test tubes using a mixture of the microbes (suspended in sterile water) and the medicament. The presence of a culture medium in the mixture is commonly seen in endodontic literature. However, culture medium or other organic material is a confounding factor: the disinfecting agents vary in their susceptibility to the inactivating effect of the various organic substances.³² Experiments done under such conditions do not give a reliable picture of the characteristics and activity of the medicament/disinfectant against the tested microbe.

“Carry-over effect” means that the medicament, in active form, follows along with the sample into the dilution series and even to the culture plate (or liquid culture), where surviving microbes are calculated [e.g., “percentage of colony forming units (CFU) surviving”]. A high enough concentration of the disinfectant, in such a situation, can cause a false-negative result: the microbes are not killed, but residual medicament in the culture media prevents their growth by a bacteriostatic effect. Thus, carry-over, if undetected, gives a too positive picture of the antibacterial effectiveness of the medicament. Endodontic irrigants and disinfecting agents, containing local antibiotics, are at particularly high risk of causing false-negative results. Effective inactivators are not available for many antibiotics. If they are used in high concentration, carry-over effect is possible even after several 10-fold dilutions.³²

Various inactivating agents are used to prevent the effects of carry-over. Citric acid has been used in the root canal to neutralize $\text{Ca}(\text{OH})_2$, sodium thiosulfate neutralizes NaOCl ,³³ and a mixture of Tween 80 and alpha-lecithin inactivates chlorhexidine (CHX).³⁴ Inactivation, however, is dependent on the concentration of the medicaments. When they are used in high concentration, inactivation may not be complete. A good example of this is CHX that cannot be effectively inactivated with Tween and alpha-lecithin if CHX concentrations of 1% or more are used (Figure 2A). The importance of the careful design of the experiments and proper controls cannot be overestimated, in order to avoid the possibility of false negative results.

Ex Vivo and In Vivo Models

In vitro models give valuable information about the spectrum and antimicrobial potential of endodontic disinfecting agents. However, information from such experiments alone is not enough to predict their performance in a clinical situation in the root canal. The effectiveness of the medicament *in vivo* can be reduced by a variety of factors. These include problems in delivery, low

Figure 2 A, Samples of *Enterococcus faecalis* from 10-fold dilution series after a brief contact with 2% chlorhexidine. Because of short contact time (2 seconds), no killing has taken place. Chlorhexidine (CHX) “carry-over” has prevented growth of the first two samples (arrows) on the plate (upper row, left) despite the presence of Tween-lecithin inactivator in the dilution series. Lower row: control sample with no CHX. If only the first two dilutions had been made, the result would have indicated complete killing of the microbes in just 2 seconds. **B**, The size of the initial inoculum and the length of the dilution series determine the depth of measurement of the colony forming units. In this example, killing effectiveness can be calculated to a level of about 99.99%. Upper row: medicament; lower row: control.

overall volume, poor/incomplete penetration in the main root canal system, poor penetration into dentin, short contact time, or inactivation of the activity of the disinfecting agent by one or more of the chemical compounds present in the necrotic root canal. Therefore, a number of ex vivo and in vivo models have been developed in order to meet the challenge by the various confounding factors of the root canal and to improve the correlation between the test results and clinical performance. The ex vivo and in vivo models include the dentin block model,^{35,36} dentin powder model,^{37–39} and several modifications using roots/root canals from extracted teeth.^{40,41} More studies are also made in vivo during the treatment of endodontic infections.^{42,43}

The dentin powder model, with its modifications, makes it possible to obtain information about the inhibition of the medicament activity by dentin and other compounds (biomolecules, microbial biomass, etc.) in various concentrations.³⁷ It also allows standardization of the experimental conditions for large series of tests. Prolonged incubation time to create dentin infection is not required because the dentin is powdered. The downsides of the powder model include partial loss of the microanatomical structure of the tooth and the difficulty to use/create microbial biofilms. In short, the dentin powder model is an effort to simulate the chemical environment of the tooth.

The dentin block model has been widely used for testing endodontic medicaments.³⁵ The benefits of the model include simulation of the chemical and microanatomical environment of the tooth and the root canal system. The root canal is usually standardized in size, making it easier to obtain compar-

able samples of dentin in different blocks. It also allows the use of microbial biofilms in the experiments. On the other hand, the dentin block model is quite laborious in use; it cannot be fully standardized as different blocks may vary in thickness and dentin microstructure. Handling of the block presents some challenges which may increase the risk for false-positive results (contaminations from outside the sampling area). Despite its limitations, the dentin block model has greatly contributed to our understanding of dentin disinfection, and it is still frequently used in endodontic research.

Newer ex vivo and in vivo models use “natural” root canals either in extracted teeth or directly in vivo. The obvious benefit of these experiments is the more complete simulation of the clinical situation; the results obtained with the various materials may best reflect their true activity clinically. However, in addition to the well-known difficulty to organize controlled clinical studies, and to gather patients for such studies, there are also other potential pitfalls that may weaken the usefulness of the results. These include the difficulty to standardize the size of the apical preparation because of the great natural variation in canal sizes, different total volume of the canals, variations in the microanatomy of the root canals, and differences in the quality and quantity of the microbial infection. In addition to this kind of natural variation, there does not seem to be any standard way of dealing with the smear layer or taking the microbiological samples. According to the treatment protocols, the smear layer has not been removed in a great number of the studies. This is likely to have an effect on the ability of several sampling methods to collect viable

microorganisms left in the dentinal tubules or lateral canals behind the smear layer. In quantitative studies where dentin is sampled, it is difficult to collect equal amounts of dentin (sample) because of the natural variations in canal sizes and shapes and different types of instruments used.

QUALITATIVE OR QUANTITATIVE RESULTS; DETECTION LEVEL: MORE CHALLENGES?

Optimally, the goal of endodontic disinfection is complete eradication of the microbes from the root canal system of the affected tooth. Although difficult to achieve, this noble goal may have affected the study design of several studies as the results are often expressed qualitatively, only as “growth” or “no growth.” This approach may in some cases hide differences in the effectiveness of different treatment protocols and chemicals used for disinfection. For example, two different treatments that cause 10% and 99.95% reduction in bacterial counts per canal, respectively, are reported as equal (“growth”), unless the overall number of “no growth” cases is higher with one of the methods. It is possible that some of the recent poor results with $\text{Ca}(\text{OH})_2$ as a disinfecting agent can be partly explained by the fact that qualitative rather than quantitative approach has been used to measure the effectiveness of the disinfection. Quantitative measurement of the effect by endodontic disinfecting agents should therefore be preferred over qualitative approach. Accordingly, quantitative reporting has been used in some studies.^{32,44}

However, there are a number of factors that create challenges for accurate and comparable counting of microbes in the samples. Residual medicament in dentin may result in a very low number of CFU per sample unless neutralizing agents are properly used. Dispersing the sample effectively may be required to detach the viable cells from the dentin chips, to increase the CFU numbers to correctly reflect the true number of microbes in the sample. Collection of small dentin samples is technically demanding and requires great care to secure a standardized yield from all samples. When the overall number of CFU in the sample is low, which is often the situation in infected and medicated dentin, it is also important not to lose the microbes during too vigorous dilution process.

Success in both qualitative and quantitative measurement of (surviving) microbes is dependent, among other factors mentioned above, on the design of the microbiological procedures that determine the detection level of the method. Detection level dic-

tates whether the most effective killing can be announced, for example, on the level of 99%, 99.9% or 99.99% (see Figure 2B). In other words, detection level tells how many cells in the test mixture must be alive so that growth can be detected by the culturing. Detection level is mainly dependent on the total number of cells in the initial reaction mixture/sample, proportion of the initial sample transferred into the dilution series, and the proportion of the mixture plated from each dilution. Theoretically, the detection limit can be easily calculated from the above numbers. In practice, detection limit is often reduced by carry-over of strong medicaments such as CHX or MTAD that may cause false-negative results at the beginning of the dilution series. Detection limit gives important information about the design and quality of the methods in studies of endodontic disinfecting agents. Unfortunately, detection limits are only rarely reported, making it more difficult to compare the results from different studies. One would hope that in the future, reporting the detection limit will be a routine requirement for studies on endodontic disinfection.

ANTIBACTERIAL IRRIGATING SOLUTIONS

The use of irrigating solutions is an important part of endodontic treatment. The irrigants facilitate removal of necrotic tissue, microorganisms and dentin chips from the root canal by a flushing action. Irrigants can also help prevent packing infected hard and soft tissue apically in the root canal and into the periapical area. Some irrigating solutions dissolve either organic or inorganic tissue. Finally, several irrigating solutions exhibit antimicrobial activity by actively killing bacteria and yeasts when in direct contact with the microorganisms. On the negative side, many irrigating solutions have shown cytotoxic activity and may cause severe pain reaction if they gain access into the periapical tissues.⁴⁵

An optimal irrigant should have all or most of the positive characteristics listed above, but none of the negative or harmful properties. Presently, none of the available irrigating solutions can be regarded as optimal. However, with a combined use of selected products, irrigation will greatly contribute to successful outcome of treatment.

NaOCl

NaOCl is the most widely used irrigating solution. In water, NaOCl ionizes to produce Na^+ and the hypochlorite ion, OCl^- , that establishes an equilibrium with hypochlorous acid, HOCl. Between pH 4 and 7,

Figure 3 A, Instrumented (upper part of the picture) and uninstrumented (lower part) root canal wall after irrigation with 5% sodium hypochlorite (NaOCl) for 10 minutes. Pulpal remnants and predentin have been effectively removed with NaOCl while the instrumented part (smear layer) seems relatively unaffected. Notice the typical calcospherites at the lower part of the image. **B**, Calcospherites on the uninstrumented canal wall after irrigation for 10 minutes with 2.6% NaOCl.

chlorine exists predominantly as HClO, the active moiety, whereas above pH 9, OCl^- predominates.⁴⁶ It is the hypochlorous acid that is responsible for bacteria inactivation, the OCl^- ion being less effective than the undissolved HOCl. Hypochlorous acid disrupts oxidative phosphorylation and other membrane-associated activities as well as DNA synthesis.^{47,48}

NaOCl is used in concentrations varying from 0.5 to 7%. It is a very potent antimicrobial agent and effectively dissolves pulpal remnants and organic components of dentin (Figure 3). It is used both as an unbuffered solution at pH 11 in concentrations mentioned above and buffered with a bicarbonate buffer (pH 9.0) usually as a 0.5% (Dakin's solution) or 1% solution.⁴⁶ Contradicting earlier statements, Zehnder et al.⁴⁹ reported that buffering had little effect on tissue dissolution, and Dakin's solution was equally effective on decayed (necrotic) and fresh tissues. In addition, no differences were recorded for the antibacterial properties of Dakin's solution with an equivalent unbuffered hypochlorite solution.⁴⁹

NaOCl is best known for its strong antibacterial activity; it kills bacteria very rapidly even at low concentrations. Waltimo et al.⁵⁰ showed that the resistant microorganism, *Candida albicans*, was killed in vitro in 30 seconds by both 5% and 0.5% NaOCl, whereas concentrations 0.05% and 0.005% were too weak to

kill the yeast even after 24 hours of incubation. The high susceptibility of *C. albicans* to NaOCl was recently also verified by Radcliffe et al.³³ Later, Vianna et al.⁵¹ contrasted these results partly, as 0.5% NaOCl required 30 minutes to kill *C. albicans*, whereas 5.25% solution killed all yeast cells in 15 seconds. In the latter study, however, organic material from the broth culture medium may have been present during the incubation with NaOCl which would explain delayed killing. Gomes et al.⁵² tested in vitro the effect of various concentrations of NaOCl against enterococcus. *Enterococcus faecalis* (Figure 4) was killed within 30 seconds by the 5.25% solution, while 10 and 30 minutes was required for killing all bacteria by 2.5 and 0.5% solutions, respectively. The higher resistance of *E. faecalis* to hypochlorite as compared with the yeast *C. albicans* was suggested also by Radcliffe et al.³³ However, both of these studies are in contrast to the results reported by Haapasalo et al.³⁷ who demonstrated rapid killing of *E. faecalis* by 0.3% NaOCl and by Portenier et al.⁵³ who were able to show rapid killing of *E. faecalis* strains in logarithmic and stationary growth phase by even 0.001% NaOCl.

Experiments with Gram-negative anaerobic rods *Porphyromonas gingivalis*, *Porphyromonas endodontalis*, and *Prevotella intermedia*, often isolated from apical periodontitis, demonstrated high susceptibility to

Figure 4 A scanning electron micrograph of growing *Enterococcus faecalis* cells.

NaOCl, and all three species were killed within 15 seconds with 0.5 to 5% concentrations of NaOCl.⁵¹

The differences between in vitro and in vivo studies include the volume of the medicament available for killing, access to all microbes, and absence of other materials in the in vitro experiments that potentially protect bacteria in vivo. Many of the in vivo studies have failed to show a better antibacterial effect in the root canal by high concentrations of NaOCl as compared to low concentrations. Byström and Sundqvist^{54,55} studied root canals naturally infected, mainly with a mixture of anaerobic bacteria, and showed that although 0.5% NaOCl, with or without EDTA, improved the antibacterial efficiency of preparations compared with saline irrigation, all canals were not bacteria free even after several appointments. No significant difference in antibacterial efficiency in vivo between 0.5 and 5% NaOCl solutions was found in the study. Siqueira et al.⁵⁶ using *E. faecalis*-infected root canals demonstrated the superior antibacterial effect against root canal bacteria of hypochlorite in comparison with physiological saline. However, no difference was detected between 1, 2.5, and 5% NaOCl solutions.

Many of the studies about the antibacterial effect of NaOCl against root canal bacteria are in vitro studies, in either “neutral” test tube conditions, in the root canals of extracted teeth, or in dentin blocks infected with a pure culture of one organism at a time. The in vivo studies, on the other hand, have focused on the eradication of bacteria from the root canals of teeth with primary apical periodontitis.

Peciulienė et al.⁵⁷ studied the effect of instrumentation and NaOCl irrigation in failed, previously root-filled teeth with apical periodontitis. Old root fillings were removed with hand instruments, and the first sample was taken. No chloroform was used to avoid false-negative cultures. Bacteria were isolated in 33 of the 40 teeth before further instrumentation. *E. faecalis* was found in 21 teeth (in 11 as a pure culture), the yeast *C. albicans* in 6 teeth, Gram-negative enteric rods in 3 teeth, and other microbes in 17 teeth. The canals were then hand instrumented to size #40 or larger and irrigated with 2.5% NaOCl (10 mL per canal) and 17% buffered EDTA (pH 7 and 5 mL per canal). After instrumentation and irrigation, *E. faecalis* was still detected in six canals. Other microbes persisted in five canals after preparation. Enteric Gram-negative rods were no longer present in the second sample.

The disappearance of yeasts but not *E. faecalis* in the root canals may reflect their different susceptibilities to the described chemomechanical instrumentation or it may be a result of different biofilm characteristics and dentin penetration by these species.

The weaknesses of NaOCl include unpleasant taste, toxicity, and its inability to remove smear layer because of its lack of effect on inorganic material.^{58,59} The poorer antimicrobial effectiveness of NaOCl in vivo than in vitro is also somewhat disappointing. There are several possible reasons for the reduced in vivo performance. Root canal anatomy, particularly the difficulty to effectively irrigate the most apical region of the canal, is generally acknowledged as one of the main challenges. In addition, the chemical milieu in the canal is different from a test tube. Haapasalo et al.³⁷ showed that the presence of dentin caused marked delays in the killing of *E. faecalis* by 1% NaOCl. The effect of other materials present in the necrotic or previously treated root canal, to the antimicrobial potential of NaOCl, has not been studied.

Studies measuring NaOCl cytotoxicity have indicated greater cytotoxicity and caustic effects on healthy tissue with 5.25% NaOCl than with 1.0 and 0.5% solutions.^{60,61} The fear of toxic and chemical complications is the main reason for that low concentrations 0.5 to 1% NaOCl solutions are used for canal irrigation instead of the 5.25% solution in many countries.⁴⁵ However, more in vivo studies on persistent endodontic infections and retreatment are necessary for a deeper understanding of the relationship between NaOCl concentration and its antimicrobial activity against specific microorganisms, before final

Figure 5 **A**, Smear layer on the surface of the root canal wall after hand instrumentation with H-files. **B**, Smear layer after instrumentation of the root canal before ethylenediamine-tetra-acetic acid irrigation.

conclusions can be drawn regarding the optimal NaOCl concentration.

EDTA, Citric Acid and Other Acids

EDTA (17%, disodium salt, pH 7) has little if any antibacterial activity. On direct exposure for extended time, EDTA releases some of the bacteria's surface proteins by combining with metal ions from the cell envelope. This can cause even bacterial death. More importantly, EDTA is an effective chelating agent in the root canal.^{62,63} It removes smear layer (Figure 5) when used together (but not simul-

taneously) with NaOCl by acting on the inorganic component of the dentin (Figure 6). Therefore, by facilitating cleaning and removal of infected tissue, EDTA contributes to the elimination of bacteria in the root canal. It has also been shown that removal of the smear layer by EDTA (or citric acid) improves the antibacterial effect of locally used disinfecting agents in deeper layers of dentin.^{35,36} Niu et al.⁶⁴ studied the ultrastructure on canal walls after EDTA and EDTA plus NaOCl irrigation by scanning electron microscopy (SEM): more debris was removed by irrigation with EDTA followed by NaOCl than with EDTA alone (Figure 7).

Figure 6 **A**, Instrumented root canal wall after irrigation with 5% sodium hypochlorite (NaOCl) and 17% ethylenediamine-tetra-acetic acid (EDTA), each for 5 minutes. Smear layer has been completely removed. **B**, Close-up scanning electron micrograph of the root canal wall after removal of smear layer with NaOCl and EDTA.

Figure 7 Partial removal of smear layer by irrigation for 10 minutes with 17% ethylenediamine-tetra-acetic acid only. Mainly organic material has been left covering the surface.

Citric acid can also be used for irrigation of the root canal and for removal of the smear layer.^{62,65,66} Similar to EDTA, complete removal of smear layer requires also irrigation with NaOCl before or after citric acid irrigation (Figure 8). Concentrations ranging from 1 to 50% have been used.⁶⁵ In comparison with ultrasound, 10% citric acid has been shown to remove the smear layer more effectively from apical root-end cavities than ultrasound.⁶⁷ In another study, powdered dentin–resin mixture was more soluble in a 0.5, 1, and 2 M citric acid

than in 0.5 M EDTA.⁶⁸ Contrary to this, Liolios et al.⁶⁹ reported better removal of smear layer by commercial EDTA preparations than with 50% citric acid, while other studies have found only small or no difference between citric acid and 15% EDTA in their capacity to remove the smear layer.^{70,71} A comparative study showed that 10% citric acid was more effective than 1% citric acid, which was more effective than EDTA in demineralizing dentin.⁷² Takeda et al.⁷³ reported that irrigation with 17% EDTA, 6% phosphoric acid, and 6% citric acid did not remove the entire smear layer from the root canal system. This is not unexpected, however, as it is known that NaOCl is also required for complete removal of the smear layer. The acids demineralized the intertubular dentin making the tubular openings larger than by EDTA. The authors also showed that CO₂ laser was useful in removing the smear layer and that the Er:YAG laser was even more effective than the CO₂ laser in smear layer removal.

Smear layer removal facilitates penetration of sealers into the dentinal tubules. It also enhances disinfection of the root canal wall and deeper layers of dentin. Both EDTA and citric acid can effectively remove the smear layer when used together with NaOCl. Citric acid and EDTA may have weak antimicrobial activity as stand-alone products. However, their antimicrobial effectiveness has not been extensively documented and appears to be of minor importance.

Figure 8 A, Instrumented root canal wall after irrigation for 10 minutes with 50% citric acid only. Similar to ethylenediamine-tetra-acetic acid, sodium hypochlorite irrigation is needed in addition for complete removal of the smear layer. **B**, Uninstrumented part of the root canal wall after irrigation for 10 minutes with 50% citric acid. Citric acid alone cannot dissolve the organic tissue within a reasonable time.

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) is a biocide that has been widely used for disinfection and sterilization.⁴⁶ However, in endodontics, H_2O_2 has not been very popular, and presently its use is generally in decline. H_2O_2 is a clear and colorless liquid. Concentrations from 1 to 30% have been used. H_2O_2 produces hydroxyl-free radicals ($HO\cdot$) that attack microbial components such as proteins and DNA.⁴⁶ H_2O_2 is nonproblematic from an environmental point of view because it degrades into water and oxygen. H_2O_2 is relatively stable in solution, but many products contain stabilizers to prevent decomposition. H_2O_2 has antimicrobial activity against various microorganisms including viruses, bacteria, yeasts, and even bacterial spores.⁷⁴ It is more effective against Gram-positive than Gram-negative bacteria. Catalase or superoxide dismutase produced by several bacteria can provide them partial protection against H_2O_2 .

Use of H_2O_2 in endodontics has been based on its antimicrobial and cleansing properties. Thirty percent H_2O_2 (Superoxol) has been recommended as the first step in tooth surface disinfection after mechanical cleaning.⁷⁵ H_2O_2 acts on the organic matter on the tooth making other disinfectants, such as iodine, more effective. It has been widely used earlier for cleaning the pulp chamber from blood and tissue remnants. It has also been used in canal irrigation, but evidence supporting the effectiveness of H_2O_2 as a root canal irrigant is scarce. On the contrary, Siqueira et al.⁷⁶ reported that a combination of NaOCl and H_2O_2 gave no advantage over NaOCl alone against *E. faecalis* in contaminated root canals ex vivo. Heling and Chandler⁷⁷ found strong synergism between H_2O_2 and Chlorhexidine (CHX) in disinfection of infected dentin: a combination of the two medicaments at low concentration was far more effective in sterilizing dentin than these or any other medicament alone. The synergistic mode of action between CHX and H_2O_2 was later documented also by Steinberg et al.⁷⁸ In a recent study, 10% H_2O_2 was used as part of the irrigating protocol in monkey teeth.⁷⁹ A total of 186 root canals in 176 teeth were inoculated with a known mixture of bacteria for several months. One group consisted of anaerobic bacteria and streptococci; the second group was identical to group one except with added *E. faecalis*. The root canals were sampled and instrumented manually to size #40 to #60 and irrigated with buffered 1% NaOCl, followed by 10% H_2O_2 . Final irrigation was with NaOCl. Sodium thiosulfate was used to inactivate hypochlorite before sam-

pling, and a second bacteriological sample was taken. In group 1 (160 canals), bacteria were found in 98% and 68% of the canals in samples 1 and 2, respectively. In group 2, with *E. faecalis*, the corresponding frequencies were 100% and 88%. Although the bacterial counts were greatly reduced, the study indicated the difficulty to completely eradicate bacteria from infected root canals in monkey teeth.⁷⁹

Despite the long history of use of H_2O_2 in endodontics, evidence supporting its use is at best weak. However, it still has a role as part of the tooth surface disinfection protocol. Furthermore, the potential benefit of the suggested synergistic effect with CHX in deep dentin disinfection remains to be evaluated clinically.

CHX

Chlorhexidine digluconate (CHX) is widely used in disinfection because of its excellent antimicrobial activity.⁸⁰⁻⁸² It has gained increased popularity in endodontics as an irrigating solution and as an intracanal medicament. Unlike NaOCl, CHX does not have bad smell, it is not equally irritating to periapical tissues, and neither does it cause dramatic spot bleaching of the patients clothes. Its antimicrobial effectiveness is well documented in endodontics. However, it completely lacks tissue dissolving capability, an important reason for the popularity of NaOCl (Figure 9).

CHX is perhaps the most widely used antimicrobial agent in antiseptic products. It permeates the cell wall or outer membrane (Gram-negative cells) and attacks the bacterial cytoplasmic or inner membrane of the yeast plasma membrane. In high concentrations, CHX causes coagulation of intracellular components.⁴⁶ CHX gluconate has been in use for some time in dentistry because of its antimicrobial properties, its substantivity (long-term continued effect), and its relatively low toxicity compared to some other agents. However, the activity of CHX is dependent on the pH and is greatly reduced also in the presence of organic matter.⁸²

CHX is effective against both Gram-positive and Gram-negative bacteria as well as yeasts, although activity against Gram-negative bacteria is not as good as against Gram-positive bacteria.⁸³⁻⁸⁵ Mycobacteria and bacterial spores are resistant to CHX.^{80,81} Therefore, CHX is not as suited to chairside sterilization of gutta-percha cones as NaOCl.^{86,87} Studies indicating equally good performance by CHX and NaOCl in gutta-percha disinfection have not used bacterial spores in testing.⁸⁸ CHX is not very effective against viruses, its activity being limited to viruses with a lipid envelope.⁸⁹ CHX is cytotoxic in direct contact with

Figure 9 **A**, Instrumentation smear layer seems intact after irrigation for 10 minutes with 2% chlorhexidine. **B**, Uninstrumented area in the root canal after irrigation with 2% chlorhexidine only. Chlorhexidine has no tissue dissolving capability.

human cells. A study using fluorescence assay on human periodontal ligament (PDL) cells showed no difference in cytotoxicity by 0.4% NaOCl and 0.1% CHX.⁶¹ The potential benefits of using CHX in endodontics have been under active research over the last several years. Several studies have compared the antibacterial effect of NaOCl and CHX against intracanal infection.

While many studies show little or no difference between their antimicrobial effectiveness,^{77,90–92} their mode of action may indicate important differences. The effects of 15 minutes of irrigation of experimental biofilms by mixtures of endodontic bacteria on dentin blocks have been evaluated by SEM and by culturing.⁹³ Six percent NaOCl was the only irrigant that completely eliminated (removed) the biofilm as verified by SEM observations and killed all bacteria. Two percent CHX was equally effective in bacterial killing, and no growth was detected in any of the samples after the CHX treatment. However, an important difference was observed in how the biofilm was structurally affected by irrigation with these two solutions: 6% hypochlorite completely removed the biofilm while the CHX solution had no effect on the biofilm structure.⁹³ Although the bacteria were killed, the result indicates that as the biofilm remains in the canal after CHX irrigation, it may continue to express its antigenic potential if allowed the possibility to

communicate with living periapical tissue. Moreover, such residual organic tissue may have a negative impact on the quality of the seal of the permanent root filling. Different types of biofilm are shown in Figure 10.

Some studies have indicated differences in the killing of certain endodontic microbes by hypochlorite and CHX. An in vitro study demonstrated differences in the killing of enterococci by CHX and NaOCl. While 5.25% NaOCl killed *E. faecalis* within 30 seconds, lower concentration (4.0 to 0.5%) of hypochlorite required 5 to 30 minutes for complete killing of the bacteria.⁵² In the same study, 0.2 to 2% CHX killed the *E. faecalis* cells in 30 seconds or less in all concentrations tested. The result was later supported by two other studies using *E. faecalis* and *Staphylococcus aureus* as test organisms.^{51,94} However, the results of these studies have been contradicted by some other studies with regard to the effectiveness of NaOCl.^{37,53}

The antifungal effectiveness of CHX has been shown in several studies.^{50,95–97} In a study of the effectiveness of various endodontic disinfecting agents, it was found that combinations of disinfectants were equally or less effective against fungi than the more effective component alone.⁵⁰

An interesting, but not yet fully understood synergism has been reported between CHX and H₂O₂.⁷⁷ In

Figure 10 **A**, Densely packed natural biofilm (in vivo) on the root canal wall of a tooth with apical periodontitis. The film consists of bacteria of different types and shapes and remnants of necrotic pulp tissue. **B**, Cocci and rod-shaped bacteria in necrotic pulp tissue of a tooth with apical periodontitis. **C**, Early stages of biofilm formation in vitro on root dentin by a mixture of oral bacteria. Binding of coccoid cells on long rod-shaped bacteria can be seen. **D**, More advanced stage of biofilm formation in vitro on root dentin by a mixture of oral bacteria. Many of the bacterial cells in the larger aggregate are embedded in extracellular matrix. **E**, Biofilm by a mixture of oral bacteria grown under increased CO₂ atmosphere *in vitro* on root dentin.

in vitro studies using the dentin block model indicated strong synergism between these two agents against *E. faecalis* infection in dentinal tubules. Complementary in vitro experiments by Steinberg et al.⁷⁸ demonstrated that the combination of CHX and H₂O₂ completely eradicated *E. faecalis* in concentrations clearly lower than required when the compounds were used alone. It is possible that CHX, as a membrane active agent, makes the bacterial membranes more permeable to H₂O₂, that can more easily penetrate the cells and cause damage to the intracellular organelles.⁷⁸ Although NaOCl and H₂O₂ are occasionally used together in root canal irrigation, such synergistic effect has not been detected between them in the dentin block model.⁷⁷ The CHX–H₂O₂ synergism has been demonstrated also in a study of antiplaque mouth rinse.⁹⁸ Surprisingly, so far there are no published studies of the clinical performance of the combinations of CHX and H₂O₂. Combinations of CHX and carbamide peroxide have been shown to be additive in their cytotoxicity,⁹⁹ but corresponding experiments with CHX and H₂O₂ are lacking.

Inhibition of the antimicrobial activity of endodontic irrigants, by substances present in the root canal, has recently been discussed in a number of studies.^{37–39} Haapasalo et al.³⁷ showed in an in vitro study that the effect of CHX is reduced or delayed, by the presence of dentin. In following studies by the same group, Portenier et al.³⁸ detected loss of CHX antimicrobial activity by high concentration (18%, v/w) of bovine serum albumin. In a clinical situation, inflammatory exudate rich in proteins may thus have a negative impact on the effectiveness of CHX. A subsequent study showed that organic dentin matrix and heat-killed microbial cells were effective inhibitors of CHX activity.³⁹ In a study by Sassone et al.,¹⁰⁰ CHX was incubated together with low concentration (0.5%, v/w) albumin, and no inhibition of the CHX activity could be detected. Albumin concentration in human serum is approximately 2 to 3% and the total protein concentration is approximately 7%.¹⁰¹

During the last few years, several studies have measured the activity of CHX gel against root canal bacteria. Vianna et al.⁵¹ found that CHX in a gel form required a longer time to kill *E. faecalis* than the corresponding concentration in a liquid. Oliveira et al.¹⁰² reported that 2% CHX gel and 5.25% NaOCl showed excellent activity against *E. faecalis*. When diluted to 1.5% solution, NaOCl reduced the *E. faecalis* counts initially, but the bacterial counts increased during the 7-day follow-up period to the level comparable to the control group.

Because CHX lacks the tissue dissolving activity of NaOCl, there have been efforts to simplify the clinical work by combining the two solutions to obtain combined benefits from both. However, CHX and NaOCl are not soluble in each other and a brownish-orange precipitate is formed (Figure 11). Although the antimicrobial and other characteristics of the precipitate and the liquid phase have not been thoroughly examined, the precipitate prevents clinical use of the mixture. Marchesan et al.¹⁰³ showed that the precipitate was soluble to 0.1 mol/L acetic acid, but the brown/orange color of the solution remained. Atomic absorption spectrophotometry indicated that the precipitate contained iron which may be the reason for the color.

Despite of some shortcomings, there is increasing evidence that CHX gluconate, as a 2% solution (liquid or gel), may offer a good alternative for root canal

Figure 11 Mixing sodium hypochlorite with chlorhexidine causes a brown/orange precipitate. The color may be due to iron impurities in hypochlorite. The mixture should not be used for irrigation of the root canals.

irrigation. However, one should bear in mind that the majority of the research on the use of CHX in endodontics is done using *in vitro* and *ex vivo* models and Gram-positive test organisms, mostly *E. faecalis*. The possibility cannot be excluded that the experimental designs give a biased (too positive) picture of the usefulness of CHX as an antimicrobial agent in endodontics. More research is needed to identify the optimal irrigation regimen for various types of endodontic treatments. CHX is presently marketed as a water-based solution, as a gel (with Natrosol), and as a liquid mixture with surface active agents. Future studies of the various CHX preparations will establish the comparative effectiveness of the various CHX combinations *in vivo*.

Iodine Potassium Iodide (IPI)

Iodine compounds are among the oldest disinfectants still actively used. They are best known for their use on surfaces, skin, and operation fields. Iodine is less reactive than the chlorine in hypochlorite. However, it kills rapidly and has bactericidal, fungicidal, tuberculocidal, virucidal, and even sporicidal activity.¹⁰¹ Molecular form, I₂, is the active antimicrobial component.¹⁰⁴ Poor stability of iodine in aqueous solutions motivated the development of iodophors ("iodine carriers"): povidone-iodine and poloxamer-iodine. Iodophors are complexes of iodine and a solubilizing agent that gradually releases the iodine.¹⁰⁴ Iodophors are less active against some yeasts and bacterial spores than are the alcoholic iodine solutions (tinctures). Iodine penetrates rapidly into the microorganisms and causes cell death by attacking the proteins, nucleotides, and other key molecules of the cell.^{104,105}

Iodine potassium iodide (IPI) has been successfully used in tooth surface disinfection.⁷⁵ Potassium iodide is used to dissolve iodine in water, but the antimicrobial activity is carried by the iodine, while potassium iodide has no activity against the microbes.

The effectiveness of 2.5% NaOCl and 10% iodine for disinfection of the operation field (tooth, rubber dam, and the clamp) has been compared by bacterial culturing and polymerase chain reaction.¹⁰⁶ The operation field was treated with 30% H₂O₂ and either by 10% iodine or 2.5% NaOCl. No significant difference in the recovery of cultivable bacteria from various sites in either group was detected. However, bacterial DNA was detected significantly more frequently from the tooth surfaces after iodine treatment (45%) than after NaOCl (13%) treatment.¹⁰⁶

Molander et al.¹⁰⁷ suggested that irrigation with 5% IPI before Ca(OH)₂ medication did not have an effect on the overall antimicrobial power. However, it is

possible that IPI reduces the frequency of persisting strains of *E. faecalis*. Peciulienė et al.⁵⁷ studied the effect of iodine irrigation in 20 teeth with previously root-filled canals and apical periodontitis. The results showed that when used after normal chemomechanical preparation, IPI increased the number of culture negative canals.

In the root canal, iodine compounds come in contact with a variety of substances such as dentin and various proteins. Studies of the interaction of IPI with the chemical environment of the necrotic root canal have shown that dentin can reduce or even abolish the effect of 0.2/0.4% IPI against *E. faecalis*.^{37,38} However, pure hydroxyl apatite or bovine serum albumin had little or no effect on the antibacterial activity of IPI. Portenier et al.³⁹ have shown that dentin matrix (mostly dentin collagen) and heat-killed cells of *E. faecalis* and *C. albicans* inhibit the antibacterial activity of IPI. These studies indicate that inactivation of iodine compounds is one factor explaining the difficulty in obtaining sterile root canals.

ANTIBIOTIC-CONTAINING IRRIGATION SOLUTIONS

MTAD and Tetraclean

MTAD [a mixture of tetracycline isomer, acid, and detergent (Biopure, Dentsply, Tulsa, OK)] is a new generation combination product for root canal irrigation.^{105,106} Tetraclean (Ogna Laboratori Farmaceutici, Muggiò, Italy) is another combination product similar or close to MTAD.¹⁰⁸ MTAD has a low pH (2.15) because it contains citric acid, it removes smear layer after NaOCl irrigation, and it has antibacterial activity against endodontic microbes. The main potential benefits of MTAD are that it makes irrigation simpler by combining smear layer removal activity with antimicrobial effect and that it may be "gentler" with dentin than EDTA.¹⁰⁹ The authors who introduced MTAD have recommended the use of 1.3% NaOCl during instrumentation, followed by MTAD to remove the smear layer.¹¹⁰ However, 1.3% NaOCl may not be strong enough to completely clean the uninstrumented parts of the root canal (Figure 12). Beltz et al.¹¹¹ found that MTAD solubilizes dentin, whereas organic pulp tissue is unaffected by it. Zhang et al.¹¹² showed that MTAD is less cytotoxic than eugenol, 3% H₂O₂, Ca(OH)₂ paste, 5.25% NaOCl and EDTA, but more cytotoxic than 2.63% NaOCl.

The antibacterial activity of MTAD is of particular interest as it contains doxycycline (tetracycline) in

Figure 12 Uninstrumented root canal wall irrigated for 5 minutes with 1.3% sodium hypochlorite (NaOCl) followed by 5-minute irrigation with MTAD (a mixture of tetracycline isomer, acid, and detergent). Although this combination produces excellently clean canal walls in the instrumented areas (smear layer), the low concentration NaOCl may be too mild to thoroughly clean the uninstrumented areas if the irrigation time is not long enough. In this figure, some of the predentin is still left to cover the mineralized dentin and the calcospherites.

high concentration. Shabahang et al.¹¹³ and Shabahang and Torabinejad¹¹⁴ investigated the effect of MTAD on root canals contaminated with either whole saliva or *E. faecalis* of extracted human teeth and reported good antibacterial activity. Portenier et al.³² showed that MTAD killed *E. faecalis* in vitro in less than 5 minutes. In an ex vivo study, Kho and Baumgartner¹¹⁵ compared the antimicrobial effectiveness of NaOCl/EDTA and NaOCl/MTAD in extracted roots infected for 4 weeks with *E. faecalis*. After chemomechanical preparation and irrigation, the roots were pulverized in liquid nitrogen and viable bacteria were counted. No difference was measured between the two irrigation regimens. Another ex vivo study using roots of 26 matched pairs of teeth compared the same irrigation regimens with a different type of sampling procedure.¹¹⁶ In this study, NaOCl/EDTA (5.25%/15%) irrigation resulted in 0/20 culture positive samples in both sample 1 (directly after irrigation) and sample 2 (after instrumenting the canals 2 instrument sizes wider) using a sensitive sampling protocol. However, in the other experimental group of 1.3% NaOCl/MTAD, the corresponding number of culture positive samples was 8 and 10 out of the total of 20 samples in each group. It should be noted that in the absence of negative control (e.g. water irrigation), it is not possible to know what may have been the reduction of bacterial CFU in the

NaOCl/MTAD group. Nevertheless, the result indicates better performance by NaOCl/EDTA than by NaOCl/MTAD irrigation. The result is interesting because EDTA alone lacks antimicrobial activity against *E. faecalis*. The mechanisms of action of sequential use of NaOCl and EDTA on bacterial viability have not been thoroughly studied. There are no reports so far on the antibacterial effectiveness of Tetraclean.

The antibacterial effect of MTAD may be based not only on the antibiotic component (doxycycline) but also on the combined effect of doxycycline and the other ingredients (Tween 80, citric acid) on the integrity and stability of the microbial cell wall. However, there is no specific information available on such effects regarding MTAD.

Physical Means of Canal Cleaning and Disinfection

ULTRASONIC CLEANING

Endodontic ultrasound has become an important tool in modern endodontic work. Ultrasound is used in a variety of tasks including finishing access cavity preparation, removing pulp stones, locating canal orifices, opening calcified canals, fractured instrument removal, placing cements and root filling materials, and retro canal preparation during surgical procedures.¹¹⁷ The use of ultrasonic energy for cleaning of the root canal and to facilitate disinfection has a long history in endodontics. The comparative effectiveness of ultrasonics and hand instrumentation techniques has been evaluated in a number of earlier studies.^{117–121} The majority of these studies concluded that the ultrasonics, together with an irrigant, contributed to a better cleaning of the root canal system than irrigation and hand instrumentation alone. Cavitation and acoustic streaming of the irrigant contribute to the biological chemical activity for maximum effectiveness.¹²² Analysis of the physical mechanisms of the hydrodynamic response of an oscillating ultrasonic file suggested that stable and transient cavitation of a file, steady streaming, and cavitation microstreaming all contribute to the cleaning of the root canal.¹²³

Several different methods have been used to study the effect of ultrasound on the cleanliness of the canal. These include bacteriological, histological, and microscopic techniques.^{124–128} Studies focusing on the ability of ultrasound to remove smear layer have shown contradictory results. This is not, in fact, surprising

because it is generally known that smear layer can be removed primarily by chemical means only, or by appropriate laser treatment.^{129,130} It has also been shown that to work effectively, ultrasonic files must be free in the canal without contact with the canal walls.¹³¹

Among the areas that are particularly difficult to clean are anastomoses between double canals, isthmuses and fins. Several studies have indicated the importance of ultrasonic preparation for optimal debridement of the root canals and isthmuses.^{130,132–134} Ultrasonics also eliminated bacteria from canals more effectively than hand instrumentation.^{134–136} However, not all studies have supported this finding.¹³⁷ It has been proposed that canal anatomy is more important than ultrasound for effectiveness of the cleaning procedures.¹³⁸

The direct bactericidal effect by ultrasonic energy seems to be very limited at best.^{139,140} Ultrasonics seems to exert its antimicrobial effect when used together with irrigants, perhaps via the physical mechanisms of cavitation and acoustic streaming. It is also possible that ultrasonics helps irrigants penetrate into areas, in complex canal systems, not easily reached by normal irrigation.

In a series of studies on the effect of canal shape (taper) and instrument design, Lee et al.¹⁴¹ demonstrated in simulated plastic root canals that the diameter and taper of root canal influenced the effectiveness of ultrasonic irrigation to remove artificially placed dentin debris. After ultrasonic irrigation, the amount of debris in the #20/04 taper group was significantly higher than that for the size #20/06 group and the size #20/08 group. Van der Sluis et al.¹⁴² using roots from human teeth *ex vivo* reported that there was a tendency for ultrasonic irrigation to be more effective in removing artificially placed dentin debris from simulated canal extensions from canals with greater tapers.

A study using a split tooth technique found that ultrasonic irrigation *ex vivo* was more effective than syringe irrigation in removing artificially created dentin debris placed in simulated uninstrumented extensions and irregularities in straight, wide root canals.¹⁴¹ In another study, passive ultrasonic irrigation with 2% NaOCl was more effective in removing Ca(OH)₂ paste from artificial root canal grooves than syringe delivery of 2% NaOCl or water as an irrigant.¹⁴³

Ultrasonic instrumentation can also have an impact on canal dimensions and in some cases can cause unwanted complications such as straightening of the canal (transportation), perforations, and extrusion of infectious material beyond the apex.^{131,144–147} A his-

tobacteriological study of teeth with non-vital pulps showed compacted debris and bacteria in the apical region and in the dentinal tubules after ultrasonic instrumentation.¹⁴⁸ In one study, the step preparation technique was shown to cause more extrusion than the standard technique, whereas the least extrusion was detected with the crown down and ultrasound techniques.¹⁴⁹ Interestingly, Van der Sluis et al.¹⁴² suggested that a smooth wire during ultrasonic irrigation is as effective as a size 15 K-file in removal of artificially placed dentin debris in grooves in simulated root canals in resin blocks. It is possible that using an ultrasonic tip with a smooth, inactive surface, preparation complications are less likely to occur.

Recently, serious damage to parodontal tissues was reported in a case where dental cement, used for cementing a post, was removed by ultrasound from a maxillary incisor.¹⁵⁰ After “several minutes” of ultrasound treatment, the patient complained of discomfort. During the following days and weeks, a large necrotic zone developed, affecting the bone and soft tissue around the tooth, resulting in the loss of the tooth. In controlled use, ultrasound together with irrigation, however, is not likely to cause harmful temperature rise.¹⁵¹

LASERS

Lasers in endodontics are dealt with in Chapter 26E, “Laser in Endodontics”. However, their role in endodontic disinfection will be summarized briefly in the following sections. The potential of different endodontic lasers in eradicating root canal microbes has been a focus of interest for many years. Early comparative studies indicated, however, that the antibacterial effectiveness of lasers in the root canal was inferior to NaOCl irrigation.^{152–154} Excellent antibacterial efficiency against *E. faecalis* was reported by Gutknecht et al.,¹⁵⁵ using a holmium:yttrium–aluminum–garnet (Ho:YAG) laser on root canals infected with this species *in vitro*, 99.98% of the bacteria were eliminated. However, Le Goff et al.¹⁵⁶ obtained only an 85% decrease in the bacterial counts by a CO₂ laser, clearly less than by irrigation with 3% NaOCl. Contrary to the main stream of results with laser treatment, Kesler et al.¹⁵⁷ indicated that complete sterility of the root canal can be obtained with a CO₂ laser microprobe coupled onto a special hand piece attached to the delivery fiber. Schoop et al.¹⁵⁸ in subsequent studies indicated that the effect of laser is dependent on the applied output power and specific for different bacteria. Complete sterility still seems to remain a

challenge with laser treatment.^{159,160} Another important aspect of laser radiation in endodontics is the effect of lasers on the smear layer, which may also facilitate effective disinfection of the canal.

New Developments in Root Canal Disinfection

Several new technologies have been introduced during the last few years to improve the effectiveness of root canal disinfection. Increasing attention has been focused on the use of ozone, photoactivated disinfection with low-energy laser, electrochemically activated water, and electric current.^{161–165} In a comparative study, 3% NaOCl was more effective than electrochemically activated water in eradicating *E. faecalis* in an ex vivo model.¹⁶² Nagayoshi et al.¹⁶⁴ reported relatively equal effectiveness in killing *E. faecalis* with ozonated water and 2.5% NaOCl, when the specimen was irrigated with sonication. However, NaOCl was superior to ozonated water in killing *E. faecalis* in broth culture and in biofilms.¹⁶⁶ Estrela et al.¹⁶⁷ studied root blocks infected for 60 days with a strain of *E. faecalis* and were unable to eradicate all bacteria with any of the methods used, including ozonated water, gaseous ozone, 2.5% NaOCl, and 2% CHX. Many of the new methods offer a biological approach to canal disinfection. However, available evidence so far has failed to show that these methods would be superior or sometimes even equal to existing ones with regard to their antimicrobial effectiveness in the infected root canal.

One of the latest new developments for canal disinfection are bioactive materials such as bio(active) glass.¹⁶⁸ In vitro studies have shown that bioglass has antimicrobial activity against a range of microbes and that this activity is, surprisingly, potentiated by dentin.^{169,170} However, studies demonstrating better antimicrobial effect when compared to Ca(OH)₂ in vivo so far are lacking. Recent experiments with nanometric bioactive glass indicated excellent antimicrobial effect in a human dentin model.¹⁷¹ More research will be needed to evaluate the value of bioglass in root canal disinfection.

Intracanal Interappointment Medicaments

In the treatment of teeth with a vital pulp, there is no need for intracanal medication. However, if time does not allow completion of the treatment in one

appointment, it is generally recommended that the root canal should be filled between appointments with an antibacterial dressing, for example, Ca(OH)₂, to provide sterility in the canal space until a permanent root filling is placed. However, there are no studies comparing the bacteriological status of the root canals following pulpectomy, when the canals have been left empty or filled with an antibacterial dressing.

The question of the role of intracanal medicaments becomes more relevant, and complex, in the treatment of pulpal necrosis and apical periodontitis. There is overwhelming evidence in the literature that many if not most root canals contain viable microorganisms after the completion of the chemomechanical preparation at the end of the first appointment.^{8–10,54,55,57,172–175}

Therefore, a variety of intracanal medicaments have been used between appointments to complete disinfection of the root canal. In addition to killing bacteria, intracanal medicaments may have other beneficial functions. Ca(OH)₂ neutralizes the biological activity of bacterial lipopolysaccharide^{176,177} and makes necrotic tissue more susceptible to the solubilizing action of NaOCl at the next appointment. Another aspect in using intracanal medicaments may be that a more thorough instrumentation is achieved because of the longer overall time used for the treatment. On the other hand, several appointments can also increase the risk for aseptic complications, for instance, through a leaking temporary filling and poor patient compliance.¹⁷⁸

Several studies have indicated a poorer prognosis of the treatment of apical periodontitis if viable bacteria are residing in the root canal system at the time of filling.^{5–7} Other studies, however, have contradicted these results and reported no significant differences in healing between teeth filled after positive or negative cultures from the root canal,⁸ or between treatments performed in one or two appointments.^{8,9} It has also been suggested that “intracanal sampling techniques suffer from deficiencies that limit their predictive value.”¹⁷⁹ A permanent root filling of high quality using endodontic cements with antibacterial activity can effectively seal and entomb residual microorganisms in the canal and prevent communication with periradicular tissues. Continued killing of the microorganisms could take place due to the antibacterial activity of the root-filling materials^{44,180} and unavailability of nutrients.

Ca(OH)₂

Ca(OH)₂ has a special position in endodontics. Indications for the use of Ca(OH)₂ in the prevention and

treatment of various pulpal and periapical conditions have been numerous. In addition to endodontic infections, use of $\text{Ca}(\text{OH})_2$ has been widely advocated in dental traumatology and in the treatment of resorptions. The classical studies in the 1970s and 1980s at the university of Umeå, Sweden, were a strong stimulus for the wide spread use of $\text{Ca}(\text{OH})_2$ as a local disinfecting medicament in the root canal for the treatment of apical periodontitis. Byström et al.⁶ reported that $\text{Ca}(\text{OH})_2$ was an effective intracanal medicament, rendering 34 out of 35 canals bacteria free after a 4-week period. The effectiveness of interappointment $\text{Ca}(\text{OH})_2$ was also reported by Sjögren et al.,¹⁸¹ who demonstrated that a 7-day dressing with $\text{Ca}(\text{OH})_2$ eliminated all bacteria in the root canal. However, these pioneer studies have been challenged by others who reported a residual flora in 7 to 35% of teeth after 1 or more weeks with $\text{Ca}(\text{OH})_2$ in the canal.^{21,182–184} Kvist et al.¹⁸⁵ reported the antimicrobial efficacy of endodontic procedures performed in a single visit (with 10-minute iodine irrigation), compared with a two-visit procedure, including an interappointment dressing with a $\text{Ca}(\text{OH})_2$ paste. Residual microorganisms were detected in 29% of the one-visit teeth and in 36% of the two-visit-treated teeth, with no statistically significant differences between the groups.

Zerella et al.⁴² compared the antibacterial activity of $\text{Ca}(\text{OH})_2$ mixed either with water or with 2% CHX in vivo. Pure $\text{Ca}(\text{OH})_2$ completely disinfected 12 out of 20 teeth, while the $\text{Ca}(\text{OH})_2$ -CHX paste disinfected 16 of 20 teeth. The difference, however, was not statistically significant because of small sample size. Siqueira et al.¹⁸⁶ examined bacterial reduction in teeth with apical periodontitis, after instrumentation and irrigation with 0.12% CHX solution and after 7 days of intracanal medicament with a $\text{Ca}(\text{OH})_2$ -CHX (0.12%) mixture. After finishing the chemomechanical preparation, 7 of the 13 cases still showed growth, while after the $\text{Ca}(\text{OH})_2$ -CHX treatment only one of 13 teeth was culture positive.

Vivacqua-Gomes et al.⁴⁰ examined the benefit of interappointment $\text{Ca}(\text{OH})_2$ medicament in root canals in an ex vivo model. The premolar teeth were infected with *E. faecalis* for 60 days, and the canals were instrumented using rotary instruments. Irrigation, interappointment medication, and root filling were performed following five different protocols, either in single visit or in multiple visits. A second bacteriological sample was obtained 60 days after the root filling (the root fillings were removed and samples taken). Bacteria were found in 3 of 15 teeth

(20%) irrigated with 2% CHX gel and filled in single visit and in 4 of 15 teeth (25%) irrigated with CHX and filled with $\text{Ca}(\text{OH})_2$ for 14 days before the gutta-percha/sealer root filling was placed. Teeth that were left empty for 1 week after irrigation and before root filling, or irrigated with saline only instead of CHX, or filled without sealer showed bacteria in 40 to 100% of the teeth 60 days after the root filling was placed. Because of the small size of the experimental groups, far-reaching conclusions cannot be made. However, the result supports the finding of other studies indicating that interappointment $\text{Ca}(\text{OH})_2$ may not add to the antibacterial effectiveness of the treatment. Moreover, the results emphasize the importance of not leaving the root canal empty (no medicament, no root filling) as well the role of sealer in the joined effort to combat infection.

CHLORHEXIDINE DIGLUCONATE

CHX is used as an irrigating solution during or at the end of instrumentation. However, CHX has also been used as an intracanal medicament between the appointments. Recently, interest has been focused on the effectiveness of CHX in gel form or as a mixture with $\text{Ca}(\text{OH})_2$ as an intracanal interappointment dressing.^{187,188} The information available is based mostly on in vitro and ex vivo experiments in which several intracanal medicaments have been compared for their activity against induced dentin infection. Siren et al.¹⁸⁸ using a bovine dentin block model reported that $\text{Ca}(\text{OH})_2$ mixed with CHX was much more effective in disinfecting dentin infected with *E. faecalis* than pure $\text{Ca}(\text{OH})_2$. Ercan et al.¹⁸⁷ reported 2% CHX gel was significantly more effective than $\text{Ca}(\text{OH})_2$ combined with 2% CHX, or $\text{Ca}(\text{OH})_2$ alone, against root dentin infected with *E. faecalis* and the yeast *C. albicans* after 7, 15, and 30 days of incubation. Similarly, it has been reported that 2% CHX gel alone completely inhibited the growth of *E. faecalis* after 1, 2, 7, and 15 days in the root canal whereas $\text{Ca}(\text{OH})_2$ allowed some microbial growth at all experimental times.⁴¹ Interestingly, in this study, the combination of the CHX gel and $\text{Ca}(\text{OH})_2$ had killed all bacteria in the 1- and 2-day samples, but failed to secure sterility in the 7- and 15-day samples. The antibacterial efficacy of intracanal medication with $\text{Ca}(\text{OH})_2$, 2% CHX gel, and a combination of both was assessed in a clinical study in teeth with chronic apical periodontitis.⁴³ Bacterial samples were taken before and 7 days after filling the canals temporarily with the medicaments. CHX and

Ca(OH)₂, alone as well as their mixture, all performed equally well, and no statistically significant differences could be detected in their antibacterial effectiveness.

OTHER ALTERNATIVES FOR INTERAPPOINTMENT MEDICAMENTS

Intracanal Medicaments Containing Antibiotics

Throughout the history of endodontics, there have been time periods with increased interest in the use of local antibiotics as temporary canal dressings for root canal disinfection.^{189–196} Locally used antibiotics have not, however, become an established part of root canal disinfection and eradication of the infection. The reasons for the failure of antibiotics to overtake endodontic infection control are many. Many of the antibiotics tested are bacteriostatic, which may not be a good strategy for treating endodontic infections. Generally, bacteriostatic antibiotics prevent the growth of the microorganisms without killing them, giving the host defense a possibility to deal with the infection. In the necrotic root canal, however, there is no host defense because of the lack of the circulation. Therefore, the antibacterial effect of such antibiotics in the root canal may be only temporary. On the other hand, it is possible that some bacteriostatic antibiotics can have a bactericidal effect when used in high concentrations, usually the case with locally used antibiotics. However, information about this is scarce and presently there is no direct evidence of bacteriostatic antibiotics used in the root canal, although one study indicated that mixing erythromycin with Ca(OH)₂ improved the effectiveness against *E. faecalis* as compared to Ca(OH)₂ alone.¹⁹⁷

With bactericidal antibiotics, the potential problem in the root canal may be the metabolic and physiological state of the microorganisms. Many bactericidal antibiotics are most effective when the microbial cells are in active growth phase, which may not be the case in the necrotic root canal with only limited nutrients available. In general, specific information about the effectiveness of intracanal antibiotics in infection control in endodontics is limited. Recently, an interesting new development has taken place with the use of antibiotic cocktails in the treatment of teeth with immature apex and apical periodontitis.^{198,199} It is possible that better circulation and survival of some pulpal cells in the apical root canal are among the key factors for the promising results reported so far. Future research will show whether this approach can

be extended to the treatment of teeth with closed apex and apical periodontitis.

Phenol Compounds.

Chemicals of the phenol group such as phenol, formocresol, cresatin, parachlorophenol (monoparachlorophenol), camphorated phenol, and camphorated parachlorophenol have a long history in endodontics as locally used root canal disinfecting agents. They have been applied into the pulp chamber in a moist cotton pellet (vapor effect), or the whole canal has been filled with liquid with various concentrations of the phenol compound.^{200–208} The rationale of using phenol compounds for root canal disinfection has its roots in their role as general disinfecting agents in the past. However, emphasis of safety in addition to effectiveness has resulted in dramatic decline in their use generally. Also in endodontics, concerns have been raised regarding the toxicity and possible mutagenicity of the disinfecting agents of the phenol group.^{209–213} There are several demonstrations of their cytotoxicity,^{209,214,215} however, recent studies indicate that the risk of genotoxicity by the various phenol compounds used in endodontics is small.^{211–213} Comparative studies of the antimicrobial effectiveness of the phenol compounds have not been able to show superiority of the substances over the other. On the contrary,^{200,203,205,208,209} Byström et al.²⁰³ reported that Ca(OH)₂ was superior to camphorated parachlorophenol (CMCP) by its antibacterial potential when used for 4 weeks as the local intracanal medicament. Several studies have indicated relatively rapid loss of activity of CMCP in the canal, although the results show variation.^{206,216} In the balance of the benefits and the demonstrated and potential weaknesses of phenol compounds, it can be predicted that they will be increasingly replaced by other, more biological disinfecting agents.

CHAPTER 29

ROOT CANAL FILLING MATERIALS

JAMES DAVID JOHNSON

Historically, many materials have been used to fill root canals. In the 1800s and before, materials ranging from tin foil, lead foil, gold foil, cotton pellets with various medicaments, wood, spunk, plaster of Paris, oxychloride of zinc, oxyphosphate of zinc, zinc oxide, paraffin, copper points, and various other concoctions were used to fill root canals. Sometimes canals were not filled at all, and only a mixture of Hill's stopping was placed over canals.¹ With Asa Hill's development of Hill's stopping in 1847, which consisted of bleached gutta-percha and carbonate of lime and quartz, the advent of gutta-percha as a root canal filling material in endodontics began.² In 1867, G. A. Bowman of St. Louis was credited with using gutta-percha points to obturate root canals.¹ The S. S. White Company began to market gutta-percha points to the profession in 1887.³ Gutta-percha, as an obturating material, has survived, and today exists in many forms, and is still the most widely used material to obturate root canals.

Requirements for an Ideal Root Canal Filling Material

Grossman⁴ modified Brownlee's⁵ criteria for the ideal root canal filling material and listed the following criteria for an ideal root canal filling material:

1. It should be easily introduced into the root canal.
2. It should seal the canal laterally as well as apically.
3. It should not shrink after being inserted.
4. It should be impervious to moisture.
5. It should be bacteriostatic or at least not encourage bacterial growth.
6. It should be radiopaque.
7. It should not stain tooth structure.
8. It should not irritate periradicular tissues.
9. It should be sterile, or easily and quickly sterilized, immediately before insertion.
10. It should be removed easily from the root canal, if necessary.

Root canal filling materials have been classified as solid-core filling materials, semisolid-core filling materials, and paste filling materials. Silver points are an example of solid-core filling materials. Gutta-percha is the most widely used semisolid-core material. Various paste systems have been used over the years, such as zinc oxide-containing pastes.

Solid-Core Filling Materials

HISTORICAL ROOT CANAL FILLING MATERIALS (SILVER POINTS)

Silver points, having the same diameter and taper as files and reamers, were introduced by Jasper in 1933.² Silver points were widely used in the 1930s to the 1960s, particularly in smaller canals. They were fabricated to the same size as instruments used in the preparation of the canal. Silver points had the advantages of being easy to insert, and length control was easier. Although silver points fulfilled many of Grossman's requirements, the main drawback of silver points is that they do not seal well laterally or apically because of their lack of plasticity. Silver points cannot adequately fill all the canal space and cannot be compacted into spaces or voids within the root canal system. They maintain their round shape and no canal is perfectly round in shape, even after instrumentation. This leaves too much space to be filled by sealer or cement, thus leading to leakage. The leakage allows corrosion of the silver points and the formation of silver salts. These products were found to be cytotoxic. Seltzer et al.⁶ found such products as silver amine sulfate amide hydrate, silver sulfides, and silver sulfates from silver points removed from canals that were obturated with silver points. Brady and Del Rio⁷ found corrosion products of sulfur and chlorides by microanalysis of

failed silver points. Goldberg⁸ found that corrosion was present microscopically in cases obturated with silver points that were deemed successful clinically and radiographically. Gutierrez et al.⁹ reported that canal irrigants could corrode silver points. Kehoe¹⁰ reported a case of localized argyria leading to “tattooing” of the alveolar mucosa associated with corrodng of a silver point in a maxillary premolar.

Silver points used in smaller canals were very successful in their era. The inappropriate use of silver points in larger canals helped to give rise to their reputation as an inferior obturation method. With the advent of different instrumentation techniques that allowed for successful obturation of smaller canals with gutta-percha, the use of silver points has declined because of their inherent disadvantages. The use of silver points in modern endodontic therapy is extremely limited, and there seems to be no indications or justification for their use today.

Semisolid-Core Filling Materials

Gutta-percha is by far the most popular and commonly used root canal filling material. Although it does not meet all the criteria for an ideal filling material, it satisfies most of them. The major disadvantage of gutta-percha as a root canal filling material is its lack of rigidity. Gutta-percha, particularly the smaller sizes, will bend easily under lateral pressure.

Gutta-percha, known as “mazer wood,” was introduced to England from Asia in the 1600s and existed as little more than a curiosity of the East for nearly 200 years.¹¹ It was not until 1848 that Ernst Werner von Siemens used gutta-percha as insulation for underwater cable. With its many desirable properties, gutta-percha soon was being used in many different ways and in many different products. Patents were applied for new products using gutta-percha, which included “corks, cements, thread, surgical instruments, garments, pipes, musical instruments, candelabras, gaiters, garters, suspenders, window shades, carpets, gloves, mattresses, pillows, tents, umbrellas, and sheathing for ships.”¹¹ Perhaps the best known use of gutta-percha was in golf balls, introduced in the later part of the nineteenth century and used until 1920. These golf balls were called “gutties.”¹¹

Natural gutta-percha has been described as the product of various species of rubber trees from Malaysia, Borneo, Indonesia, and South America, mainly Brazil. Some of the species mentioned as sources of natural gutta-percha are *Palaquium gutta*,

Mimusops globsa, and *Manilkara bidentata*, and are of the same botanical family as the natural rubber tree *Hevea brasiliensis*. Raw gutta-percha is the flexible hardened juice of these tropical trees.

Gutta-balata is identical in chemical structure and physical properties to gutta-percha and has long been used as gutta-percha, or added to gutta-percha in commercial brands. Additionally, synthetic *trans*-polyisoprene may be added to commercial gutta-percha. Raw gutta-percha from the tree undergoes a rigorous process to convert it into commercial grade gutta-percha. This process involves purification, dissolving of resins, and denaturing of proteins.¹²

Friedman et al.¹³ investigated the ingredients of five commercial brands of gutta-percha points. They found the composition of these commercially available gutta-percha points, as seen in Table 1, to consist of 18 to 22% gutta-percha, 59 to 76% zinc oxide, 1 to 4% waxes and resins, and 1 to 18% metal sulfates. Although gutta-percha is not the major ingredient, it serves as the matrix. Zinc oxide acts as the filler, whereas the waxes and resins serve as plasticizers. Metal sulfates, such as barium sulfate, provide the radiopacity to identify the material radiographically.

Evidence of slight antibacterial activity from gutta-percha points exists, presumably from the zinc oxide in commercially available gutta-percha¹⁴; however, it is too weak to be an effective microbicide. As the destruction of bacteria is key to endodontic success, a new formulation of gutta-percha that contains iodoform, medicated gutta-percha (MGP) (Medident International, Inc., Woodside, NY), has been developed by Martin and Martin.¹⁵ Within the filled root canal, the iodine/iodoform depot in the MGP point is a biologically active source for inhibiting microbial growth. The iodoform is centrally located within the gutta-percha and takes about 24 hours to leach to the surface. “The iodoform remains inert until it comes in

Table 1 Composition of Gutta-Percha Endodontic Filling Materials (Mean Percentage ± SD)

Sample	Gutta-Percha	Wax and/or Resin	Heavy Metal Sulfates	Zinc Oxide
Premier	18.9 ± 0.1	4.1 ± 0.2	14.5 ± 0.4	61.5 ± 0.5
Mynol	19.9 ± 0.1	3.9 ± 0.02	16.2 ± 1.8	59.1 ± 2.0
Union Broach	21.8 ± 0.2	1.0 ± 0.02	17.3 ± 0.3	59.6 ± 0.1
Schwed	19.9 ± 0.2	2.8 ± 0.2	1.5 ± 0.3	75.3 ± 0.5
Star Dental	20.6 ± 1.4	2.9 ± 0.2	3.4 ± 2.1	73.4 ± 2.0

Composition of commercially available gutta-percha by quantitative analysis as performed by Friedman, Sandrik, Heuer, and Rapp.

contact with tissue fluids that activate the free iodine.¹⁵ A canal filled with MGP gutta-percha could serve as a protection against bacterial contamination from coronal microleakage reaching the apical tissue. The use of heat during obturation does not affect either the release of iodoform or its chemical composition.¹⁶ Presumably, the use of iodine containing gutta-percha points would be contraindicated in a patient with a history of allergy to iodine.

An *in vitro* assessment of iodoform containing gutta-percha tested the ability of the iodoform containing gutta-percha to delay the infiltration of *Enterococcus faecalis* using a bacterial microleakage model.¹⁷ The results showed no difference between regular gutta-percha points and iodoform-containing gutta-percha points, both with Roth's 801 sealer, in their ability to delay microleakage of *E. faecalis*.

Gutta-percha points have also been introduced that contain a high percentage of calcium hydroxide (40–60%) (Roeko/Coltene/Whaledent, Langenau, Germany). This permits a simple placement of the medicament within the canal space between appointments. Calcium hydroxide points combine the efficacy of calcium hydroxide in a matrix of 42% bio-inert gutta-percha. Once the calcium hydroxide has leached out, the point is no longer useful as a filling material and must be removed. Holland et al.¹⁸ have reported on the use of an experimental calcium hydroxide containing gutta-percha point that can be used for root canal filling. Their results indicate that these points produced an improvement in the apical sealing quality of the root canal filling.

There are also gutta-percha points available that contain chlorhexidine (Activ Point) (Roeko/Coltene/Whaledent) that have a slow release of the chlorhexidine, and are used in a similar manner as the calcium hydroxide-containing gutta-percha. Some studies have shown that the points containing chlorhexidine had a better antibacterial effect than the calcium hydroxide containing gutta-percha points.¹⁹

Podbielski et al.²⁰ tested gutta-percha points containing calcium hydroxide and zinc oxide, points con-

taining zinc oxide and chlorhexidine, points containing iodine–polyvinylpyrrolidone, and gutta-percha points containing a mixture of chlorhexidine and iodine–polyvinylpyrrolidone for their ability to inhibit growth of pure cultures of bacterial species commonly involved in endodontic infections. The calcium hydroxide-containing gutta-percha points proved to possess the strongest antibacterial activity, compared with the other three of the four types, for all bacteria tested, with the exception *Peptostreptococcus micros*.

One study investigated the antimicrobial efficacy of medicated filling materials, including standard gutta-percha, iodoform gutta-percha (MGP), and gutta-percha with tetracycline.²¹ These medicated filling materials were tested against several strains of bacteria including *Actinomyces israelii*, *Actinomyces naeslundii*, *E. faecalis*, and *Fusobacterium nucleatum*. Standard gutta-percha and the iodoform-containing gutta-percha weakly inhibited *F. nucleatum* and *A. naeslundii*. In addition, the iodoform gutta-percha also inhibited *A. israelii*. Only the tetracycline-containing gutta-percha inhibited all bacterial strains, including *E. faecalis*.

In 1942, Bunn²² discovered that natural gutta-percha existed in a 1,4-*trans*-polyisoprene stereochemical structure. Natural rubber has a 1,4-*cis*-polyisoprene stereochemical structure. Both gutta-percha and natural rubber are high-molecular-weight stereoisomers of polyisoprene. In the *cis* form of natural rubber, the CH₂ group is on the same side of the double bond, whereas in the *trans* form of polyisoprene (gutta-percha) the CH₂ groups are on the opposite side of the double bond as shown in Figure 1. The *cis* configuration of natural rubber allows for mobility of one chain past another and gives rise to the elastic nature of rubber, whereas the *trans* configuration of gutta-percha is more linear and crystallizes more readily making gutta-percha harder, more brittle, and less elastic than natural rubber.^{11,23} The scientific methods available to Bunn in 1942 did not allow for 100% identification of the 1,4-polyisoprene configuration, as he could not rule out the presence of a minority *cis* form.²⁴ In 1993, Marciano et al.,²⁴ using nuclear

Figure 1 Stereochemical structure of gutta-percha, 1,4-*trans*-polyisoprene isomer (natural gutta-percha). CH₂ groups are on opposite sides of the double bond for each successive monomer. Adapted and reproduced with permission from Marciano J et al (1993).²⁴

magnetic resonance, were able to confirm that both natural and commercial gutta-percha mainly have a 1,4 *trans* stereochemical structure and that the coloring agent in commercial gutta-percha is erythrosine. Less than 1% of the sample had the 1,4 *cis* stereochemical structure.

Gutta-percha exists in two distinct crystalline forms, alpha and beta.²² Raw gutta-percha, as it comes directly from the tree, is in the alpha form. Once purified, gutta-percha, as it appears commercially in manufactured gutta-percha products, is in the beta crystalline form. There are few differences in physical properties between the two forms, merely a difference in the crystalline lattice depending on the annealing and/or drawing process used when manufacturing the final product.²⁵ Although there is apparently no difference in the mechanical properties of the two crystalline forms, there are thermal and volumetric differences.¹¹ Unlike many materials, there are volumetric changes associated with temperature changes in gutta-percha, which has clinical implications.

If the natural alpha form which comes from the tree is heated above 65°C, it will melt and become amorphous. If it is very slowly cooled at a rate of 0.5° per hour, the original alpha form will recrystallize. However, if the heated amorphous form cools normally, the beta form will crystallize.¹¹ Schilder et al.²⁶ investigated the temperatures at which the crystalline phase transitions occurred. They found that, when dental gutta-percha in the beta crystalline form was heated, a crystalline phase transition to the alpha form took place between 42° and 49°C, depending on the specific compound being tested. The alpha-to-amorphous phase transition occurred at a higher temperature of between 53° and 59°C, again depending on the make up of the specific compound being tested. This information is useful clinically, when the clinician needs the amorphous form of gutta-percha in order to flow gutta-percha into all parts of the canal and to utilize thermoplastic techniques.

In a study on the thermomechanical properties of gutta-percha, Schilder et al.²⁷ found that compaction, as opposed to compression, is what occurs in clinical situations with gutta-percha. Additionally, the reduction in volume that takes place with mechanical manipulation of gutta-percha is due to the consolidation and collapse of internal voids in gutta-percha, and this occurs within compaction forces. Finally, there is no molecular spring back after compaction of gutta-percha that would aid in the seal of gutta-percha within the root canal system. To overcome the shrinkage of gutta-percha as it cools, it is necessary to put pressure on the gutta-percha with a plugger.

Traditionally, the beta form of gutta-percha was used to manufacture endodontic gutta-percha points to achieve an improved stability and hardness and to reduce stickiness. However, through special processing and/or modifications to the formulation of the gutta-percha compound, more alpha-like forms of gutta-percha have been introduced, resulting in changes in the melting point, viscosity, and tackiness of the gutta-percha. Gutta-percha with low viscosity will flow with less pressure or stress,²⁵ whereas an increase in tackiness will help create a more homogeneous filling. Various manufacturers have introduced products to take advantage of these properties (e.g., Themafil, Densfil, MicroSeal).¹⁶

Gutta-percha points come in the standardized ISO (International Standards Organization) sizes to correspond to endodontic instruments. Initially, the ISO-sized gutta-percha points came in the standard 0.02 taper to match the instruments available in that era. Now gutta-percha points are available in the increased taper sizes of 0.04, 0.06, etc to match the endodontic instruments that have these greater tapers. Color coding to match the ISO size is available on most gutta-percha points marketed today (Figure 2).

The traditional configuration of gutta-percha points is manufactured in a form that does not correspond to

Figure 2 Assorted gutta-percha points and absorbent paper points with 0.06 taper are shown here, with color coded ends for easy identification of the size of the point. Reproduced with permission of Brasseler USA.

ISO sizes but has tapers that closely match the final instrumented size of canals. These traditional sizes (extra-fine, fine-fine, medium-fine, fine, fine-medium, medium, medium-large, large, and extra-large) have long been used in warm vertical obturation techniques and also match spreader sizes used in lateral compaction techniques.

With the thermoplasticized injectable techniques of gutta-percha placement and obturation of canals, the gutta-percha is produced in pellet form that may be loaded into the heating device (Obtura III) or as prepackaged cannulas or cartridges (UltraFil, Calamus, Elements). Carrier-based gutta-percha products have gutta-percha surrounding a carrier made of metal or plastic.

Gutta-percha that has been stored for extended periods of time can become brittle with aging. Sorin et al.²⁸ presented a method to rejuvenate aged and brittle gutta-percha by immersing it in hot tap water (above 55°C) until the grasping forceps indents the now softened gutta-percha. The gutta-percha is then removed from the hot water and immediately quenched in cold tap water (less than 20°C) for several seconds. The gutta-percha point can now be sterilized and used to obturate the canal.

Gutta-percha should be stored in a cool location with low humidity. Kolokruis et al.²⁹ investigated the effects of moisture and aging on gutta-percha. They found that high humidity causes the absorption of water by the gutta-percha points, which lowers the values for tensile strength and torsional strain resistance, increases the value for elongation, and has a plasticizing effect on the gutta-percha cones. The plasticizing effect is due to the insertion of water molecules in the polymer chains.

Senia et al.³⁰ suggested sterilizing gutta-percha prior to insertion into the canal by immersion into 5.25% sodium hypochlorite for at least 1 minute to kill bacteria and spores on gutta-percha. Examination with a dissecting microscope showed no adverse effects on the gutta-percha points that were immersed for 5 minutes in 5.25% sodium hypochlorite.

In a scanning electron microscope (SEM) study, Short et al.³¹ examined the effect of the sodium hypochlorite on gutta-percha points and determined that gutta-percha fresh from the box had no crystals on its surface. All the gutta-percha points placed in sodium hypochlorite had sodium chloride crystals present after the rapid-sterilization technique using 5.25 and 2.5% sodium hypochlorite. However, the sodium chloride crystals could be removed from the gutta-percha surface

by 96% ethyl alcohol, 70% isopropyl alcohol, or distilled water.

The structural effects of sodium hypochlorite solutions on gutta-percha points were examined in an atomic force microscopy study by Valois et al.³² They found aggressive deteriorating effects on the gutta-percha points that had been placed in 5.25% sodium hypochlorite for 1 minute. After 5 minutes in either 2.5% or 5.25% sodium hypochlorite, there were topographic changes. However, a 0.5% solution of sodium hypochlorite did not cause any alteration in the topography or elasticity of gutta-percha points. They concluded that a 0.5% solution of sodium hypochlorite would be a safe alternative for rapid decontamination of gutta-percha points.

As another alternative for the disinfection of gutta-percha points, Gomes et al.³³ looked at the effectiveness of chlorhexidine and sodium hypochlorite as solutions for the disinfection of gutta-percha points. In their boxes, gutta-percha points had a contamination rate of 5.5%. Microbes found most frequently, after intentional contamination with gloves, were *Staphylococcus* organisms. Chlorhexidine was not effective in eliminating *Bacillus subtilis* spores on gutta-percha, whereas 5.25% sodium hypochlorite eliminated spores on gutta-percha after 1 minute of disinfection.

THERMOPLASTICIZED GUTTA-PERCHA

Yee et al.³⁴ introduced the concept of obturating root canals using injection-molded thermoplasticized dental gutta-percha. They developed a prototype device (PAC-160) where gutta-percha points were loaded into a pressure syringe and heated to 160°C. They injected the heated and softened gutta-percha into prepared canals, with and without sealer. They found injected thermoplasticized gutta-percha could produce an effective apical seal, especially when used with sealer. They introduced what would become the Obtura unit.

Injectable thermoplasticized gutta-percha may be used as a primary obturation technique, or, as it is used most often today, as a back-filling technique to fill the coronal aspects of the canal after the initial placement and compaction of gutta-percha by other techniques in the apical portion of the canal. The thermoplasticized gutta-percha injection techniques are classified as high-temperature and low-temperature thermoplasticized gutta-percha injection systems. These systems have made obturation quicker with the back-filling technique.

The first commercially available thermoplasticized gutta-percha system was the *Obtura system*. The Obtura

Figure 3 Obtura III Thermoplasticized gutta-percha delivery system by Obtura Spartan. Reproduced with permission from Obtura Spartan.

III Unit (Obtura/Spartan Corp., Fenton, MO) (Figure 3) is a high-temperature thermoplasticized gutta-percha system that requires gutta-percha pellets to be inserted into a delivery system gun, and then the gutta-percha pellet is heated to 150° to 200°C prior to delivery into the canal system. The warmed and softened gutta-percha is then delivered through 20-, 23-, or 25-gauge needles. Obtura gutta-percha also comes in the Flow-150 pellets, which is lower temperature thermoplasticized gutta-percha, and requires heating only to 150°C. The Obtura III also can be used with Resilon pellets, and lower temperatures are required to thermally soften the Resilon.

In a clinical study using the Obtura II system, Tani-Ishii and Teranaka³⁵ reported an overall success rate of 96% with a 1-year follow-up with cases obturated only with the Obtura II thermoplasticized injection technique.

Several studies have evaluated the safety of the temperatures used with injectable thermoplasticized systems and, for the most part, found them to be well below the critical 10°C rise in temperature that will cause damage to the periodontal ligament and bone.^{36–39} According to a study by Lipski,⁴⁰ high-temperature thermoplasticized injectable gutta-percha in mandibular incisors may show an increase in temperature above the 10°C rise that is crucial if damage to the attachment apparatus is to be prevented. Maxillary incisors, however, did not show an external temperature rise above 10°C.

Figure 4 Elements thermoplasticized gutta-percha delivery system with System B heat source by Sybron Endo. Reproduced with permission from Sybron Endo.

The *Elements* system (Sybron Endo, Orange, CA) is a high-temperature thermoplasticized gutta-percha system that uses preloaded gutta-percha cartridges that are heated prior to delivery through the unit by an activation button. The gutta-percha is heated to 200°C. The gutta-percha is delivered through a 45° pre-bent needle that comes in sizes 20, 23, or 25 gauges (Figure 4).

The *Calamus* system is manufactured by (Tulsa Dental Products, Tulsa, OK). The high-temperature system heats the gutta-percha cannulas from 60° to 200°C. The delivery system may be activated by finger pressure on a blue ring with multiple positions. Besides the temperature control, the flow rate may be controlled by the operator as well. The flow rate of the softened and heated gutta-percha may be

Figure 5 Calamus thermoplasticized gutta-percha delivery system by Tulsa Dentsply. Reproduced with permission of Tulsa Dentsply.

regulated from 20, 40, 60, 80, and 100%. The Calamus unit only comes with needle sizes of 20 and 23 gauges (Figure 5).

UltraFil (Hygienic Corp., Akron, OH) is a low-temperature thermoplasticized gutta-percha delivery system that has prepackaged cannulas with attached 22-gauge needles. The gutta-percha is prepared in the alpha phase form so that it softens at a temperature of 70° to 90°C in the heating unit. Once heated, the cannulas are then placed in the injection syringe and the softened thermoplasticized gutta-percha is ready for injection into canal.

Michanowicz and Czonstkowsky⁴¹ in a dye study using a low-temperature injection system (70°C) found that when sealer was used, there was very little leakage. They used no compaction with this technique. Lipski⁴² found temperatures transmitted to the periodontal ligament with the Ultra-Fil system were below levels causing damage or injury.

Thermomechanical Compaction of Gutta-Percha

Several thermomechanical compaction methods and products have been marketed. McSpadden first introduced the McSpadden Compactor, which resembled a reverse Hedstrom file, which was rotated at up to 20,000 rpm. Heat generated by friction softened

gutta-percha, and the blade design pushed material apically.

The *MicroSeal System* (Sybron Endo) was also developed by John McSpadden. He redesigned the Compactor into the NT Condenser that is used with the *MicroSeal System*. The NT Condenser rotates at slower speeds (1,000 to 4,000 rpm) than the original McSpadden Compactor and utilizes nickel–titanium instruments.

The system uses MicroSeal gutta-percha master cones, and specially formulated gutta-percha, termed low-fusing or ultra-low-fusing gutta-percha, in a cartridge that is heated in the MicroSeal heater. This specially formulated low-fusing gutta-percha is advertised to be alpha phase gutta-percha, as are the points. A rotating mechanical condenser in a handpiece is coated with the heated gutta-percha and inserted into the canal. This rotating condenser creates heat from friction that thermally softens the single gutta-percha master point previously seated in the canal. It also flows laterally, by centrifugal force, the low-fusing or ultra-low-fusing gutta-percha coated on the condenser into all aspects of the canal.⁴³

Cathro and Love⁴⁴ compared MicroSeal with a technique using the System B with Obtura II backfill obturation. The MicroSeal technique produced a dense homogenous gutta-percha fill at the apical 1 and 2 mm similar to the System B/Obtura II technique. Further coronally, the sealer became mixed into the MicroFlow gutta-percha, producing a heterogeneous mass with less solid gutta-percha compared with the System B/Obtura II technique.

Carrier-Based Gutta-Percha

The concept of a carrier-based thermoplasticized gutta-percha obturation method was introduced by Johnson in 1978.⁴⁵ These products are marketed today as *ThermaFil Plus Obturators* (Tulsa Dental Products) (Figure 6), GT Obturators (Tulsa Dental Products), ProTaper Obturators (Tulsa Dental Products), Densfil

Figure 6 ThermaFil Plus Obturator by Tulsa Dentsply. Reproduced with permission of Tulsa Dentsply.

(Dentsply Tulsa, Tulsa, OK), and Soft-Core (Soft-Core System, Inc., CMS Dental, Copenhagen, Denmark).

The original ThermaFil obturators had a metal carrier, now replaced with a grooved plastic carrier. Gutta-percha, which coats the carrier, is said to be alpha phase gutta-percha, and certainly after heating in the ThermaFil oven, the gutta-percha is in the alpha or amorphous phase.

Gutmann et al.⁴⁶ compared lateral compaction with ThermaFil obturation and found that curved canals, treated with ThermaFil, resulted in a denser, better-adapted obturation on radiographic examination than those obturated with lateral compaction. However, both showed acceptable root canal fills in the apical one third, and ThermaFil extruded more material beyond the apex. In the second part of the study, no significant difference was seen in dye leakage after obturation with lateral compaction or ThermaFil. Both demonstrated dye leakage over a 5-month period.⁴⁷

Becker and Donnelly⁴⁸ in a literature review of ThermaFil obturation made these observations. ThermaFil appears to seal the apical foramen as well as other thermoplasticized techniques, lateral compaction techniques, or vertical compaction techniques.^{47,49-60} ThermaFil appears to adapt well to canal walls, but the long-term seal may be affected by exposed (bare) carrier.⁶¹ Corrosion of metal carriers should not cause concern. There is significantly more extrusion of gutta-percha compared with lateral compaction.^{46,56,60} Coronal leakage varies by study, but ThermaFil appears to allow significantly more leakage.⁶²⁻⁶⁴ The effect of post-space preparation on the apical leakage of ThermaFil obturators varied depending on the particular study.⁶⁵⁻⁷² Re-treatment may be more difficult, especially with metal carriers and if the canal has been prepared for a post.⁷²⁻⁷⁶ Metal carriers may limit the ability to perform root-end resection.^{77,78}

Felstead et al.⁵² examined apical leakage and found no statistically significant difference among teeth obturated with ThermaFil when heated to 100°, 120°, or 144°C, but there was a trend toward less leakage with lower temperatures. There was no significant leakage difference between teeth obturated with ThermaFil or lateral condensation.

Clark and El Deeb⁵⁶ investigated the sealing ability of plastic versus metal carriers in ThermaFil obturators. Both carrier types were rarely completely entombed by gutta-percha in the apical third; how-

ever, no leakage was detected in any of the obturated canals. Both ThermaFil groups yielded significantly more cases of apically extruded gutta-percha compared with the lateral condensation group. Extrusions were found to occur significantly more in straight than curved canals.

Weller et al.⁷⁹ compared three types of ThermaFil obturators, the Obtura II technique, and lateral compaction for the ability of the gutta-percha to adapt to the canal walls. The Obtura II injectable technique demonstrated the best adaptation of gutta-percha to the prepared root canal followed by the plastic and titanium ThermaFil obturators that were similar, followed by the stainless steel ThermaFil obturators, and finally by the lateral compaction technique, which showed the poorest adaptation of gutta-percha to the canal walls.

GT Obturators are designed to be used after preparation with GT files (Tulsa Dental Products), and ProTaper obturators after preparing a canal with ProTaper files (Tulsa Dental Products).

Robinson et al.⁸⁰ compared extrusion of gutta-percha in teeth instrumented with ProFile 0.06 or ProFile GT and obturated with ThermaFil Plus obturators or ThermaFil GT obturators, respectively, or with warm vertical condensation. Extrusion of gutta-percha was seen more often in the teeth obturated with ThermaFil GT obturators, followed by teeth obturated with ThermaFil Plus obturators, with the least amount of extrusion occurring with the warm vertical condensation technique with either instrumentation method.

In one study, the percentage of gutta-percha-filled area in the apical third of root canals obturated with either lateral condensation technique, System B technique, or ThermaFil technique was examined. There was no significant difference between the percentages of gutta-percha-filled area for lateral condensation or System B technique, but the coated carrier gutta-percha system (ThermaFil) produced a significantly higher percentage of gutta-percha-filled area than the other two techniques.⁸¹

Temperatures produced by heated carrier-based gutta-percha have been found to be at levels safe for bone and periodontal ligament.^{40,82}

Densfil (Maillefer/Dentsply International, York, PA) is a carrier-based gutta-percha system with both plastic and titanium carriers, a spin-off of ThermaFil.

Figure 7 SimpliFil has a metal carrier that comes in ISO sizes 35 to 130 with a 5 mm plug of gutta-percha or Resilon on the end. Reproduced with permission of LightSpeed.

SimpliFil (LightSpeedUSA, San Antonio, TX) (Figure 7) is a 5 mm apical plug of gutta-percha or Resilon on the end of a file and is used similar to a carrier-based system. It has the advantage of not leaving the carrier in the canal, as it is twisted off of the apical plug.

Jarrett et al.⁸⁵ compared the apical density of gutta-percha in palatal roots of maxillary molars when filled with SimpliFil, as recommended by the manufacturer; ThermaFil; warm vertical condensation Schilder technique; warm vertical continuous wave technique; mechanical lateral technique; cold lateral condensation technique; and a modified SimpliFil technique. SimpliFil, as recommended, and ThermaFil had the greatest mean obturated area, but neither was statistically better than mechanical lateral or warm vertical condensation (Schilder) technique. SimpliFil, as recommended, and ThermaFil were statistically better than cold lateral condensation technique, warm vertical condensation (continuous wave) technique, and the modified SimpliFil group. Mechanical lateral and warm vertical condensation (Schilder) techniques had statistically more obturated area than warm vertical condensation (continuous wave) and modified SimpliFil techniques. Cold lateral and warm vertical condensation (continuous wave) had significantly more obturated area than modified SimpliFil.

Shipper and Trope⁸⁴ compared microbial leakage in canals obturated with one of the following techniques: lateral compaction, vertical compaction, Obtura II thermoplasticized injection technique, SimpliFil with Obtura II, FibreFil (Pentron Clinical Technologies, Wallingford, CT), or a combination of FibreFil and SimpliFil. Microbial leakage occurred more quickly in the lateral and vertical compaction techniques compared with SimpliFil and FibreFil techniques. A combination of an apical plug of gutta-percha with SimpliFil and a FibreFil coronal seal provided the best obturation.

SuccessFil is a carrier-based gutta-percha system combined with the UltraFil thermoplasticized injection system to create what is marketed as the Trifecta System (Hygenic/Coltene/Whaledent). Goldberg et al.⁸⁵ compared the sealing ability of Trifecta, lateral condensation and SuccessFil with lateral condensation. No statistically significant differences in leakage were seen between the groups.

JS Quick-Fill (JS Dental Manufacturing, Inc., Ridgefield, CT) is an alpha phase gutta-percha-coated titanium core in ISO sizes 15 to 60. The carrier-based material is spun into the canal at low speed, and the core may be left in the canal or slowly removed.

Properties of Gutta-Percha

Gutta-percha is generally regarded as a very acceptable material with good biocompatibility with the periapical tissues. This has, for the most part, been verified in several studies, with the exception that some formulations of gutta-percha have produced localized severe inflammatory reactions in animals.⁸⁶ Wolfson and Seltzer,⁸⁷ in a 1975 study, found severe tissue reaction to eight brands of gutta-percha they injected into the skin of rats.

Tavares et al.⁸⁸ looked at the reaction of rat subcutaneous tissue to implants of different commercially available gutta-percha compared with Teflon control cylinders. Studies were conducted on Kerr and Hygenic brands of gutta-percha, and cylinders used with the UltraFil thermoplastic injectable gutta-percha from Hygenic Corp. The Kerr points gave mild reactions throughout all experimental periods, and the UltraFil cylinders initially produced a foreign body reaction caused by the dispersion of filling material particles mediated by macrophages and giant cells, but this response decreased with time and thus was considered biologically acceptable. The Hygenic gutta-percha points caused a severe initial inflammatory tissue reaction suggestive of bioincompatibility.

The ingredients of gutta-percha, such as zinc oxide, may contribute to the cytotoxic effects of some commercial gutta-percha.⁸⁹ However, other studies have suggested that the zinc oxide component may reduce the toxicity of other ingredients, especially rosin and resin acids.⁹⁰

The tissue toxicity exerted by gutta-percha is more evident in the advent of an overfill or overextension of gutta-percha into the periapical area. Sjögren et al.⁹¹ demonstrated that the size of gutta-percha particle may make a difference in the intensity of the inflammatory response. Large gutta-percha particles had very little inflammation around them, and appeared to be well encapsulated, whereas the smaller particles of gutta-percha caused a more intense localized response. Additionally, they found that gutta-percha with a rosin and chloroform component invoked a response considered severe.

In a study by Holland et al.,⁹² one brand or formulation of gutta-percha caused a severe inflammatory response in rat connective tissue with a fibrous capsule formation, whereas another brand was well tolerated.

Serene et al.⁹³ looked at the activation of complement to examine the inflammatory response of four different commercially available brands of gutta-percha, and the ingredients in one of the brands. This in vitro study showed that each of the four brands of commercially available gutta-percha and each of the ingredients could cause activation of the complement system.

Although some gutta-percha has been shown to be cytotoxic, invoking inflammatory reactions in connective tissue, the most toxic portion of the sealer–gutta-percha obturation is the sealer.⁸⁶

Because gutta-percha and gutta-balata are derived from the *Paliquium gutta* and *M. globsa* trees, which are of the same botanical family of trees as the natural rubber latex tree, *H. brasiliensis*, there was concern about the possible cross-reactivity between gutta-percha and natural rubber latex in individuals who may have immediate-type hypersensitivity to natural rubber latex. There have been case reports suggesting that gutta-percha may release proteins that induce reactions in latex-allergic individuals.^{94,95} In these cases, the symptoms were uncharacteristic of those routinely experienced by patients with latex allergies. Other causes, more directly related to the quality of the endodontic treatment itself, may have been the reason for the patients' symptoms. These case reports did not prove the cross-reactivity between *Hevea* latex and gutta-percha. On the other hand, Knowles et al.⁹⁶ and Kleier and Shibilski⁹⁷ presented case reports where gutta-percha was successfully used to obturate

canals in patients with documented IgE antibody-mediated allergy to natural rubber latex.¹² Studies by Costa et al.¹² and Hamann et al.⁹⁸ using the radioallergosorbent test (RAST) inhibition and enzyme-linked immunosorbent assay (ELISA)⁹⁸ showed that commercially available gutta-percha alone is not likely to induce symptoms in the patient with type I natural rubber latex allergy and that commercially available gutta-percha can safely be used in these patients. The refining process for gutta-percha is so severe that most proteins would be denatured by the process. Raw gutta-balata was the only substance that showed cross-reactivity with natural rubber latex.¹² None of the processed gutta-percha products, or natural raw gutta-percha, showed any cross-reactivity with natural rubber latex.¹² Nevertheless, it is always prudent to investigate natural rubber latex allergies in patients because it is very common, particularly among health care workers (17%) and spina bifida patients (67%).^{99–101}

Newer Solid-Core Filling Materials

Resilon (Pentron Clinical Technologies), and *RealSeal* (Sybron Endo), is a polycaprolactone core material with difunctional methacrylate resin, bioactive glass, bismuth and barium salts as fillers, and pigments, which is used with a resin sealer (*Epiphany* or *Real-Seal*) that is packaged with the core filling material (Figures 8). The rationale behind the product is to create a “monoblock” consisting of a resin sealer with

Figure 8 Epiphany sealer is a resin type of sealer used with polycaprolactone core materials such as Resilon core material. Courtesy, James David Johnson.

resin tags that enter into and bond to dentinal tubules, and to the dentin on the canal wall, as well as adhesively bonding to the core material, and which can also be light cured and sealed coronally as well. The Resilon system consists of a primer, a sealer, and synthetic polymer points or pellets.

Whereas the sealer used with Resilon is discussed under the discussion on sealers later in this chapter, the Resilon system, core material and sealer, has to be used together, as it is one system, and each part relies on the other parts to be successful.

The polyester core material is marketed in ISO-sized points with accessory points for lateral compaction and warm vertical techniques, or pellets for use in thermoplasticized techniques.¹⁰¹ The temperatures used in the thermoplasticized techniques for the polyester resin core materials are lower than those used for gutta-percha techniques (150°C, compared to 200°C), but otherwise has handling characteristics that are similar to gutta-percha and allows for lateral compaction or warm vertical obturation techniques. In the case of using Resilon with the System B unit, the temperature is set at 150°C and the power is set at 10. If Resilon is used with the Obtura III thermoplasticizing unit with 25-gauge needles, the temperature is set at 160°C; with 23-gauge needles, the temperature is set at 140°C; and for use with 20-gauge needles, the temperature is set at 120° to 130°C.

One study compared Resilon with gutta-percha in terms of the melting point, specific heat capacity, enthalpy change with melting, and heat transfer. It was found that there was no difference in the melting point temperatures for the two materials, but Resilon had a significantly greater specific heat capacity and endothermic enthalpy change. There was a significant difference in the heat transfer test in the temperature increase between gutta-percha and Resilon within 3 mm of the heat source, with gutta-percha having a greater temperature change. They concluded that Resilon may not be thermoplasticized the same as gutta-percha because there is a higher specific heat, higher enthalpy change with melting, and less heat transfer.¹⁰²

Nielsen and Baumgartner¹⁰³ examined the depth of nickel–titanium spreader penetration in root canals having a 0.04 preparation size taper using 0.02 and 0.04 tapered master gutta-percha or Resilon points. A significant difference in penetration depth was found for both taper of the point and the material used. The depth of spreader penetration was greatest for 0.02 tapered Resilon, followed by 0.02 gutta-percha, followed by 0.04 tapered Resilon, and the least spreader penetration occurred with the 0.04 gutta-percha.

Shipper et al.¹⁰⁴ investigated the resistance to bacterial penetration of gutta-percha with AH 26 sealer, gutta-percha with Epiphany sealer, and Resilon with Epiphany sealer. Each combination of core material and sealer was obturated with both lateral and vertical condensation techniques. The Resilon groups were found to have less leakage than the gutta-percha groups with respect to the number and rate of the specimens in each group that leaked. All Resilon and Epiphany sealer groups leaked significantly less than all groups in which AH 26 was used as a sealer.

By contrast, other investigators¹⁰⁵ performed an ultrastructural evaluation of the apical seal in roots filled with a polycaprolactone-based root canal filling material. This study compared the ultrastructural quality of the apical seal achieved with Resilon and Epiphany sealer with that produced by gutta-percha and AH Plus sealer. The SEM revealed both gap-free regions and gap-containing regions in canals filled with both materials. The transmission electron microscope revealed the presence of silver deposits along the sealer-hybrid layer interface in the Resilon/Epiphany samples and between the sealer and gutta-percha samples. They concluded that a complete apical seal cannot be achieved with either combination of root canal filling material and sealer.

The susceptibility of a polycaprolactone-based root canal filling material (Resilon) to degradation has been investigated. Tay et al.¹⁰⁶ examined what effect alkaline hydrolysis would have on disks of Resilon or gutta-percha using scanning electron microscopy and energy dispersive X-ray analysis. They found that for Resilon, the surface resinous component was hydrolyzed after 20 minutes of immersion in sodium ethoxide, which exposed the spherulitic polymer structure and subsurface glass and bismuth oxychloride fillers. Gutta-percha did not undergo alkaline hydrolysis when immersed in sodium ethoxide.

Tay et al.¹⁰⁷ evaluated the susceptibility of Resilon, gutta-percha, and polycaprolactone disks to hydrolytic enzymes present in saliva or secreted by endodontically-relevant bacteria. All three materials had slight weight gains when incubated in phosphate-buffered saline. Gutta-percha showed similar weight gains with the enzymes, lipase polysaccharide, and cholesterol esterase, but Resilon and polycaprolactone exhibited extensive surface thinning and weight loss after incubation in lipase polysaccharide and cholesterol esterase. Glass filler particles in Resilon were exposed following surface dissolution of the polymer matrix, which created a rough surface topography. They concluded that biodegradation of Resilon by bacterial and salivary enzymes warrants further investigation.

The interfacial strengths of Resilon with Epiphany sealer have been compared with those of gutta-percha with AH Plus sealer by Gesi et al.¹⁰⁸ The gutta-percha/AH Plus testing group exhibited significantly higher interfacial strength than did the Resilon/Epiphany group, when premature failures that occurred in Resilon root slices were included. The gutta-percha root slices failed exclusively along the gutta-percha/sealer interface. The Resilon root slices failed predominantly along the sealer/dentin interface with recognizable, fractured resin tags. Detachment of Resilon from the Epiphany sealer was also observed in some specimens. The relatively low interfacial strengths of materials, gutta-percha/AH Plus, and Resilon/Epiphany seemed to challenge the concept that root strengthening is accomplished with either material.

Stratton et al.¹⁰⁹ looked at the sealing ability of Resilon and Epiphany sealer versus that of gutta-percha and AH Plus sealer, by means of fluid filtration testing. They found significantly less leakage using Resilon and Epiphany as compared with the gutta-percha and AH Plus sealer.

Another study found Resilon with Epiphany sealer had less leakage after 30 days than gutta-percha and sealer. All canals obturated with gutta-percha and sealer, and those obturated with Resilon or gutta-percha without sealer leaked within 30 days.¹¹⁰

Wang et al.¹¹¹ investigated the effects of calcium hydroxide medication on the sealing ability of Resilon and found that calcium hydroxide did not adversely affect the seal of the root canal system that was subsequently filled with Resilon.

In an investigation comparing the completeness of root canal obturation with gutta-percha techniques versus Resilon with Epiphany sealer, using lateral compaction and continuous wave obturation, results showed that lateral compaction of gutta-percha was the only group with significantly more voids than gutta-percha with the continuous wave obturation, or Resilon with Epiphany sealer using either obturation technique.¹¹²

Resilon has been reported to reinforce the root canal system because of its adhesion to the canal wall and integration of the core material.¹¹³ On the other hand, another study compared cohesive strength and the stiffness of Resilon and gutta-percha under dry conditions and after 1 month of water storage, to determine whether they are stiff enough to reinforce roots. They found that both Resilon and gutta-percha had relatively low cohesive strength and modulus of elasticity, and did not have enough stiffness to reinforce roots after endodontic therapy.¹¹⁴

Long-term results and clinical trials will be useful in the evaluation of Resilon as compared with gutta-percha, and the evolution of newer generations of Resilon may further improve the material.

Paste Filling Materials

Zinc oxide is a major component of many paste materials used in endodontics. It is the other ingredients in many zinc oxide paste materials that are responsible for other properties and potential toxicity. These pastes will be discussed under the pastes containing other ingredients. Because of the solubility of zinc oxide, they do not make effective core filling materials.

A paste filling material that has been widely used in Eastern European countries and some Asian and Pacific Rim nations is a resin type of material known as "Russian Red."¹¹⁵ This is resorcin-formaldehyde paste, a type of phenol-formaldehyde or Bakelite resin.¹⁰¹ Ørstavik¹⁰¹ reported it is strongly antimicrobial, but with the disadvantage of shrinkage in the canal once placed, and that it often stains tooth structure a dark red. Sometimes re-treatments can be difficult, if the resin sets completely and there is sufficient bulk to the material.¹¹⁵

Trailement SPAD is another resin-based type of paste material that has been used in Europe.

Mineral Trioxide Aggregate

Mineral trioxide aggregate (MTA) has many uses in endodontics (Figure 9). MTA is used as a pulp-capping material,^{116–118} as a perforation repair agent,^{119–122} as a root-end filling material,^{123–125} as an apical barrier,^{126–128} and as an intraorifice barrier,¹²⁹ and

Figure 9 White and gray ProRoot mineral trioxide aggregate (MTA) by Tulsa Dentsply. Reproduced with permission of Tulsa Dentsply.

may be considered as a paste filling material for the obturation of root canals. Because of its sealing ability, biocompatibility, and other desirable properties, it would seem to be a paste filling material that is indicated when more conventional core filling materials cannot be used. The major drawbacks of MTA are its somewhat difficult handling characteristics, which may be overcome with experience, and its extended setting time of at least 3 hours or more. Its many favorable properties and characteristics make it a valuable material in many aspects of endodontics.

ProRoot MTA (Tulsa Dental Products, Tulsa, OK) was introduced by Torabinejad et al.¹²³ in 1993 as a root-end filling material and as a root perforation repair material.¹¹⁹ They reported the ingredients as tricalcium silicate, tricalcium aluminate, tricalcium oxide, and silicate oxide, with some other mineral oxides that were responsible for the chemical and physical properties of the aggregate. The powder consists of fine hydrophilic particles that set in the presence of moisture. The hydration of the powder results in a colloidal gel with a pH of 12.5 that will set in approximately 4 hours.¹³⁰

Several studies have stated that MTA is very similar in nature to commercial Portland cement.^{131–135} Wucherpfenning and Green¹³² analyzed MTA and Portland cement by X-ray diffraction and reported that they were similar macroscopically and microscopically. Estrela et al.¹³³ showed that Portland cement contains the same chemical elements as MTA, with the exception of bismuth oxide, which is added to MTA to increase its radiopacity. Duarte et al.¹³⁶ reported that MTA Angelus is 80% Portland cement and 20% bismuth oxide. Sarkar et al.¹³⁷ stated that MTA is a mechanical mixture of three powder ingredients, which are Portland cement (75%), bismuth oxide (20%), and gypsum (5%), with trace amounts of SiO₂, CaO, MgO, K₂SO₄, and Na₂SO₄. They also listed the ingredients of the major component, Portland cement, as dicalcium silicate, tricalcium silicate, tricalcium aluminate, and tetracalcium aluminoferrite.

One of the very favorable properties of MTA is its outstanding sealing ability. This has been verified in many studies using MTA as a root-end filling material and for sealing perforations in both dye leakage and bacterial leakage models. Torabinejad et al.¹²³ using an aqueous solution of rhodamine B fluorescent dye found MTA leaked significantly less than amalgam or ethoxybenzoic acid (Super EBA) as a root-end filling material. In another dye study, Torabinejad et al.¹³⁸ found MTA sealed better as a root-end filling material

than amalgam, Intermediate Restorative Material (IRM), or Super EBA, even in the presence of blood contamination. Gondim et al.¹³⁹ demonstrated, with a dye study, that MTA leaked significantly less than Super EBA or IRM, regardless of the finishing technique employed. In a bacterial leakage investigation of root-end filling materials, Torabinejad et al.¹⁴⁰ showed that MTA leaked significantly less than the other root-end filling materials tested. MTA was also found to allow less leakage of endotoxin in a study by Tang et al.¹⁴¹ Tselnik et al.¹²⁹ examined bacterial leakage with MTA or a resin-modified glass ionomer as a coronal barrier. They found both gray and white MTA, when used as a coronal barrier, prevented microbial leakage for over 90 days. Nakata and coworkers¹²¹ found that MTA provided a better seal than amalgam to prevent the leakage of *F. nucleatum* into furcation perforations.

In a SEM study, Torabinejad et al.¹⁴² showed that MTA had better marginal adaptation than amalgam, Super EBA or IRM. Other studies using the SEM have agreed with these findings with regard to MTA adaptation.^{143,144} Xavier et al.¹⁴⁵ examined both dye leakage and marginal adaptation as viewed under the SEM and found that MTA Angelus leaked significantly less than a glass ionomer, but statistically more than Super EBA. They found that MTA Angelus had much better marginal adaptation than EBA, or the glass ionomer when viewed under the SEM. Mangin et al.¹⁴⁶ found no difference in leakage of radioactive labeled bacteria between hydroxyapatite cement, MTA, and Super EBA when used as root-end filling materials.

In a fluid filtration model, Bates et al.¹⁴⁷ found MTA was comparable with Super EBA in the prevention of leakage, but Wu et al.¹⁴⁸ reported MTA leaked significantly less than Super EBA. DeBruyne et al.¹⁴⁹ using a fluid transport and capillary flow porometry technique found that after 1 day, and after 1 month there was no statistical significant difference in leakage between a reinforced glass ionomer cement and white MTA in root-end fillings. At 6 months, however, the glass ionomer leaked significantly less than MTA. There were no significant differences observed with flow porometry between pore diameters of the materials tested.

The effects of the thickness and of resection of MTA have been investigated. Andelin et al.¹⁵⁰ examined leakage after the resection of MTA placed in canals before the root end was resected and found that the resection of set MTA did not affect its sealing ability. Lamb et al.¹⁵¹ had similar findings, as long as at least 3 mm of MTA remained. Valois et al.¹⁵² examined the influence of thickness of MTA on the sealing ability of the

material and showed that a 4 mm thickness of MTA was significantly more effective in preventing protein leakage than lesser thicknesses of MTA. Matt et al.¹⁵³ found that for an apical barrier, 5 mm of MTA was significantly harder than a 2 mm barrier, and allowed significantly less leakage. These dimensions may be important, not only in the depth of root-end fillings with MTA but when it is used as an apical barrier, or as a perforation repair material, or for other purposes.

MTA has been studied extensively for its biocompatibility with its application as a root-end filling material in root-end endodontic surgery. Cell culture studies have demonstrated that the cytotoxicity of MTA was significantly less than that of IRM or Super EBA.¹⁵⁴ Implantation of MTA into tibias and mandibles of guinea pigs resulted in a tissue reaction considered favorable and slightly milder than that of Super EBA.¹⁵⁵ Koh et al.¹⁵⁶ found favorable biologic responses to MTA from human osteoblasts, and favorable cellular response to MTA.¹⁵⁷

Haglund et al.¹⁵⁸ compared MTA, amalgam, IRM, and a composite resin for their effects on mouse fibroblasts and macrophages. They found all four materials inhibited cell growth. There were significantly fewer cells cultured with the fresh IRM and composite groups compared with the MTA and amalgam groups, and there was no difference between a fresh mix of MTA and a fresh mix of amalgam. For set materials, there was no significant differences in the fibroblast cell growth between MTA, amalgam, and the composite resin. In the fibroblast cell line, set IRM had significantly fewer surviving cells than the other set materials. There was a significant difference in the survival of cells in the macrophage cell line in the presence of the set materials between the composite resin group and MTA, and between the composite resin group and amalgam, with fewer macrophages surviving in the presence of the composite resin set material. Set IRM had significantly fewer cells survive than the other set material in the macrophage cell line also. DeDeus et al.¹⁵⁹ compared the cytotoxicity of ProRoot MTA, MTA Angelus, and Portland cement and found no significant difference between the three materials in terms of cytotoxicity and that all three initially showed similar elevated cytotoxic effects that decreased gradually with time, allowing the cell culture to become reestablished.

Hernandez et al.¹⁶⁰ studied the effect of mixing chlorhexidine with MTA versus MTA mixed with water on the apoptosis and cell cycle of fibroblasts and macrophages. They found that mixing MTA with chlorhexidine induced apoptosis of fibroblasts and macrophages and decreased the percentage of both cell

types in the S phase (DNA synthesis) of cell cycles. Thus, mixing sterile water with MTA was determined to be less cytotoxic than mixing MTA with chlorhexidine. Melegari et al.¹⁶¹ studied the production of prostaglandin E₂ (PGE₂) and the viability of cells cultured in contact with freshly mixed Roth's 801 sealer, Sealapex sealer, and MTA. It was found that none of the materials stimulated the release of PGE₂.

MTA is also reported to have qualities that may provide an environment for repair and regeneration of periapical tissues. MTA has shown an inductive effect on cementoblasts in dogs and monkeys.^{124,125} Zhu et al.¹⁶² showed osteoblasts attaching and spreading on MTA. Regan et al.¹⁶³ demonstrated that both MTA and Diaket can support almost complete regeneration of the periradicular periodontium when used as a root-end filling material on teeth that are not infected. Baek et al.¹⁶⁴ found that MTA showed the most favorable periapical tissue response and that there was neoformation of cemental coverage over MTA.

There is conflicting information as to whether gray and white MTA have the same physical properties and biocompatibility. Holland et al.^{135,165,166} have shown that both white and gray formulations are biocompatible when implanted into rat connective tissue. Perez et al.¹⁶⁷ demonstrated that white MTA was less biocompatible than gray MTA. Camilleri et al.¹⁶⁸ showed no difference between the gray and white formulations of MTA. Ribeiro et al.¹⁶⁹ showed no difference in cytotoxic effects for gray MTA, white MTA, or Portland cement. The same group found no difference in genotoxicity or cytotoxicity between gray or white MTA.¹⁷⁰ Asgary et al.¹⁷¹ by electron probe microanalysis observed that the concentrations of Al₂O₃, MgO, and particularly FeO in white MTA are considerably lower than those found in gray MTA. The FeO is thought to be the primary ingredient responsible for the color differences between white and gray MTA. Oviir et al.¹⁷² investigated the proliferation of oral keratinocytes and cementoblasts on gray and white MTA. They found both cell types grew significantly better on the surface of white MTA compared with gray MTA. In addition, both cell types showed significantly higher proliferation when grown on 12-day-cured gray MTA compared with 24-hour-cured gray MTA. Matt et al.¹⁵³ found that white MTA leaked significantly more than did gray MTA and that a two-step technique, where a moist cotton pellet is placed over the MTA for 24 hours to allow it to set, showed less leakage than a one-step technique for placing an apical barrier.

There is some conflicting opinion as to whether a moist cotton pellet is needed to allow the MTA to set properly when used within the root canal system, other than as a root-end filling material where it is in contact with moisture. This step adds another appointment to the treatment when MTA is used as a perforation repair material, as an apical barrier, or as an intraorifice barrier. There have been case reports where a moist cotton pellet is used between appointments to allow for the MTA to set.^{126–128} On the other hand, Sluyk et al.¹⁷³ showed that the retention characteristics of MTA used as a perforation repair material was not altered by the placement of either a dry or a moist cotton pellet over the MTA, and the moisture from the periradicular tissues may provide adequate moisture to allow the MTA to set properly. Matt et al.¹⁵³ did show, however, that the application of a moist cotton pellet significantly reduced leakage of MTA used as an apical barrier.

The long-term solubility of MTA was investigated by Fridland et al.¹⁷⁴ Their results showed that MTA is capable of partially releasing its soluble fraction into an aqueous environment over a long period of time and it still maintains its high pH level of 11 to 12 over at least 78 days, while also maintaining its insoluble matrix of silica which produces MTA's structural integrity even while in contact with water. This soluble fraction is mainly composed of calcium hydroxide, which may provide the alkalinity favorable for cell division and matrix formation for healing of periradicular tissues and for antimicrobial activity. Sarkar et al.¹³⁷ speculated that after placement of MTA in root canals and its gradual dissolution, hydroxyapatite crystals nucleate and grow, filling the microscopic space between MTA and the dentinal wall. This seal is first mechanical, but then they envision a reaction between the apatite layer and the dentin in the form of a chemical bond, and a seal between MTA and dentin.

Some investigators are looking into modifications of Portland type cements to alter the setting properties and handling characteristics. One of the main disadvantages of using MTA is its extended setting time. In industrial uses of Portland cement, the setting time may be increased by adding gypsum or reduced to a flash set by removing gypsum. Camilleri et al.¹⁷⁵ investigated a new accelerated Portland cement. The setting time of the Portland cement was reduced by excluding gypsum in the last stage of the manufacturing process. The biocompatibility testing of this accelerated Portland cement was not altered by adding bismuth oxide for radiopacity and had similar biocompatibility as gray MTA, white MTA, and white Portland cement. Future research

will have to determine whether altering the undesirable aspects of MTA can be accomplished without affecting its very desirable properties of sealing, biocompatibility, and favorable conditions for repair and regeneration of periradicular tissues.

Paraformaldehyde Pastes

Paraformaldehyde pastes may also be considered as sealers, and are used as sealers by some. The addition of paraformaldehyde is for its antimicrobial and mummifying effects, but unfortunately its severe toxicity to host tissues outweighs any antimicrobial effects it may possess as an ingredient in endodontic materials.

N2 paste (Indrag-Agsa, Losone, Switzerland) and its US counterpart, RC2B, is a liquid and powder paste. The liquid contains zinc oxide, bismuth nitrate, bismuth carbonate, paraformaldehyde, and titanium oxide. The liquid consists of eugenol, peanut oil, and rose oil.¹⁷⁶ The contents of N2 have changed over the years in response to studies identifying toxic substances, such as lead oxide and organic mercury.¹⁷⁷ It still contains large amounts of paraformaldehyde (4–8%).⁸⁶ N2 has been found to be extremely toxic.^{178,179} Furthermore, because it is used as a paste, the extrusion of this toxic material is easier and has caused severe neurological damage in reported cases.^{180–183} The Food and Drug Administration (FDA) lists N2 or RC2B as an unapproved new drug not legally imported or shipped across interstate lines.¹⁸⁴ The American Dental Association (ADA) Council of Dental Therapeutics does not approve the use of paraformaldehyde pastes or sealers. A case report of a dentist who was found liable for a patient's permanent disability as a result of root canal therapy with N2 (Sargenti's) paste was presented in the status report. The canal was obturated with N2, which reportedly extruded into the mandibular canal causing nerve damage, facial dysesthesia, and pain. The patient was awarded \$250,000 (US) for injury.¹⁸⁵

The American Association of Endodontists has issued a position paper on the use of paraformaldehyde-containing endodontic materials, recommending against their use.¹⁸⁶ Some states, including Florida, have banned the use of paraformaldehyde pastes.¹⁸⁷ Because of the toxicity, legal issues, risks to patients, and the fact there are numerous other obturating materials available that provide a better outcome, without risk to the patient, the use of these materials in modern-day endodontics cannot be supported.

Endomethasone (Septodont, Paris, France) is a liquid-powder sealer used in Europe. The powder

contains dexamethasone, hydrocortisone acetate, thymol iodide, paraformaldehyde, and a radiopaque excipient, whereas the liquid contains eugenol, peppermint oil, and Anise oil.¹⁷⁶ The difference between Endomethasone and other paraformaldehyde-containing sealers is the addition of the hydrocortisone. The toxicity of the paraformaldehyde still remains.

Riebler's paste (Amubarut; Wera Karl, Biesingen, Germany) is another paraformaldehyde-containing paste as is *Trailement SPAD*, another resin-based type of paste material that has been used in Europe.

Sealers

REQUIREMENTS FOR AN IDEAL ROOT CANAL SEALING MATERIAL

In addition to the basic requirements for core filling materials, Grossman also listed the following 11 requirements for a root canal sealer:^{188,189}

1. It should be tacky when mixed to provide good adhesion between it and the canal wall when set.
2. It should make a hermetic seal.
3. It should be radiopaque so it can be visualized in the radiograph.
4. The particles of powder should be very fine so they can mix easily with the liquid.
5. It should not shrink upon setting.
6. It should not stain tooth structure.
7. It should be bacteriostatic or at least not encourage bacterial growth.
8. It should set slowly.
9. It should be insoluble in tissue fluids.
10. It should be tissue tolerant, that is, nonirritating to periradicular tissues.
11. It should be soluble in a common solvent, if it is necessary to remove the root canal filling.

One might add the following to Grossman's original basic requirements:

12. It should not provoke an immune response in periradicular tissues.¹⁹⁰⁻¹⁹³
13. It should be neither mutagenic nor carcinogenic.^{194,195}

Zinc Oxide-Containing Sealers

For many years, zinc oxide-containing sealers have been the most popular and widely used sealers. There are many formulations and brands of sealers that have

zinc oxide as the primary ingredient, differing only by other components added to the sealers.

Zinc oxide sealers allow for addition of other chemicals, such as paraformaldehyde, rosin, Canada balsam, and others, all of which may increase their toxicity.⁸⁶ Zinc oxide-containing sealers that have other ingredients will be discussed under those sections.

Grossman's original formula contained zinc oxide, staybelite resin, bismuth subcarbonate, barium sulfate, and sodium borate (anhydrous) with eugenol as the liquid component.¹⁸⁸ It has been marketed as *Procosol* sealer, as well as other product names.

Roth's 801 sealer (Roth's Pharmacy, Chicago, IL) is essentially the same as Grossman's original formulation, with the substitution of bismuth subnitrate for bismuth subcarbonate. Eugenol is used as the liquid of the sealer (Figure 10).

Rickert's formula was an early zinc oxide-containing sealer. It has long been an acceptable standard, meeting most of Grossman's requirements for an ideal sealer. Its major drawback was the staining of tooth structure from the silver that was used for radiopacity.¹⁶ Rickert's formula was marketed as *Kerr's Pulp Canal Sealer* (Sybron Endo/Kerr, Orange, CA). *Pulp Canal Sealer* has been popularized by clinicians using the warm vertical obturation techniques. A major disadvantage of *Pulp Canal Sealer* was its rapid setting time, especially with heat and in regions with high temperatures and high humidity.¹⁶ To overcome this disadvantage, researchers formulated *Pulp Canal Sealer EWT* (Extended Working Time) (Sybron

Figure 10 Roth Root Canal Cement is an example of a zinc oxide and eugenol sealer. Courtesy, James David Johnson.

Endo/Kerr) which reportedly has a working time of 6 hours.¹⁶

Tubli-Seal (Sybron Endo/Kerr) is a two-paste system contained in two separate tubes. Developed as a nonstaining alternative to the silver-containing Pulp Canal Sealer, Tubli-Seal is a zinc oxide-base paste with barium sulfate for radiopacity, and mineral oil, cornstarch, and lecithin. The catalyst tube has polypale resin, eugenol, and thymol iodide. Tubli-Seal is easy to mix but has the disadvantage of rapid setting time.¹⁶ Tubli-Seal EWT has the same properties as the regular setting Tubli-Seal but has an extended working time.

Wach's cement (Roth International Inc., Chicago, IL) consists of a powder of zinc oxide, bismuth subnitrate, bismuth subiodide, magnesium oxide, and calcium phosphate. The liquid contains oil of cloves, eucalyptol, Canada balsam, and beechwood creosote. The liquid gives Wach's cement a rather distinctive odor of an old-time dental office.¹⁶ It has the advantage of having a smooth consistency, and the Canada balsam makes the sealer tacky.

Nogenol (GC America, Inc., Alsip, IL) was developed to overcome the irritating effects of eugenol.¹⁹⁶ This product is an extension of the noneugenol periodontal dressings. It is a two-tube, base and catalyst system with a base of zinc oxide, barium sulfate, bismuth oxychloride, and vegetable oil. Hydrogenated rosin, methyl abietate, lauric acid, chlorothymol, and salicylic acid in the catalyst accelerate the setting time.¹⁶

Medicated Canal Sealer (Medidenta International, Inc.) was developed by Martin.¹⁵ This sealer contains iodoform for antibacterial purposes and is to be used with MGP gutta-percha, which also contains 10% iodoform.¹⁶

Calcium Hydroxide-Containing Sealers

Sealapex (Sybron Endo/Kerr) is a calcium hydroxide-containing noneugenol polymeric sealer that is packaged as two tubes. Sealapex has zinc oxide in the base along with calcium hydroxide and also contains butyl benzene, sulfonamide, and zinc stearate. The catalyst tube has barium sulfate and titanium dioxide for radiopacity, and a proprietary resin, isobutyl salicylate, and aerocil R792.¹⁶ Sealapex had no greater dissolution than Tubli-Seal at both 2 and 32 weeks. It appears that Sealapex had a sealing ability comparable with Tubli-Seal and could withstand long-term leakage.¹⁹⁷

Holland and De Souza¹⁹⁸ studied Sealapex sealer to see if it could induce hard tissue formation. Sealapex

with calcium hydroxide did encourage apical closure by cementum deposition. Closure was also observed in the control groups (5%) and in Kerr Pulp Canal Sealer groups (10%), but was associated with dentin chips that also stimulate cementum formation. Both Sealapex and Kerr Pulp Canal Sealer, when overextended, provoke a chronic inflammatory reaction in the periodontal ligament (PDL).

Apexit (Ivoclar Vivadent, Schaan, Liechtenstein) is a calcium hydroxide sealer with salicylates also incorporated into the formula.

CRCS (Calciobiotic Root Canal Sealer; Coltene/Whaledent/Hygenic, Mahwah, NJ) is a calcium hydroxide-containing sealer with a zinc oxide-eugenol-eucalyptol base. CRCS is a rather slow setting sealer, especially in dry or in humid climates. It may require up to 3 days to fully set.¹⁶ The set sealer is quite stable, which improves its sealing qualities, but may mean that calcium hydroxide is not as readily released, and the stimulation of cementum and bone formation may be severely limited.

Beltes et al.¹⁹⁹ did an in vitro evaluation of cytotoxicity of calcium hydroxide-based root canal sealers. Sealapex was the most cytotoxic, followed by CRCS, with Apexit being the least cytotoxic with the least decrease in cell density.

Siqueira et al.²⁰⁰ investigated the sealing ability, pH, and flow rate of three calcium hydroxide-based sealers (Sealapex, Sealer 26, and Apexit). There was no significant difference found between apical sealing ability and dye penetration. All calcium hydroxide sealers alkalinized adjacent tissues. Sealer 26 had significantly superior flow characteristics. They concluded calcium hydroxide sealers compare favorably with zinc oxide and eugenol (ZOE) cements for use in obturation.

Vitapex (NEO Dental International, Inc, Federal Way, WA) is a sealer, which was developed in Japan, and contains, not only calcium hydroxide, but also 40% iodoform and silicone oil among other ingredients.

Resin Sealers

Epoxy resin sealers have an established record in endodontics, especially in the form of AH 26 and its successor AH Plus (Dentsply International, York, PA).

AH 26 (Dentsply International/Maillefer) is a bisphenol epoxy resin sealer that uses hexamethylenetetramine (methenamine) for polymerization and has been used for many years as a sealer.^{101,201} The methenamine will give off some formaldehyde as it sets, and this has been one of its major drawbacks. The highest amount of formaldehyde release is in the freshly mixed sealer, and the amount of formaldehyde

Figure 11 AH Plus Root Canal Sealer by Tulsa Dentsply is a resin type sealer shown here in a mixing syringe. Reproduced with permission of Tulsa Dentsply.

released goes down after 48 hours, and after 2 weeks the amount released is insignificant.²⁰² The amount of formaldehyde produced during the setting process has been reported to be several thousand times lower than the long-term release from formaldehyde-containing sealers such as N2.^{86,201} Other disadvantages are staining and an extended working time. On the other hand, AH 26 does not seem to be affected by moisture, and will even set under water.¹⁶

AH Plus and ThermaSeal Plus (Dentsply International) (Figure 11) were formulated with a mixture of amines that would allow for polymerization without the unwanted formation of formaldehyde,^{201,203} but with all the advantages of AH 26, such as increased radiopacity, low solubility, slight shrinkage, and tissue compatibility. AH Plus is an epoxy-bis-phenol resin that also contains adamantane.¹⁰¹ AH Plus comes as a two-paste system, unlike the liquid-powder system of AH 26. AH Plus has a working time of 4 hours and a setting time of 8 hours. Other improvements over the older AH 26 formulation are the thinner film thickness and the decreased solubility of AH Plus, both about half that of AH 26. AH Plus has been shown to be less cytotoxic than AH 26, but both caused a dose-dependent increase in genotoxicity.¹⁷⁶

Epiphany (Pentron Clinical Technologies) or *Real-Seal* (Sybron Endo) is a sealer that contains urethane dimethacrylate (UDMA), Poly(ethylene glycol) dimethacrylates (PEGDMA), ethoxylated bisphenol A-dimethacrylate (EBPADMA), Bisphenol-A-glycidyl-dimethacrylate (BisGMA) resins designed for use with the polycaprolactone core materials. Additionally, these sealers contain silane-treated barium borosilicate glass, barium sulfate, silica, calcium hydroxide, bismuth oxychloride with amines, peroxide, a photo inhibitor, and pigments. *Epiphany* sealer is a dual-cure dental resin composite sealer that self-cures in about 25 minutes. It comes with a self-etch primer with

sulfonic acid-terminated functional monomer, Hydroxyethylmethacrylate (HEMA), water, and polymerization initiator. Sodium hypochlorite may negatively affect bond strength of the primer, so after using sodium hypochlorite for irrigation, one should irrigate with ethylenediaminetetraacetic acid (EDTA) and sterile water. Peroxide-containing lubricants might also have a retarding effect on the resins, so a final rinse with EDTA and sterile water is recommended after using these lubricants. Chlorhexidine does not affect the bond strength. When obturation is completed, the coronal surface may be light-cured for 40 seconds to create a coronal seal.

In a study comparing *Epiphany* sealer with AH Plus and EndoREZ sealers for intraosseous biocompatibility for 4 and 12 weeks, as recommended by the Technical Report 9 of the Federation Dentaire Internationale (FDI), Sousa et al.²⁰⁴ found the inflammatory tissue reaction to EndoREZ was severe and the AH Plus inflammatory reaction went from severe to moderate with time, whereas *Epiphany* showed biological compatibility in regard to bone formation, and it also produced either no, or very slight inflammation.

In a direct comparison of physical and chemical properties of AH Plus and *Epiphany* sealers, Versiani et al.²⁰⁵ found there was no significant difference in flow or film thickness between AH Plus and *Epiphany* sealers. There was a statistical difference between the two with the solubility of *Epiphany* being 3.41% versus 0.21% for AH Plus, and for dimensional stability, there was also a statistical difference with AH Plus expanding 1.3% on setting and *Epiphany* expanding 8.1% following setting. The setting time, flow, and film thickness tests for both cements conformed to American National Standards Institute (ANSI)/ADA standards. Dimensional alteration tests for both sealers were greater than values considered acceptable by ANSI/ADA standards, and the values for *Epiphany* sealer with regard to solubility were also greater than values considered acceptable by ANSI/ADA.

Ungor et al.²⁰⁶ evaluated the push-out bond strength of the *Epiphany*-Resilon root canal filling system with the bond strengths of different pairings of AH Plus, gutta-percha, *Epiphany*, and Resilon. Their results showed that *Epiphany* with gutta-percha had significantly greater bond strength than all the other groups. There was no significant difference between the *Epiphany* with Resilon combination and the AH Plus with gutta-percha. Inspection of the surfaces revealed the bond failure to be mainly adhesive to dentin for all groups.

Diaket (3M/ESPE, Minneapolis, MN) has been a popular sealer in Europe for many years and is a

polyketone compound containing vinyl polymers mixed with zinc oxide and bismuth phosphate.⁸⁶ Diaket is a sealer that sets by chelation, but it contains polyvinyl chloride in polymer form as a main ingredient.¹⁰¹ It has a liquid component of B-diketone. It is a tacky material that contracts upon setting, but this is offset by its absorption of water.¹⁶ It has done well in in-vitro tests, including biocompatibility studies.¹⁰¹ Studies have shown that after initial mild tissue reactions, and after longer times of 2 weeks or more, there seems to be a decrease in tissue irritation.^{207–209} Ørstavik and Mjör²¹⁰ reported that Diaket demonstrated good biocompatibility compared with other sealers.

Eldeniz et al.²¹¹ evaluated the shear bond strength of three resin-based sealers (Diaket, AH Plus, and EndoREZ) to dentin with and without the smear layer. Bond strength of root canal sealers to dentin is an important property for the integrity of the sealing of root canals. A significant difference was found among the bond strength of the sealers, smear layer, and control groups. AH Plus sealer showed the highest bond strength in smear layer-free surfaces, and had the strongest bond to dentin with the smear layer intact.

Glass Ionomer-Based Sealers

There are currently no glass ionomer sealers being marketed. Ketac-Endo (3M, Minneapolis, MN) is mentioned here because it appears in many studies as a comparative sealer.

Silicone-Based Sealers

Silicone-based sealers utilize the same qualities as caulking compounds used in household construction around kitchen and bathroom structures providing adhesion, a moisture-resistant seal, and stability.¹⁰¹

Lee Endo-Fill (Lee Pharmaceuticals, El Monte, CA) is an example of a silicone-based root canal sealer.

RoekoSeal (Roeko/Coltene/Whaledent, Langenau, Germany) is a polyvinylsiloxane that is a white paste-like sealer.²¹² RoekoSeal is reported to polymerize without shrinkage and utilizes platinum as a catalyzing agent.¹⁰¹

Wu et al.²¹³ reported a 1-year follow-up study on leakage, using a fluid transport model, of single-cone fillings with RoekoRSA sealer. The apical filling in all roots did not show leakage either at 1 week or at 1 year.

GuttaFlow (Roeko/Coltene/Whaledent) is a polyvinylsiloxane with finely milled gutta-percha particles added to the RoekoSeal sealer. GuttaFlow also contains silicone oil, paraffin oil, platinum catalyst, zirconium dioxide, nano-silver as a preservative, and a coloring agent. It is eugenol free. It is a cold flowable gutta-percha filling system for the obturation of root canals. GuttaFlow is triturated in its cannula and passively injected into the canal and then used with single or multiple gutta-percha points.

Solvent-Based Sealers

The use of chloroform or solvent-based sealers was popularized by Johnston and Callahan.²¹⁴ The technique is still practiced today with various types of chloroform sealers, including chloropercha and Kloropercha N-Ø. Gutta-percha particles are added to the chloroform to produce a sealer, which has the same color as gutta-percha. The mixture can then be used as a sealer with gutta-percha points for obturation of the canal. There is more shrinkage with the chloroform solvent techniques, and this often translates into leakage, with the material pulling away from the canal walls as it shrinks creating voids through which leakage may occur.²¹⁵

Chlororosin lateral condensation uses 5% to 8% rosin in chloroform, which leaves a very adhesive residue.

Chloropercha is white gutta-percha with chloroform and has no adhesive properties.

Kloropercha N-Ø contains additional resin, plus Canada balsam, that adds adhesive property to the material.

Urethane Methacrylate Sealers

EndoRez (Ultradent, South Jordan, UT) is a hydrophilic UDMA resin sealer that reportedly has good canal wetting and flow into dentinal tubules.²¹² The hydrophilic property improves its sealing abilities, if some moisture is still in the canal at obturation.¹⁰¹ EndoRez is introduced into the canal with a narrow 30-gauge Navitip needle (Ultradent). A single gutta-percha point technique or the lateral compaction obturation technique may be used.

EndoRez resin-coated gutta-percha is also marketed, which reportedly chemically bonds to the EndoRez sealer and works with all resin-based sealers. EndoRez points come in ISO standard sizes.

Tay et al.²¹⁶ investigated the effectiveness of obturating root canals with the polybutadiene–diisocyanate–methacrylate resin-coated gutta-percha (EndoREZ). This enables the polyisoprene in the gutta-percha to chemically couple with the methacrylate-based resin sealer (EndoREZ). This study examined the effectiveness of using passively fitting resin-coated gutta-percha points with the dual-cured version of EndoREZ sealer. It was found that the hydrophilic nature of the sealer enabled the creation of an extensive network of 800 to 1200 μm long sealer resin tags after removal of the endodontic smear layer. Still there were interfacial gaps and silver leakage could be observed along the sealer–dentin interfaces. This was primarily attributed to polymerization shrinkage of the sealer. Gaps and silver leakage was also seen between the resin-coated gutta-percha and the sealer.

The shear strength of EndoREZ to resin-coated gutta-percha was examined, and it was also examined whether shear strength is improved by creating an oxygen inhibition resin layer via the application of a dual-cured dentin adhesive to resin-coated gutta-percha.²¹⁷ The authors concluded that in-situ dentin adhesive application may be valuable in enhancing the coupling of resin-coated gutta-percha to methacrylate sealers.

A study of bone response to the methacrylate-based sealer, EndoREZ, revealed, that at 10 days after placement, the amount of reactionary bone formation in direct contact with EndoREZ was significantly less than that observed with the controls, and the number of inflammatory cells next to the EndoREZ sealer was significantly higher than the controls. However, after 60 days, no differences were noted between the experimental and control groups. This indicated that the sealer produces a response similar to that of many sealers.²¹⁸ Zmener et al.²¹⁹ looked at the apical seal produced with the methacrylate-based sealer (EndoREZ) and Grossman's sealer. Three groups were evaluated. The first combination of materials and techniques was a single gutta-percha point with the methacrylate sealer, the second was lateral compaction with the methacrylate sealer, and the third technique was gutta-percha with Grossman's sealer. The results demonstrated that the dye penetration in the two methacrylate sealer groups occurred at the sealer–dentin or sealer–gutta-percha interface. In the Grossman's sealer group, the dye leakage occurred at both interfaces, and throughout the mass.

EZ Fill (Essential Dental Systems, South Hackensack, NJ) is a noneugenol epoxy resin sealer that is placed with a bidirectional spiral, rotating in a hand-piece, and used with a single gutta-percha point tech-

Figure 12 Micrograph showing hybrid bond between MetaSEAL and gutta-percha by penetration of the gutta-percha. Courtesy, Parkell.

nique. The spiral is designed to spread the sealer laterally in the apical region of the canal. It is reportedly nonshrinking on setting and is hydrophobic in nature, making it resistant to fluid degradation. One study has shown EZ fill to seal as well as other techniques.²²⁰ Favorable clinical outcomes have also been reported.^{212,222}

MetaSEAL (Parkell, Inc., Edgewood, NY) marketed in the United States and Canada is a thinner version of 4-Meta, used for years as a restorative sealer. Belli et al.²²³ compared *MetaSEAL* for leakage against *Epi-phany/Real Seal* and *AH Plus* and found it to show significantly lower leakage after the first week. After 4 and 12 weeks, there was no significant difference among the groups. *MetaSEAL*'s self-etching formula hybridizes the canal wall preventing leakage and bonds to gutta-percha (Figure 12) and *Resilon*.

Paraformaldehyde-Containing Sealers (Riebler's)

Riebler's paste is a paraformaldehyde-containing sealer and was discussed earlier under paraformaldehyde-containing paste materials.

Evaluation and Comparison of Sealers

Ørstavik^{101,224} has listed the various evaluation parameters for testing endodontic sealers. They include technologic tests standardized by the ADA/ANSI in the United States, and the ISO internationally. These technologic tests include flow, working time, setting

time, radiopacity, solubility and disintegration, and dimensional change following setting. Additionally, biologic tests, usage testing, and antibacterial testing are useful. Clinical testing should be included to establish outcomes of treatment.

LEAKAGE

The influence of root canal shape (curved or straight) on the sealing ability of sealers has been studied in a fluid transport model.²²⁵ Canals were laterally compacted with gutta-percha with either Pulp Canal Sealer or Sealapex sealer. It was found that Sealapex allowed more leakage than Pulp Canal Sealer at 1 year. The authors concluded that canal form affects sealing ability at 1 month, but the sealer affects the quality of seal at 1 year.

The sealing ability of four sealers was evaluated quantitatively by Cobankara et al.²²⁶ The sealers tested were Rocanal, a zinc oxide–eugenol powder–liquid system; AH Plus, an epoxy resin-based sealer; Sealapex, a calcium hydroxide-based sealer; and RC Sealer, an adhesive resin sealer. Apical leakage decreased gradually for all sealers from 7 to 21 days. Sealapex demonstrated better apical sealing than the other sealers, and AH Plus, RC Sealer, and Rocanal all showed similar apical leakage at every time period.

Another *in vitro* study evaluated the apical leakage, by a fluid filtration meter, of three root canal sealers, AH Plus, Diaket, and EndoREZ.²²⁷ Statistical analysis indicated that root canal fillings with Diaket in combination with the cold lateral compaction technique showed less apical leakage than the other two sealers.

Saleh et al.²²⁸ used the SEM and energy dispersive spectroscopy to evaluate the adhesion of sealers. The microscopic details of the debonded interfaces between endodontic sealers and dentin or gutta-percha were assessed in this study. Grossman's sealer, Apexit, Ketac-Endo, AH Plus, RoekoSeal Automix, and RoekoSeal Automix with an experimental primer were examined. After tensile bond strength testing, the morphologic aspects of the fractured surfaces were assessed. The energy-dispersive spectroscopy successfully traced sealer components to the debonded surfaces. Some of the sealers penetrated into the dentinal tubules when the dentin surface had been pretreated with acids. However, these sealer tags remained, occluding the tubules after bond failure in some instances only (Grossman's sealer, RoekoSeal Automix with an experimental primer, AH Plus/EDTA). Penetration of the endodontic sealers into the dentinal tubules, when the smear layer was removed, was not associated with higher bond strength.

Pommel et al.²²⁹ examined the efficacy of four types of sealers in obtaining an impervious apical seal, and to correlate those seals with their adhesive properties. Pulp Canal Sealer, Sealapex, AH 26, and Ketac-Endo were the sealers evaluated. The results showed that teeth filled with Sealapex displayed higher apical leakage than the other sealers. No statistically significant difference was found between AH 26, Pulp Canal Sealer, and Ketac-Endo. No correlation was found between the sealing efficiency of the four sealers and their adhesive properties.

Lee et al.²³⁰ investigated the adhesion of endodontic sealers to dentin and gutta-percha. The bond strength to the dentin of the four sealers gave the following order from lowest to highest: Kerr Sealer < Sealapex < Ketac-Endo < AH 26. The bond strengths to gutta-percha gave the following order from lowest to highest: Ketac-Endo < Sealapex < Kerr < AH 26. The bond between the Kerr Sealer and dentin all failed adhesively, whereas the Sealapex bonds failed cohesively (80%). AH 26 demonstrated no adhesive failures. The AH 26 gave the highest bond strength values to both dentin and gutta-percha. These findings suggest that the resin may not only react with the collagen to form bonds but react with gutta-percha as well.

In another study, Tagger et al.²³¹ showed AH 26 had a significantly stronger bond to gutta-percha than the remaining five sealers, including Roth's 801 and Sealapex.

TISSUE TOLERANCE

The cytotoxicity of RoekoSeal Automix and AH Plus was evaluated using human cervical carcinoma cells and mouse skin fibroblasts.²³² AH Plus was significantly more cytotoxic for both cell lines after 1 hour, 24 hours, and 48 hours, compared with the 7-day and 1-month setting periods. RoekoSeal had no cytotoxic effects on either cell line at any setting time.

Spångberg and Pascon²³³ examined the cytotoxicity of seven endodontic sealers (Wach's, Grossman's, Tubli-Seal, AH 26, Nogenol, Diaket, and Endo-Fill). Evaluated as solid materials, Wach's Sealer, Grossman's Sealer, Tubli-Seal, and Diaket were the most toxic. Nogenol was less toxic and the least toxic materials were AH 26 and Lee Endo-Fill. When solubilized, however, Grossman's sealer, Tubli-Seal, and Endo-Fill had very low toxicity, Nogenol had low to medium toxicity, and AH 26, Diaket, and Wach's sealers were very toxic as liquids.

Economides et al.²³⁴ investigated the biocompatibility of four root canal sealers (AH 26, Roth's 811, CRCS, and Sealapex). Sealapex and Roth's 811 sealers

caused moderate to severe inflammation reactions, whereas CRCS caused a mild to moderate reaction. AH 26 caused the greatest irritation initially, but this inflammatory reaction decreased with time.

Bernath and Szabo²³⁵ examined tissue reaction initiated by different sealers. The aim of this study was to analyze the tissue reactions of the calcium hydroxide sealer, Apexit, and to compare it with the reactions of sealers with different chemical compositions (Endomethasone, AH 26, and Grossman's sealer). When filled within the root, AH 26 and Endomethasone initiated a mild lymphocytic/plasmocytic reaction in some cases. In the group of overfilled canals, all four sealers initiated an inflammatory response: Endomethasone initiated a foreign body-type granulomatous reaction; AH 26 particles were engulfed by macrophages; Apexit and Grossman's sealers initiated only a lymphocytic/plasmocytic reaction.

Huumonen and coworkers²³⁶ evaluated the healing of patients with apical periodontitis after endodontic treatment by comparing a silicone-based sealer (RoekoSeal Automix) and a zinc oxide-based sealer. After a 1-year follow-up, 199 teeth were assessed to evaluate their periapical status. The results of the study showed that there was no statistical difference between the success rates of the two study groups. The overall success rate at 12 months was 76%.

FLOW

Ørstavik²²⁴ rated the flow for Tubli-Seal to be greater than that of Kerr's PCS, which was better than Diaket and Kloroperka NØ. He also stated that flow properties may be affected by changes in the powder-to-liquid ratio.

The rheologic properties of Apexit, Tubli-Seal EWT, Grossman's sealer, and Ketac-Endo were tested in a capillary system by Lacey and coworkers.²³⁷ Tubli-Seal EWT had a thinner film thickness than the other sealers. Tubli-Seal EWT had lower viscosity and better flow than the other sealers. Increased strain rate gave a significant increase in the flow rate of all sealers. The reduction in powder-to-liquid ratio for Grossman's sealer significantly increased flow in narrow tubes, and at a higher strain rate. Increasing the rate of insertion gave increased volumetric flow and therefore a reduced viscosity for all sealers. As the internal width of the canals was reduced, there was a reduction in volumetric flow and therefore an increased viscosity.

McMichen et al.²³⁸ did a comparative study of selected physical properties of five root canal sealers. This study sought to investigate the physical proper-

ties of five sealers: Roth's 801, Tubi-Seal EWT, AH Plus, Apexit, and Endion. Solubility in water, film thickness, flow, working time, and setting time were tested. AH Plus had the greatest stability in solution. But AH Plus also had the greatest film thickness. Flow rates were similar, and the working times for all were greater than 50 minutes. Setting time for Roth's 801 was 8 days.

Tagger et al.²³⁹ studied the interaction between sealers and gutta-percha cones. AH 26 silver-free had a notable softening effect on most gutta-percha brands, resulting in increased flow. Liquid (bisphenol epoxy resin) and chemical-bond formation could act as partial solvent effect of the resin. Eugenol has a solvent effect on gutta-percha. The combination of Apexit and UDM gutta-percha cones (United Dental Manufacturers, Zipperer, VDW, Munich, Germany) gave the greatest penetration in lateral canals. Understanding the interaction between gutta-percha and sealers may serve as a guide for using the most suitable combination for specific clinical cases. A tooth with a wide apical foramen should be filled with a combination that provides little flow; conversely, canals with very fine apical foramina and internal irregularities should be filled with a more fluid combination.

SETTING TIME

The setting time for 11 sealers was determined in both aerobic and anaerobic environments by Nielsen et al.²⁴⁰ Kerr Tubli-Seal and Ketac-Endo were the fastest sealers to set under aerobic environments, and Ketac-Endo and Resilon sealer (Epiphany) were the fastest sealers to set under anaerobic environments. Roth's 801 and Roth's 811 sealers were the slowest sealers to set under both aerobic and anaerobic environments, taking over 3 weeks to set. Resilon sealer (Epiphany) set in 30 minutes under anaerobic conditions, but in the presence of air, Resilon sealer (Epiphany) took a week to set, and an uncured layer remained on its surface.

WORKING TIME

Ørstavik²²⁴ stated that the assessment of working time is preferably done with measurements of flow as a function of time. It is the time from the start of mixing to the point at which the flow has been reduced to 90% of the initial flow measurement. The working time for zinc oxide-eugenol sealers demonstrated an initial increase in flow, followed by a later reduction in flow.

SOLUBILITY

The zinc oxide sealers and the calcium hydroxide sealers appear to have greater solubility than other sealers.^{197,241–243}

Schafer and Zandbiglari²⁴⁴ studied the solubility of root canal sealers in water and artificial saliva. The sealers examined were (epoxy resin [AH 26, AH Plus], silicone [RSA RoekoSeal], calcium hydroxide [Apexit, Sealapex], zinc oxide–eugenol [Aptal-Harz], glass ionomer [Ketac-Endo], and a polyketone-based sealer [Diaket]). Most sealers were of low solubility, although Sealapex, Aptal-Harz, and Ketac-Endo showed a marked weight loss in all liquids. Even after 28 days of storage in water, AH 26, AH Plus, RSA RoekoSeal, and Diaket showed less than 3% weight loss. AH Plus showed the least weight loss of all sealers tested, independent of the solubility medium used. Sealapex, Aptal-Harz, and Ketac-Endo had a marked weight loss in all liquids.

DIMENSIONAL CHANGE FOLLOWING SETTING

Kazemi et al.²⁴⁵ examined the long-term comparison of the dimensional changes of four sealers, ZnOE, AH 26, Endo-Fill, and Endomethasone. The two zinc oxide and eugenol sealers started to shrink within hours after mixing. The first volumetric loss for AH 26 and Endo-Fill was recorded after 30 days. The least dimensional change at any time period was observed for Endo-Fill. Significant dimensional change and continued volume loss can occur in some endodontic sealers. The setting times for Endo-Fill, ZnOE, Endomethasone, and AH 26 were 2.5, 4, 9, and 12 hours, respectively. Endo-Fill and AH 26 had lower rates of solubility, water sorption, and dimensional change than ZnOE and Endomethasone over 180 days.

ANTIBACTERIAL ACTIVITY

The *in vitro* antibacterial activity of Fill Canal (zinc oxide based sealer), Sealapex, Sealer 26, Apexit, and calcium hydroxide against various species of microorganisms was studied.²⁴⁶ Fill Canal demonstrated large zones of inhibition against all bacteria tested. Sealer 26 was not effective against *Porphyromonas endodontalis* or *Porphyromonas gingivalis*. Sealapex and calcium hydroxide showed similar effects against the various bacteria, being effective against *Actinomyces israelii*, and *Actinomyces naeslundii*. Sealapex was not effective against *Staphylococcus aureus*, but calcium hydroxide was effective against *Staphylococcus aureus*. Apexit was not effective against any of the microorganisms tested.

An *in vitro* antibacterial activity study of four root canal sealers tested AH Plus, Endomethasone, Pulp Canal Sealer, and Vcanalare, a zinc oxide and ortho-phenylphenol containing sealer.²⁴⁷ All of the freshly mixed sealers showed complete inhibition of bacterial growth. Similar results were obtained after 24 hours, with the exception of AH Plus. Vcanalare was the only sealer still inhibiting bacterial growth 7 days after mixing.

The amount of bacterial endotoxin penetration through root canals obturated either with cold lateral compaction or with a continuous wave technique with backfill of thermoplasticized gutta-percha, with either Roth's 801 sealer or AH 26 sealer, was evaluated by Williamson et al.²⁴⁸ The groups differed significantly. Thermoplasticized gutta-percha with Roth's 801 sealer permitted the least amount of endotoxin penetration, suggesting that the Roth's 801 sealer may have a role in inhibiting endotoxin penetration into obturated root canals.

Siqueira and Goncalves²⁴⁹ found that zinc oxide–eugenol sealers inhibited all the bacteria tested in their study. Sealer 26, the epoxy resin containing calcium hydroxide, was inhibitory on most strains of bacteria tested, but not against *Porphyromonas endodontalis* and *Porphyromonas gingivalis*. Sealapex had low antibacterial activity.

Leonardo et al.²⁵⁰ examined the antimicrobial activity of four root canal sealers (AH plus, Sealapex, Ketac-Endo, and Fill Canal), two calcium hydroxide pastes (Calen and Calasept), and a zinc oxide paste against seven bacterial strains. All sealers and pastes presented *in vitro* antimicrobial activity for all bacterial strains after a 24-hour incubation period at 37°C.

Kayaoglu et al.²⁵¹ tested short-term antibacterial activity of root canal sealers toward *E. faecalis*. *E. faecalis* suspensions were exposed to freshly mixed sealers (MCS [Medidenta International, Inc.], AH Plus, Grossman's, Sealapex, Apexit). MCS contains iodoform. MCS, AH Plus, and Grossman's sealer significantly reduced the number of viable bacteria in both tests. Sealapex and Apexit were not statistically different from the controls. MCS, AH Plus, and Grossman's sealer were effective in reducing the number of cultivable cells of *E. faecalis*. Calcium hydroxide-based sealers, Sealapex and Apexit, were ineffective in this short-term experiment.

Intraorifice Barriers

The prevention of coronal bacterial leakage back into the root canal system is crucial for the ultimate

success of endodontic therapy. Several studies have shown that leakage can occur through the obturated root canal system in a relatively short time period.^{252–255} The issue of coronal leakage and its effect on endodontic outcomes has been investigated. Whereas some authors feel that the quality of the endodontic obturation is a more important factor than the quality of the coronal restoration,^{256–258} others feel that preventing coronal microleakage can play a significant role in the success of endodontic therapy.²⁵⁹ In any event, the placement of another barrier to the penetration of microorganisms into the obturated root canal system would seem to prevent leakage due to delay in placement of a permanent restoration or leakage from failed or inadequate coronal restorations. Several studies have looked at materials that may be used as intraorifice barriers placed 1 to 2 mm into the orifice of canals, or on the pulpal floor, to add another layer to prevent microleakage.^{129,260–268}

COMPOSITE RESINS

Yamauchi et al.,²⁶⁹ in a dog study, examined the effect of an orifice plug of 2 mm of IRM or a dentin bonding/composite resin on coronal leakage of teeth that had canals obturated with gutta-percha and the access cavities left open for 8 months. Periapical inflammation was observed in 89% of the group without plugs, but in those with composite plugs only 39% had periapical inflammation and only 38% in the IRM-plugged group.

An investigation, comparing Cavit, against a flowable light-cured composite resin (Tetric), and MTA (ProRoot) as intraorifice barriers at 1, 2, 3, or 4 mm in canals obturated with gutta-percha, demonstrated a better seal with the flowable composite than with either MTA or Cavit.²⁷⁰

GLASS IONOMERS

Chailertvanitkul et al.²⁶¹ investigated coronal bacterial leakage, through coronal access using Vitrebond (3M), a resin-modified glass ionomer liner, as a barrier on the pulpal floor. The teeth with the Vitrebond liner that had been placed on the pulpal floor showed no leakage of bacteria, whereas 60% of the specimens without a Vitrebond liner showed leakage after 60 days.

Wolcott et al.²⁶⁰ found that there was no significant difference between Vitrebond, a colored trial GC America glass ionomer, and Ketac-Bond. There was significantly less coronal leakage when the glass ionomers were used than when no barrier was placed.

Maloney et al.²⁶⁷ found that thermocycling Triage (GC America, Inc.), a colored resin-modified glass ionomer, had no effect on the seal produced by Triage, when it was used as an intraorifice barrier at depths of 1 or 2 mm. The 1 and 2 mm intracoronal barrier significantly reduced coronal microleakage compared with no barrier placement.

Mavec et al.²⁷¹ investigated the use of a glass ionomer barrier against bacterial leakage when post space is required. They found that a 1 mm barrier of glass ionomer over as little as 2 or 3 mm of gutta-percha could reduce the risk of recontamination of the apical gutta-percha. This could be beneficial in cases where there is a minimum amount of root length for a post.

OTHER MATERIALS

Pisano et al.²⁶² compared Cavit, IRM, and Super EBA as intraorifice barriers to prevent coronal microleakage and found that all three groups leaked less than those obturated canals that did not receive a barrier.

Wolanek et al.²⁶⁵ tested the effectiveness of a dentin-bonding agent used as an intraorifice barrier and found that it reduced coronal bacterial leakage.

Galvan et al.²⁶⁴ evaluated Amalgabond Plus, C&B Metabond, One-Step Adhesive with Eliteflo composite, One-Step Dentin Adhesive with Palfique composite, and IRM as intracoronal barriers. At 7 days, the IRM, AEliteflo, and Palfique composite leaked significantly more than Amalgabond or C&B Metabond. Amalgabond consistently produced the best seal through all time periods.

Temporary Filling Materials

The problem of coronal leakage is also important in the choice of an interim restoration material to seal off the access preparation, either between appointments or before the endodontically treated tooth receives a permanent restoration.

Cavit (ESPE, Seefeld, Germany), in a number of studies, has been found to prevent leakage, when used as a temporary filling material to close access preparations, either as an interim filling material or after final obturation before a permanent restoration is placed.^{272–280} *Cavit* is premixed and is easily introduced into the access cavity, as well as being easy to remove from the access cavity at the subsequent appointment. The ingredients in *Cavit* are zinc oxide, calcium sulfate, zinc sulfate, glycoacetate, polyvinylacetate resin, polyvinylchloride-acetate, triethanolamine, and red pigment.²⁷² The calcium sulfate is hydrophilic and causes hygroscopic expansion of

Cavit. This absorption of moisture and subsequent expansion cause Cavit to seal very well as it sets in a moist environment.

In a survey of Diplomates of the American Board of Endodontics, Vail and Steffel²⁸¹ found that Cavit was the temporary restoration of choice for both anterior and posterior teeth.

Webber et al.²⁸² found that to seal adequately, Cavit must have a depth of at least 3.5 mm.

The ability of Cavit to prevent bacterial penetration into root canals containing four medicaments was evaluated.²⁸³ The medicaments were calcium hydroxide, chlorhexidine, an antibiotic-corticoid compound (Ledermix), and chloromono-campherphenolic compound (ChKM). The authors found that Cavit prolonged the protection of all the medicaments from 13 to 18 days but that an adequate seal could not be provided for more than 1 month.

Balto²⁷⁴ assessed microbial leakage of three temporary filling materials (Cavit, IRM, and Dyract). IRM began to leak after 10 days, whereas Cavit and Dyract did not leak until after 2 weeks.

After 3 weeks, Beach et al.²⁷³ found that 4 of 14 TERM samples and 1 of 18 IRM samples leaked and showed positive bacterial growth. None of the Cavit samples in the study leaked. It was shown that Cavit provided a significantly better seal than the other temporary filling materials.

Kazemi and coworkers²⁷⁷ found that Tempit (Centrix, Milford, CT) and IRM (Dentsply International/L.D. Caulk Division, Milford, DE) seemed less appropriate as an interim endodontic restoration than Cavit based on an assessment of marginal stability and permeability to dye penetration.

IRM is a temporary filling material that comes in a liquid-powder form that requires mixing. It is a polymer-resin-reinforced zinc oxide-eugenol material. Although many studies show it has inferior sealing abilities compared with Cavit, in clinical situations, however, which require greater bulk and resistance to occlusal forces, IRM may be used as a temporary restorative material. Zinc oxide and eugenol materials, such as IRM, possess about double the compressive strength value of Cavit.²⁸⁴ Glass ionomer cements or composite resins may also be used in these situations and may have better sealing ability and greater compressive strength.

The antibacterial properties of several temporary filling materials were examined. Revoltek LC (GC Corporation, Tokyo, Japan), Tempit (Centrix), Systemp inlay (Vivadent, Schaan, Liechtenstein), and IRM were tested against *Streptococcus mutans* and *E. faecalis*. Systemp inlay exhibited antibacterial properties when in

contact with *S. mutans* for at least 7 days, whereas Tempit and IRM sustained this ability for at least 14 days. When in contact with *E. faecalis*, Tempit and IRM were antibacterial immediately after setting, and IRM sustained this activity for at least 1 day.²⁸⁵

Zmener et al.²⁸⁶ found no statistically significant difference in the marginal leakage between Cavit, IRM, and Ultratemp Firm after thermocycling. All of the materials leaked at the interface of the material with the dentin, and some of the IRM specimens absorbed the dye into the bulk of the material.

Orahood et al.²⁸⁷ found there was no difference in marginal leakage between Cavit and ZOE when used to seal access preparations through either alloy or composite restorations. One study found IRM more watertight than Fermit-N or Cavit G intermediate restorative materials.²⁸⁸

TERM (Dentsply International/L.D. Caulk Division) is a composite resin interim restorative material for endodontics. It is a visible-light-cured resin containing UDMA polymers, inorganic radiopaque filler, pigments, and initiators.²⁷²

Seiler²⁸⁹ studied bacterial leakage of three glass ionomers, IRM, and Cavit as used as a temporary endodontic restorative material. Cavit provided a slightly better seal than IRM; however, the glass ionomer and resin-modified glass ionomer materials provided better seals against bacteria than either IRM or Cavit. If 3.5 mm of space does not exist for a temporary filling material, Hansen and Montgomery²⁹⁰ found that TERM may provide a superior temporary restoration. They found that TERM provides an adequate seal at 1, 2, 3, and 4 mm.

Summary

As new materials are introduced to fill the root canal system, it is important to remember Grossman's tenets and to remember the proven success of many of the materials currently in use. However, there still is a need to constantly improve what we can offer our patients, and to improve the outcome of endodontic treatment, in order to preserve the natural dentition. Long-term randomized clinical trials are needed on all the materials, new and time tested, which are used in modern-day endodontics.

With advances in materials and other aspects of endodontics, one cannot imagine materials that will be available to use in root canal systems in the future. They, no doubt, will be much more biocompatible and, one might hope, may promote regeneration of tissues within the tooth and bone.

CHAPTER 30

OBTURATION OF THE RADICULAR SPACE

FRED W. BENENATI

It has been four decades since the late Dr. Herbert Schilder published his classic article on filling the root canal space in three dimensions.¹ Ironically, it came 7 years before his treatise on cleaning and shaping the root canal system.² One might extrapolate from this fact that closing off or obturating a cleaned and shaped radicular space has considerable importance.

Rationale of Obturation

HISTORICAL PERSPECTIVE

Obturation of the radicular space has been described in various ways for well over 100 years, including Edward Hudson's 1825 report of filling with gold foil.³ Controlled length obturation of the root canal system was not verified until Edmund Kells produced the first endodontic radiograph in 1899.

Root canal therapy, including obturation, experienced a setback in 1910 when William Hunter delivered his address entitled "the role of sepsis and asepsis." Chivian³ stated that Hunter's thesis regarding focal infection was "misinterpreted to include periapical lesions and root canal therapy in general." This likely led to, as the modern-day challenge against amalgam has, more careful practice and a rebirth of research and development in the specialty of endodontics. Perhaps one could view this as a *déjà vu* impetus for the modern-day call for evidence-based endodontics!

In 1967 Grossman⁴ described the reasons for the growth and acceptance of endodontics in spite of the focal infection theory. These included better research methods, minimal health risks, and the demand for restorative dentistry. His principles may be considered classic, including his "Principle 9," having to do with obturation, or as he termed it "hermetic seal of the canal" terminating at the dentinocemental junction. Principle 10 dealt with the acceptability of the filling material. The term "hermetic seal" is now considered

inaccurate. "Hermetic" is defined as "airtight by fusion or sealing." The concern in closing or obturating the canal space is not related to air; it is about fluid leakage at the apex or the coronal level. An "impermeable seal" is a more accurate term.⁵

OBJECTIVE OF OBTURATION

Schilder¹ describes the final objective of endodontic procedures as being "the total obturation of the root canal space." He also stated "in the final analysis, it is the sealing of the complex root canal system from the periodontal bone that ensures the health of the attachment apparatus against breakdown of endodontic origin." Nearly a decade later, Dubrow⁶ questioned the validity of a "hermetic seal" produced by silver points or gutta-percha and sealer. He described cases that healed after instrumentation, medication, and a coronal seal, but no obturation. The question has not been answered, however: will this last, and for how long, without full canal length obturation?

In the previous edition of this text, the authors of the chapter on obturation of the root canal space described bacteria and bacterial toxin ingress as the major cause of tissue irritation. Even in bacterial absence, degraded serum may serve as a periapical tissue irritant. They pointed out that "bacteria are the primary source of persistent periradicular inflammation and endodontic failure."⁷ Thus, it may be deduced that following total débridement of the radicular space, "the development of a fluid-tight seal of the apical foramen and the total obliteration of the root canal" must follow to ensure the best chance of long-term success (Figure 1). The present-day knowledge of the importance of a coronal seal cannot be overlooked as well.

WHEN IS THE CANAL READY TO OBTURATE?

Radicular space obturation is ideally accomplished after cleaning and shaping has been completed to an optimum

Figure 1 **A**, Failure of reactive iodine (^{131}I) to penetrate into well obturated root canal. Only periapical cementum that was not coated with sticky wax has absorbed isotope. **B**, Massive reaction to penetration of radioactive iodine (^{131}I) into poorly filled canal. Violent response at periapex is comparable to *in vivo* response to toxic and/or infective canal products. Reproduced with permission from Dow PR, Ingle JI.²²

size.⁷ Although there is no universal agreement on what constitutes an optimal size, it seems that the canal(s) should be dry, with no “weeping” of fluids into the radicular space.⁷

The tooth should ideally be asymptomatic, although those completely instrumented, yet with mild symptoms or even significant symptoms, have been shown to become asymptomatic upon obturation.^{7,8} There are also reports showing the importance of obturating canals following negative bacterial cultures.^{9,10} Sjogren et al.¹⁰ found that upon a 5-year recall, 94% of cases exhibiting negative cultures were found to be successful, whereas only 68% of those filled with positive cultures were successful.

APICAL EXTENT OF OBTURATION: WHERE AND WHY?

As early as 1930 and again in 1967, Grossman⁴ remarked that there was no general agreement on where a canal filling should end. However, the consensus was that it should be the dentinocemental junction. The trend at the time was to obturate a canal “even with the root apex or just short of it, rather than to overfill the canal.” Today, we recognize a difference in semantics between *overfilling* and *overextension*. Overfilling actually denotes “total obturation of the root canal space with excess material extruding beyond the apical foramen.”¹¹ Overextension also denotes filling material beyond the apex, but the canal may not have been filled adequately within its confines.

The dentinocemental junction has been described by Kuttler¹² as an average of approximately 0.5 to 0.7 mm from the external surface of the apical foramen (Figure 2). Thus, it could be construed that filling to the radiographic

Figure 2 Ideal termination of canal preparation and obturation. **A**, Apical constriction at cementodentinal junction marks end of root canal. From this point to anatomic apex (0.5 to 0.7mm), tissue is periodontal. **B**, Photomicrograph of periapex. Small arrows at cementodentinal junction. Large arrow (bottom) at denticle inclusion. **A**, Reproduced with permission from Goerig AC in Besner E, Practical Endodontics CV Mosby; 1993. **B**, Permission from Brynolf I in Odontol Revy; 1967.

apex is actually overfilling. Blayney¹³ advocated filling just short of the radiographic apex, while Morse and coworkers¹⁴ had better clinical success with radiographically flush fillings than with fillings short of the radiographic apex. More recently, using optical microscopy, Ponce and Fernandez¹⁵ found great variation in the measurements of the extension of the cementum into the root canal, suggesting that precise measurement of such is even more inconsistent. Wu et al.¹⁶ advocated different positions for the extent of apical obturation based on the pulpal status, with vital pulp root canals faring better with obturations 2 to 3 mm short of the radiographic apex. They also found that better success in nonvital cases was achieved when filled within 2 mm of the radiographic apex. Schaeffer and associates¹⁷

recently presented an analysis of several success/failure studies based on different obturation lengths. Their findings are presented in Tables 1 and 2 and indicate a better success rate when obturation is short of the radiographic apex.

DESIRED PROPERTIES OF OBTURATING MATERIALS

Grossman's description of ideal properties of obturating materials is a classic benchmark and has stood the test of several decades of time.¹⁸ The desired properties of both core and sealer materials are more extensively discussed in Chapter 29, "Root Canal Filling Materials."

Table 1 Comparison of the Four Studies that were Used in the Meta-analysis. Reproduced with permission from Schaeffer MA et al.¹⁷

Study	Method	Participants	No. of teeth	Treated by	Results
Harty et al. (1970)	Does not state who read the radiographs. Retrospective study	All patients accepted for RCT on upper and lower incisor and canine teeth between 1954 and 1963 at the Department of Conservative Dentistry, Institute of Dental Surgery (London, England)	1025 teeth	Post-graduate students and staff at the Department of Conservative Dentistry, Institute of Dental Surgery	The teeth obturated between 0 and 1 mm (acceptable) were more successful (92.6%) than short (87.82%) or long (86.81%)
Kerekes et al. (1979)	Interpretation of the radiographs was done independently by two endodontists. Prospective study	All patients accepted for RCT and treated by undergraduate students at the University of Oslo (Norway) in 1971 and who participated in regular clinical and radiographic follow-up exams	501 of 647 teeth were evaluated	Undergraduate students at the University of Oslo (Norway)	In vital teeth, roots that were short of the apex > 1 mm had a higher success rate (96%) than at the apex (0–1 mm) (92%). In necrotic teeth, roots that were short of the apex > 1 mm had a lower success rate (85%) than those at the apex (93%)
Matsumoto et al. (1987)	Does not state who read the radiographs. Prospective study 62% loss to follow-up (85 of 223 evaluated)	Patients were treated at the School of Dentistry, AichiGakuin University in Nagoya, Japan	85 of 223 teeth were eval for the minimum 2–3 year follow-up exam	Members of the endodontic staff at the School	The teeth obturated between 1.1 and 2.0 mm underextended (100%) were more successful than 0.5–1.0 mm underextended (88%) or 0–0.4 mm underextended (61.5%) or overextended (40%)
Kerekes et al. (1978)	The interpretation of the radiographs was done independently by two endodontists. Retrospective study. Clinical exam	Two retrospective studies were done. The first survey evaluated 188 root canals treated by undergraduate students (US) at the University of Oslo in 1969 and had been followed for 3–5 years. The second survey consisted of 379 root canals treated by general dentists (GP)	188 teeth done by undergrads at University of Oslo and 379 teeth done by general dentists (GP) in Norway	RCT done by Undergraduate students at the University of Oslo (Norway) in 1969. Second group of RCT done by general dentists (GP) in Norway in 1968	Those root canals done by US short of apex 1–3 mm were more successful (88%) than at the apex 0–1 mm (84%), than overfilled (79%), than short of apex > 3 mm (79%) Those root canals done by GP at the apex (0–1 mm) were more successful (73%) than short of apex 1–3 mm (71%), than short of apex > 3 mm (54%) than overfilled (44%)

Criteria for Evaluation of Obturating Materials and Sealers

It is well known that most obturating materials do not completely fill the root canal system. This has been confirmed by several methods of microleakage evaluation, including dye penetration, radioisotopes, electrochemical, fluorometrics, scanning electron microscopic examination, root clarification (Figure 3), fluid filtration, and fluid transport.^{19–29} The limitation of these methods is of course that they do not precisely duplicate the clinical situation of the periapical tissue and the fluid environment, although Friedman et al.³⁰ developed an in vivo model to assess the efficacy of obturation.

VOIDS IN OBTURATING MATERIALS

A concern when using gutta-percha (or other core materials) to obturate canals is its potential of creating voids in the root canal filling. Eguchi et al.³¹ compared four different methods of gutta-percha and sealer techniques, viewing three sections at different levels of obturation. Voids were found in the apical third with at least one of the techniques (lateral condensation). They cautioned that using different condensation techniques and different sealers would likely produce more sealer (and less gutta-percha) in some areas of the canal than in others and that the obturating techniques producing the most mass of

core filling material (least voids) would require much sealer for an adequate canal seal.

TISSUE TOXICITY

Obturating materials are currently evaluated for tissue toxicity by four methods: (1) cytotoxicity evaluation, (2) subcutaneous implantation, (3) intraosseous implantation, and (4) in vivo periapical reactions.¹⁸ Despite some materials exhibiting tissue toxicity, they have been used successfully for many years in the practice of clinical endodontics. For example, over 130 years ago, Chisholm introduced zinc oxide and oil of cloves to dentistry.³² Surprisingly, eugenol (refined oil of cloves) is quite cytotoxic but still stands as a commonly used component of sealers.^{33,34} This is one example of a material that in spite of its cytotoxicity has stood the test of time in clinical endodontics with a proven track record. For a more in-depth discussion of toxicity of obturating materials, the reader is referred to Chapter 29, “Root Canal Filling Materials.”

Techniques of Obturation: Semisolid and Solid Core Materials

Gutta-Percha: The use of gutta-percha for obturation of canals has been enhanced by its ability to change volumetrically upon heating. Force applied to gutta-percha causes it to become *compacted*, not

Reproduced with permission from Venturi M, DiLenarda R, Prati C et al.²⁹

compressed as originally thought.³⁵ It has also been used in its cold (unheated) state with condensation pressures laterally, resulting in minimal deformation.³⁶ In contrast to this, Camps et al.³⁷ reported that warm gutta-percha compaction was maximized by plugger advancement apically to produce the best permanent deformation with compaction. An important concept in the use of gutta-percha for obturation is that it does not seal purely by itself. Sealing agents are necessary to accomplish this, since gutta-percha does not adhere to the dentinal wall.^{38–40}

No matter what technique is used for the placement of gutta-percha in the canal, a good aseptic technique dictates that it should be disinfected. Sequira et al.⁴¹ found that a simple immersion in 5.25% sodium hypochlorite eliminated *Bacillus subtilis* spores after

just 1 minute of contact. Melker et al.⁴² found that tetracycline-containing gutta-percha inhibited the growth of four common oral cavity bacterial inhabitants.

LATERAL COMPACTION

The most widely taught method of obturating root canals in dental schools is lateral compaction of cold gutta-percha and sealer, although compaction of heated gutta-percha is overtaking it.⁴³ This method is most optimally accomplished following meticulous canal preparation with a continuous tapered shape. The spreader used for lateral compaction should be placed within 1 to 2 mm of the working length when an apical stop has been created.⁴⁴ Criteria for the use of lateral

Figure 4 Microleakage into obturated canals related to flare of cavity preparation and depth of spreader penetration. **Left**, Final depth of spreader, A, is 5mm short of prepared length of canal. Radioisotope leakage is 4.8mm (between arrows) into canal. **Right**, Canal with flared preparation allows spreader depth to within 1mm of primary point length. Radioisotope leakage (between arrows) only 0.8mm into canal. Reproduced with permission from Allison DA, Weber CR, Walton RE.⁴⁵

condensation should include the shape and size of the preparation, the sealer used, and the spreader size (Figure 4) required to be placed within the apical 2 mm. This “deep spreader penetration” assures the best likelihood to minimize apical leakage or percolation.⁴⁵

More recent popularity of wider-flared canal preparations prompted Bal et al.⁴⁶ to compare the quality of seals in canals prepared with 0.06 and 0.02 tapered instruments and filled by lateral condensation with like tapered master cones. They noted spreader penetration to greater depth with 0.02 tapered preparations and cones.

Hembrough⁴⁷ and associates studied the differences in lateral condensation efficiency and quality using three different types of master cones in canals prepared with Profile ISO 0.06 nickel–titanium rotary instruments (Dentsply Tulsa Dental Specialties, Tulsa, OK). They found greater efficiency (less accessory cones required) with traditional cones compared to ISO standard points, but no difference in the quality of obturation.

Wilson and Baumgartner⁴⁸ compared similar size nickel–titanium with stainless steel spreaders with regard to penetration depth using lateral compaction of 0.02 and 0.04 tapered master cones. They found that NiTi spreaders penetrated to a greater depth with 0.02 tapered gutta-percha in canals with curvatures greater than 20° than when using 0.04 tapered gutta-percha regardless of curvature. Both types of spreaders penetrated to a shallower depth with 0.04 tapered gutta-percha.

Pomeranz⁴⁹ has described a technique for laterally condensing gutta-percha with a #10 file after initial spreader placement, solving a myriad of problems related to both instrumentation and condensation errors.

Although lateral compaction has worked well as a standard, it has been challenged with the more recent popularity of vertical compaction of heated gutta-percha. Gilhooly et al.⁵⁰ found more apical leakage to dye with in vitro teeth obturated with lateral condensation rather than with heated multiphase gutta-percha obturation. Interestingly enough, they also found that lateral condensation yielded better radiographic quality than did the multi-phase obturation.

DaSilva et al.⁵¹ using plastic blocks, compared the quality of obturations accomplished by lateral compaction, ThermaFil, and a new backfilling technique with the emphasis on length control. Although lateral compaction and ThermaFil backfill techniques yielded fewer overfills, blocks obturated by ThermaFil had no voids, while the other techniques demonstrated small voids.

Other studies regarding density and fill by weight of obturations showed heat-related techniques of compacting gutta-percha to have advantages over lateral

Figure 5 Obturated transparent resin block by cold lateral compaction. Reproduced with permission from Lea CS, Apicella MJ, Mines P et al.⁵³

compaction (Figures 5 and 6) as well as gutta-percha to sealer ratio.^{52,53} More recently, Collins et al.⁵⁴ used a split tooth model to assess the ability of cold lateral, warm lateral, and warm vertical compaction methods to replicate intracanal wall defects. They found a statistically better result with warm techniques over cold lateral compaction, but no significant difference between the two warm techniques.

VERTICAL COMPACTION

Arguably the most classic article describing this technique is Schilder's² treatise that describes in detail the technique offering an alternative to lateral compaction. This technique was based on a single cone adaptation and compaction, followed by additional

Figure 6 Obturated transparent resin block by warm vertical compaction. Reproduced with permission from Lea CS, Apicella MJ, Mines P et al.⁵³

segments of gutta-percha, a technique previously described by Berg.⁵⁵ Historically, a single cone technique was also described in 1961 by Marshall and Massler.⁵⁶ This technique was touted as ensuring that potentially more than one portal of exit, lateral, and accessory canals may be filled over 40% of the time.⁵⁷

An ongoing comparison of canal wall adaptability and microleakage studies has existed between lateral compaction and warm gutta-percha/vertical compaction. Brothman⁵⁸ found “no statistically significant difference in filling efficiency,” but found that more accessory canals were filled with sealer using vertical compaction. He also concluded, however, that lateral

Figure 7 Compaction results from three methods of obturation purposely done without sealer. **A**, Chloropercha filling presents best immediate appearance. Unfortunately, a 12.4% shrinkage follows, leading to massive leakage. **B**, Lateral compaction –cold gutta-percha showing coalescence of primary and accessory points at apex but separating mid-canal. **C**, Warm gutta-percha/vertical compaction. Filling is homogeneous; replication is excellent. Reproduced with permission from Wong M et al.

compaction was more appropriate for ribbon-shaped canals, whereas vertical compaction was better suited for centric canals. Torabinejad and coworkers⁵⁹ compared multiple obturation techniques and found that all gave favorable results, but the vertical method resulted in closer adaptation to the canal walls in the middle and apical thirds. Wong et al.⁶⁰ compared homogeneity/replication of canal walls using chloropercha, lateral compaction, and warm gutta-percha vertical compaction without sealer and found the best results with the latter technique (Figure 7). With regard to microleakage, Benner et al.⁶¹ used radioisotopes to study the difference in three obturation methods, including warm gutta-percha/vertical compaction and found no significant differences. Perhaps of more significance is a study by a Toronto group⁶² who found a 10% higher rate of clinical success with warm vertical compaction versus cold lateral compaction in cases with apical periodontitis.

Since Schilder's description of vertical compaction, there have been criteria expressed by Glickman and Gutmann⁶³ that could apply to all subsequent techniques of gutta-percha placement utilizing heat. These relate to tapered shaped cones, cone selection, sealer amounts, and full-length softening and condensing instruments used.

THERMOMECHANICAL COMPACTION OF GUTTA-PERCHA

A different method of softening and compacting gutta-percha was introduced in 1979 by McSpadden.⁶⁴ After some difficulties with instrumentation, he was

able to improve compaction, as well as length control. The technique has enjoyed more popularity in Europe, and a hybrid method was introduced by Tagger and associates in Israel.⁶⁵ They promoted placement of a master cone with sealer, lateral action with a finger spreader, and placement of an accessory cone. This was followed by rotary compaction that resulted in less apical leakage than lateral compaction alone. Fuss et al.⁶⁶ agreed that there was no difference in apical leakage between the two techniques. However, Budd and coworkers⁶⁷ found that thermomechanical compaction resulted in a better apical seal. Saunders⁶⁸ added a note of caution with this technique, as the heat generated in his in vitro study resulted in 25% of ferrets in an in vivo study developing root resorption or ankylosis.

THERMOMECHANICAL SOLID CORE GUTTA-PERCHA OBTURATION

This system, employing a titanium core/carrier coated with alpha-phase gutta-percha, can be used with core retention or removal, followed by hand plugger compaction. Pallares and Fuss⁶⁹ found no difference in apical leakage with this system compared to lateral compaction. Canalda-Sahil et al.⁷⁰ also found good results in attempting to seal canals in teeth with large, straight canals.

ULTRASONIC PLASTICIZED GUTTA-PERCHA

The use of an ultrasonic instrument to plasticize gutta-percha was first described by Moreno.⁷¹ He

Figure 8 Comparison in obturation between hand-lateral compaction and **ultrasonic compaction**. **Left**, Accessory point folded in canal during lateral compaction following finger spreading. G, individual gutta-percha points. C, canal wall. High power (x320 original magnification). **Center**, Gutta-percha compacted by **Enac ultrasonic** spreader tips (no fluid coolant). Note uniformity of gutta-percha mass with only two “crevice marks” at (A). C denotes canal walls. employed its friction plus hand or finger pluggers for condensation. Joiner et al.⁷² studied the effect of heat generated by this technique and concluded that it was safe. Baumgardner and Krell⁷³ attached an Enac ultrasonic point (Osada, Los Angeles, CA) to a spreader to penetrate the gutta-percha mass and found more homogeneous compaction and less apical microleakage than hand lateral compaction (Figure 8).

THERMOPLASTICIZED INJECTABLE GUTTA-PERCHA

A group at Harvard/Forsythe Institute⁷⁴ developed an injection device in 1977 to deliver heat-softened gutta-percha to the canal space. Currently, the latest model of this system, Obtura II Heated Gutta-Percha System (Obtura Spartan, Fenton, MD), uses temperatures up to 200°C and beta-phase gutta-percha or less viscous Easy Flow gutta-percha (Charles B. Schwed Co., Kew Gardens, NY). Gutmann and Raskin⁷⁵ stressed the importance of a meticulously tapered preparation with this system to minimize flow and containment of the gutta-percha. Lambrianidis et al.⁷⁶ found in their 1990 study that no matter what was the distance of the needle tip to the foramen, there was no significant difference in linear dye leakage using Obtura II in canals.

A question may be raised about the safety of heat generated and delivered to canals by the above method. Gutmann and associates⁷⁷ found in their *in vitro* study that the temperature of gutta-percha

emerging from the needle was 71.2°C in a body temperature environment. Their *in vivo* study in dogs concluded that it was safe with only a 1.1°C rise in temperature over 60 seconds, in the overlying bone.

Hardie⁷⁸ reported much higher temperatures in the canal (137.8°C) and a rise of 9.65°C on the root surface. If maintained for 1 minute, this is reported to cause injury.⁷⁹ Weller and Koch⁸⁰ reported safe (less than 10°C) temperature rises when using gutta-percha thermoplasticized to 200°C. More recently, Sweatman et al.⁸¹ have verified these findings. It is also documented that these injectable gutta-percha techniques still require a sealer to avoid microleakage.⁸² Care in apical preparation design is emphasized, as more studies have indicated overextensions or extrusions of material with inadequate apical taper.^{83,84} Tan-Ishii and Teranaka⁸⁵ followed 236 obturated canals filled with the Obtura II system, achieving a 96% success rate. They also found that “root filling excess had no impact on the healing process.”

SYSTEM B PLUGGER TECHNIQUE

An additional heat-assisted gutta-percha compaction technique was introduced by Buchanan in 1996 and was marketed by Analytic Technology (Sybron Endo, Orange, CA) as System B.⁸⁶ This was an upgrade or improvement to their 1982 Touch ‘n Heat and was reported to be more rapid, simple, and more effective. Pommel and Camps⁸⁷ studied its ability to resist

leakage in vitro and found that initially it was more resistant than lateral compaction or single cone technique. After 1 month, however, there was no difference. It was also found to be as effective in initial resistance to apical leakage as warm vertical condensation and ThermaFil.

Guess et al.⁸⁸ studied the in vitro influence of System B plugger depth on gutta-percha filling adaptation to the canal wall using single cone continuous wave technique in one group and lateral compaction followed by continuous wave downpack in the other. They found no significant difference in adaptability, and the best results were obtained with plugger depth 3 to 4.5 mm from the working length. Jung and associates⁸⁹ compared gutta-percha filled areas in plastic blocks, with varying temperatures and plugger depths for System B-assisted obturation. They found no significant differences with temperature variation, but better adaptability with deeper plugger depth placement.

Villegas et al.⁹⁰ in 2004 used Obtura II to backfill extracted teeth filled by single versus multiple positioned System B pluggers and compared each to assess gutta-percha mass adaptability to the canal wall. They found that there was better adaptation of this mass (Figure 9) when the System B plugger was used in three steps instead of one insertion at 3 mm short of working length.

LATERAL/VERTICAL COMPACTION OF WARM GUTTA-PERCHA HYBRID TECHNIQUE

Considering the ease and speed of lateral compaction, as well as the superior density achieved with vertical compaction of warm gutta-percha, Martin⁹¹ developed a device that incorporates the qualities of both techniques. The Endotec II (Medidenta, Woodside, NY) is a battery-powered, heat-controlled spreader/plugger. Similar units are marketed as Thermique (Parkell, Edgewood, NY) and as DownPak (Hu Friedy, Chicago, IL). Several studies⁹²⁻⁹⁴ found the technique to be better than other methods tested for preventing leakage and for filling canal irregularities. Jurcak et al.,⁹⁵ concerned about possible ill effects of warm gutta-percha on vital tissues, found that heating a mass of gutta-percha to 102°C “would not be of significant magnitude to cause damage to the periodontal tissues.”

INJECT-R FILL

This system is marketed by Miltex Corporation (Troy, PA) and consists of a small metal tube filled with gutta-percha and a plugger/plunger attached. It is heated

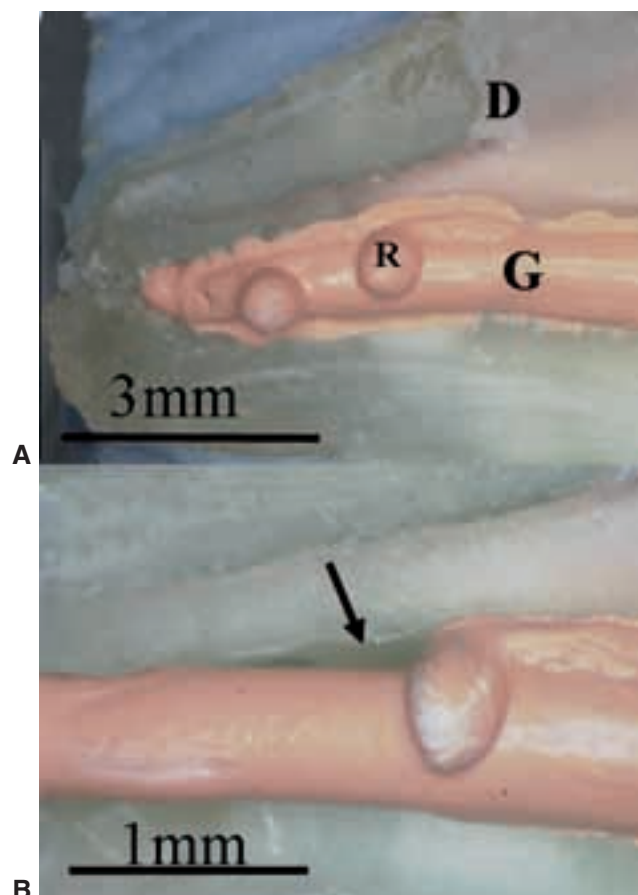

Figure 9 **A**, Representative Group A gutta-percha root filling in the split tooth model with a straight and round canal. either by a flame or an electric warmer/container and produces a result similar to vertical compaction, when injected and compacted upon a preexisting downpack of gutta-percha, according to Roane.⁹⁶

CONDENSATION FORCES: VERTICAL VERSUS LATERAL

A concern was expressed in the early 1980s about the forces generated during vertical compaction and their possible transference, inducing vertical cracks in roots. Gimlin and associates⁹⁷ studied both lateral and vertical “condensation forces” using a mathematical model. Their results suggested that lateral condensation was

Figure 10 Root fracture occurs when the wedging force is absorbed by the canal walls. Premeasuring the spreader depth can reduce the risk of fracture.

more likely to produce undesirable stress concentration (near the apex) than was vertical condensation (for gutta-percha compaction) (Figure 10).

Solid Core Carriers with Manual Placement Techniques

The previously mentioned techniques for condensing or compacting gutta-percha aimed at minimizing sealer or maximizing gutta-percha content. The past two decades have seen an increase in the use of carrier-based gutta-percha techniques to accomplish this task. A discussion of these systems follows, including their advantages and limitations.

THERMAFIL

A new concept in delivering gutta-percha to the radicular space was introduced in 1978 by Johnson.⁹⁸ It consisted of alpha-phase gutta-percha on a fluted metal instrument, while the current version has the gutta-percha on a plastic carrier. There are additional similar systems, namely Densfil (Dentsply Maillefer, Tulsa, OK), Soft-Core (Axis Dental Corp., Irving, TX), and Three Dee GP (Deproco Ltd., Dorking, UK). The ThermaFil technique was found to exert less strain on the root when placing and compacting its gutta-percha core when compared to Obtura or lateral compaction.⁹⁹

The importance of a good apical stop or constriction when using ThermaFil was stressed by Scott and Vire¹⁰⁰ when compared with other techniques, in avoiding extrusion of filling material. Gutmann et al.¹⁰¹ reported that ThermaFil placement was at least

Figure 11 Each pair of columns represents lateral canals A to E with each left hand column representing obturation with cold lateral (CL) and each right hand column representing obturation with the coated rigid carrier (CRC). Reproduced and adapted with permission from Wolcott J, Himel VT, Powell W et al.¹⁰⁰

comparable to lateral compaction when filling irregularities of any type in a canal space. A similar study by Kytridou et al.¹⁰² showed equivalent results for ThermaFil when comparing it with the System B technique. When comparing adaptation to the canal wall, Wolcott et al.¹⁰³ found that ThermaFil gutta-percha and sealer moved into lateral canals as well as did lateral compaction; however, ThermaFil surpassed it in this regard in the main canal (Figure 11).

Gutmann et al.¹⁰¹ found similar microleakage between contemporary (plastic core) ThermaFil and lateral compaction after 3 to 5 months. Fabra-Campos¹⁰⁴ reported similar findings in his 1993 study. Another study by Valli et al.¹⁰⁵ found more in vitro depth of coronal leakage in lateral compaction than with Densfil. In 2001, Abarca et al.¹⁰⁶ investigated apical linear leakage and apical extrusion in mesial roots of mandibular molars obturated with lateral compaction and ThermaFil. There were no statistically different findings for either technique in both areas studied. ThermaFil did not fare as well as System B in a 1999 study by Kytridou et al.¹⁰⁷ in which they found greater apical leakage with ThermaFil after 67 days when both groups of teeth were stored in Hanks Balanced Salt Solution.

Levitan et al.¹⁰⁸ studied the effect of insertion rate of ThermaFil Plus on apical extension and found that the faster insertion resulted in more overextension, while

slower rates resulted in shorter obturations. Recently, Chu et al.¹⁰⁹ followed 71 teeth (in vivo) in 64 clinical patients after 3 years, with 34 teeth being filled with ThermoFil and 37 teeth filled with laterally compacted gutta-percha. Radiographically, they found no statistical difference in success rates between the two groups.

THE EFFECT OF HEAT ON PERIAPICAL TISSUES

Concern for the health of periodontal tissues, when using heat-softened gutta-percha techniques, has continued into the new millennium. Romero et al.¹¹⁰ studied extracted teeth with artificial periodontal ligaments that were subjected to the System B obturation technique set at 200°C. They found significantly lower root surface temperature increases than previously reported by Hardie.⁷⁸ Subsequent studies have confirmed root surface temperature changes of less than 10°C, concluding no detriment to periodontal tissue adjacent to root surfaces.^{111,112}

RESIN-BASED CORE (RESILON)

Resilon, a thermoplastic synthetic (polycaprolactone) polymer-based obturating material (Resilon Research LLC, Madison, CT), has gained considerable popularity in the past few years. Studies regarding its attributes began to appear in 2004 when Shipper et al.¹¹³ discussed its ability to resist microbial leakage. They compared laterally and vertically compacted gutta-percha and sealer groups with Resilon and its sealer and their resistance to leakage with *Streptococcus mutans* and *Enterococcus faecalis* and found that the Resilon groups were “superior to gutta-percha groups” in amounts of leakage allowed (Figures 12 and 13). Teixeira et al.¹¹⁴ studied the fracture resistance under load in vitro of teeth obturated with lateral and vertical compaction of gutta-percha and that of those obturated with Resilon. They found that filling canals with Resilon increased the resistance to root fracture.

Using both scanning electron microscope (SEM) and transmission electron microscope (TEM), Tay et al.¹¹⁵ studied the quality of apical seal between Resilon/Epiphany sealer and gutta-percha/AH Plus. They looked for gaps along the canal walls with an SEM (Figure 14) and for apical leakage with a TEM and concluded that “a complete hermetic (sic) apical seal cannot be achieved with either root filling material.”

The implied increased resistance to root fracture as a result of the Teixeira et al.¹¹⁴ study was challenged in 2005 by Gesi et al.¹¹⁶ when studying interfacial strength and dislocation resistance between gutta-percha/sealer and Resilon/sealer, and intraradicular

Figure 12 High power SEM (650x) micrograph of a longitudinal section of a root filled with gutta-percha. The resin tags of the sealer penetrated the dentin, but a gap is evident between the sealer-dentin interface and the gutta-percha filling. Reproduced with permission from Shipper G, Ørstavik D, Teixeira FB et al.¹¹⁰

Figure 13 Low-power SE (40x) micrograph of a longitudinal section of a root filled with Resilon™. No gap is evident between the Resilon™ filling and the dentin. Reproduced with permission from Shipper G, Ørstavik D, Teixeira FB et al.¹¹⁰

dentin using a thin slice push-out test design. Their results indicated a higher interfacial strength for gutta-percha, with more failure along the sealer/dentin interface with Resilon.

Nielsen and Baumgartner¹¹⁷ studied the penetration depth of a nickel–titanium spreader in 0.04 taper prepared canals against 0.02 and 0.04 tapered gutta-percha and Resilon master cones and found significant differences in penetration depth, with 0.02 tapered Resilon permitting the deepest penetration, followed by 0.02 tapered gutta-

Figure 14 Fe-ESEM micrographs of wet, non-dehydrated sectioned specimens of vertical condensation filled roots, showing the variability of gap formation. **A**, Specimen that was filled with Resilon bonded with the self-etching resin system Epiphany, taken at a level 4mm from the apex. No gap could be seen between the filled resin sealer (S) and the root dentin. Numerous resin tags (pointer) extended into the dentinal tubules. **B**, Another region from the opposite side of the Resilon/Epiphany-filled root canal, taken 4mm from the apex. A gap (arrow) could be seen between the S and the root dentin (RD). No resin tags could be identified in dentinal tubules. **C**, Control specimen that was filled with gutta-percha (GP) and AH Plus, taken at a level 4mm from the apex. No gap could be discerned between the sealer (S) and root dentin. Numerous resin tags (pointer) were present. **D**, Another region from the same tooth, showing separation of the GP from the sealer (S), and the presence of a gap (arrow) between the sealer and the RD, despite the presence of resin tags (pointer). percha, 0.04 tapered Resilon, and 0.04 tapered gutta-percha.

The adhesive strength of a methacrylate-based sealer (Real Seal) to Resilon was evaluated by Tay et al.¹¹⁸ using a modified microshear bond testing design. A composite control was used to compare results. There was phase separation of the polymeric components in Resilon, suggesting that the amount of dimethacrylate in it may not be optimal for coupling to Real Seal. Another study by Nielsen et al.¹¹⁹ addressed the differences in setting time between 11 sealers in both aerobic and anaerobic environments. There were several conditions used for observation, including aerobic and anaerobic incubators and buffering solutions. Ketac-Endo and Resilon were found to set the quickest in anaerobic environments. However, when exposed to air, Resilon took 7 days to set and when placed in phosphate buffer solution, “an uncured layer remained on the surface.”

Recently, Stratton et al.¹²⁰ compared the sealing ability of gutta-percha with AH Plus sealer versus Resilon and Epiphany Resilon Sealer. Using a fluid filtration system, they found significantly less leakage in canals filled with Resilon and Epiphany Sealer using the continuous wave obturation method. Because of the very recent introduction of Resilon, further studies are certainly warranted to assess its long-term effectiveness in clinical usage.

SILVER POINTS

This solid core material is becoming more and more of historical significance. It was commonly used in previous times when less efficiently designed instruments and lesser quality metallurgy prevented larger, more accurate preparation of the canal space. Silver points were machined round in cross section and were

Figure 15 Cross section of extracted maxillary molar showing inadequately enlarged canals, and the disparity between the circular silver points and ribbon or oval shaped canals and lack of adaptation. Note undetected second mesio-buccal canal (white arrow). (Courtesy Dr. Fred Benenati)

sometimes placed into canals more often ovoid than round (Figure 15). Not surprisingly, long-term success rates may not be as high in these situations.

Siskin¹²¹ published a classic article in 1957 that included the use of silver points in straight, round-shaped canals and credited Jaspers for introducing them. Using the SEM, Seltzer et al.¹²² showed the appearance of corrosion on silver points from extracted endodontically treated teeth. Another SEM study of silver points placed in bones showed sulfur and chlorine corrosive products on their surfaces.¹²³ A report by Timpawat and coworkers¹²⁴ in 1983 involved an in vitro study of gutta-percha cones, stainless steel files, and silver points filling curved canals. They found that canals filled with silver cones actually resisted dye penetration better than gutta-percha.

Present-day instrumentation allows larger and more accurate canal preparations, and to accommodate these preparations often with many irregularities, gutta-percha as a core material appears better suited than the round silver points.

Cements and Pastes as Root Canal Filling Materials

N2/SARGENTI PASTE

Although first used in Europe, N2 paste has been produced in the United States as RC2B. The constituent of most concern in the paste is paraformaldehyde (6.5% concentration), which is quite toxic.¹²⁵ Several other reports have produced negative connotations for it, including a position by the American Association of Endodontists condemning its use.^{126–130}

Two well-known in vivo studies regarding the effects of paraformaldehyde, which Sargenti refused to remove from his paste, were conducted at the University of Indiana^{131,132} and showed severe inflammation of the pulp when RC2B was applied against it (Figure 16). An additional study even showed evidence of osteomyelitis in the apical tissue from teeth filled with RC2B.¹³³

Two other common problems with Sargenti paste, or RC2B in the United States, were overextension (even 15% of the cases submitted for Fellowship in the American Endodontic Society had overextensions) and required cortical trephinations 20.5% of the time in a survey conducted by the American Endodontic Society (supporters of the Sargenti technique).^{134,135} Perhaps of more magnitude of concern are the cases of persistent paresthesia from the misuse of these paraformaldehyde cements, unlike the temporary effects of such from other cements (J. Weichman, D.D.S., J.D., personal communication, June 1982).^{136,137,138} This type of cement or paste filling has not gained favor with organized dentistry or its component regulatory systems as a result of the above-described problems.

CALCIUM PHOSPHATE CEMENT

Based on the earlier experience with calcium phosphate gels, tricalcium phosphate has been suggested by Harbert¹³⁹ for use as an apical plug. In 1985, calcium phosphate cement (CPC) was advocated for use as a complete canal obturation material.¹⁴⁰ A blend of cements—one acidic and one basic—are combined to set as hydroxyapatite. It is nearly insoluble, except in the presence of strong acids.¹⁴¹ A dye leakage study conducted

Figure 16 N2/RC2B formalin cement study. **A**, Control specimen, pulp necrosis 3 months standing. Apical periodontitis with epithelial proliferation. **B**, Osteomyelitis 6 months after treatment of necrotic canal with RC2B. Note epithelial lining within dense inflammatory infiltrate. Reproduced with permission from Newton CW et al.

against it was impressive from the standpoint that there was only 0.15 mm penetration in vitro.¹⁴² The resistance to dye penetration was so impressive that it prompted Goodell et al.¹⁴³ to recommend CPC as a replacement for calcium hydroxide in apexification cases.

RESIN CEMENTS

There have been few studies that have addressed resin as a complete root canal filling material.^{144,145,146} The problem lies with its inability to bond with gutta-percha and to wet dentin walls. Kanca¹⁴⁷ commended All Bond 2 since it adheres to both wet and dry dentin.

CALCIUM HYDROXIDE

This compound has been called the endodontic panacea and an ultimate medicament.¹⁴⁸ Its use as a permanent obturating material has been mostly confined to the apical portion of the canal. Calcium hydroxide has been shown to encourage cementogenesis and osteogenesis and promotes apexification after thorough cleaning and shaping (Figure 17).^{149,150} Due to its solubility, calcium hydroxide has been used mainly as an apical obturation or a dentinal plug.¹⁵¹ Weissen-seel et al.¹⁵² found less apical leakage with calcium hydroxide plugs and laterally compacted gutta-percha than without apical plugs. Schumacher and Rutledge¹⁵³ endorsed a technique for placing calcium hydroxide as an apical barrier followed by immediate obturation with gutta-percha and sealer in open apex

cases, suggesting an end or an alternative to the laborious traditional multiple appointment apexification technique.

More recently, the placement of calcium hydroxide has been studied, and Torres et al.¹⁵⁴ found that placement of calcium hydroxide with a Lentulo spiral was more effective than with an Ultradent tip. Robert et al.¹⁵⁵ used an in vitro agar model to study three calcium hydroxide medicaments of varying viscosity through simulated root canals with various sizes of apical foramina. They found that a “thinner mix of 10% calcium hydroxide in sterile water can produce a higher pH and calcium ion concentration in an agar environment could similarly produce both a higher pH and calcium levels in a periapical lesion than Pulpdent or calcium hydroxide and sterile water mixed to a similar consistency.”

Haenni et al.¹⁵⁶ compared conventional calcium hydroxide/saline paste to calcium hydroxide mixed with chlorhexidine, with sodium hypochlorite, or with iodine potassium iodide solutions. Each was exposed to *E. faecalis* and *Candida albicans* in a diffusion assay. They found that none of these mixtures provided a better antimicrobial effect than conventional calcium hydroxide and saline.

DENTIN CHIP APICAL OBTURATION

Dentin chips or dentinal debris often occupy the apical portions of prepared and even sealed canals.¹⁵⁷ It has been well established that dentin filings stimulate both

Figure 17 Periapical repair following intracanal application of calcium hydroxide. **A**, Low-power view of periapex. Acute inflammatory resorption of dentin and cementum following pulpectomy. Reproduced with permission from Jeansonne BG.

osteo- and cementogenesis.^{158,159} El Deeb et al.¹⁶⁰ and Oswald et al.¹⁶¹ all concluded that dentin chips, acting as an apical barrier, confined materials to the canal space and led to quicker healing, minimal inflammation, and cementum deposition (Figure 18). A study by Torneck et al.¹⁶² contradicted the previous studies, finding that some dentin chips could interfere with repair.

A study by Holland et al.¹⁶³ mentioned a previous finding that infected dentin chips could impede healing and compared cementogenesis and inflammation between dentin chips and calcium hydroxide in ferrets. They found thicker cementum formation with dentin

chips but no overall difference between the materials. Based upon these findings and the previous study by Pitts et al.¹⁵¹ this technique has been endorsed as a "new technique," and a "biologic seal" and should be considered for wider use.^{164,165}

Endodontic Sealers and Apical Leakage

RATIONALE FOR THE USE OF SEALERS

The importance of filling the prepared root canal system with a sealer and a protective core has been

Figure 18 Dentin chip root canal plug after 3 months. **Left**, Periapical area, B, bone, C, cementum, DP, dentin plug. **Arrows** indicate canal wall. **Right**, High-power view of same periapical area. previously discussed.⁴ Friedman et al.¹⁶⁶ reiterated that importance and addressed the assessment of leakage of sealers. Wu, Fan and Wesselink¹⁶⁷ investigated the long-term success of gutta-percha with and without the use of a sealer and concluded that the “long-term seal of root fillings is affected by the volume change of both gutta-percha and sealer.” They found that leakage up to 6 months was always worse in canals filled with gutta-percha alone compared to those with gutta-percha and sealer. After 6 months, leakage amounts in both groups were similar. This may have been due to the ability of gutta-percha to flow and approximate canal walls. On the other hand, a solubility study by Peters¹⁶⁸ found that after 2 years, canals filled only with zinc oxide were completely free of the material. This should dispel the notion of core material being optional or unnecessary.

The properties of sealers are discussed in Chapter 29, “Root Canal Filling Materials,” so the following will emphasize how they perform in the canal space as well as their comparative abilities to resist apical microleakage. Coronal microleakage will be discussed separately.

MICROLEAKAGE AND ITS EVALUATION

Microleakage and how it is evaluated are important issues in endodontics. Clinical studies addressing the causes of endodontic failure found that incomplete obturation accounted for many of them, and an *in vitro* study indicated that incomplete obturation caused microleakage.^{169,170} These studies agree that an “evaluation of the apical leakage of particles or solutions between a root canal filling and the root canal walls is a proper method to establish the quality of an endodontic obturation.”

The most common method for the evaluation of microleakage has been the linear measurement of tracer dye penetration.^{171,172} These include eosin, methylene blue, India ink, radioisotopes, and even bacteria. They have been measured by longitudinal splitting, cross sectioning or decalcification, and clearing of the root.

Recently, Lyroudia et al.¹⁷³ evaluated a method involving computer-aided three-dimensional construction to measure and study apical microleakage. They used collaged stereoscopic microscope photos, after immersion in India ink, to reconstruct the roots three dimensionally via computer imaging, photorealistic effects, color and texture addition, light, and shading (Figure 19). Other recent methods of testing apical leakage include a vacuum technique, fluid

filtration, and movement of an air bubble in a glass tube.^{174–176}

ZINC OXIDE–EUGENOL-CONTAINING SEALERS

Early zinc oxide–eugenol (ZOE)-containing sealers included Rickert’s Kerr Pulp Canal Sealer and Procosol (Grossman’s sealer). They were reported upon by Marshall and Massler,⁵⁶ who studied their resistance to leakage to radioisotopes in human teeth. They found that the Kerr formula was better than Procosol in this regard. A more recent study showed the current formula, Kerr EWT (Extended Working Time), to surpass Roth 801 and AH 26 at 24 weeks.¹⁷⁷ Other ZOE sealers include Wach’s cement and Nogenol, neither of which shows a long-lasting seal against liquid exposure.¹⁷⁸

ROTH’S 801

This modern-day Grossman’s formula has been shown to inhibit bacterial growth.¹⁷⁹ A newer version of this sealer has been produced as Roth’s 811.

KERR PULP CANAL SEALER EWT

Perhaps the longest surviving ZOE sealer, it has been compared with the more current calcium hydroxide-containing sealers and resin-based sealers, with regard to apical leakage. The results of these comparisons will be discussed with each of those sealers.

CALCIOBIOTIC ROOT CANAL SEALER

This ZOE/eucalyptol sealer with calcium hydroxide has shown some promise in minimal water sorption; however, if the calcium hydroxide is bound to other ingredients, it would be difficult to exert its purported osteogenic effect.^{180,181}

SEALAPEX

This calcium hydroxide sealer has been noted to have minimal dissolution at the apex in one study.¹⁸² In contrast to this, Gutmann and Fava¹⁸³ found in an *in vivo* study that this material had disappeared from periapical tissues and may do the same in the canal system.

In a previously mentioned study, Pommel et al.¹⁷⁵ used a fluid filtration method to compare apical leakage between SealApex, Kerr Pulp Canal Sealer, AH 26, and Ketac-Endo and found SealApex to leak significantly more than the others. There was no significant leakage difference between the other sealers. On the other hand, Cobankara et al.¹⁸⁴ used the same method to evaluate leakage between SealApex, RC Sealer,

Figure 19 **A**, Cross-section of the apical third of the treated tooth. Microleakage is obvious in almost half of the perimeter of the root canal. **B**, Cross-section of the coronal third of the treated root. **C**, Three-dimensional reconstruction of the case. The external surface of the tooth is shown as purple, the root canal as yellow, and apical microleakage as cherry red. Reproduced by permission from Lyroudia K, Pantelidou O, Mikrogeorgis G et al.¹⁷⁰

AH Plus, and Rocanal 2 and found that SealApex had less leakage than the others.

APEXIT

This additional calcium hydroxide-based sealer was found to seal better than SealApex in a 1991 study by Limkangwalmongkol et al.¹⁸⁵. However, in 2002, Miletic et al.¹⁸⁶ used the measurement of an air bubble in a tube to compare apical leakage among five sealers and concluded that “Apexit showed significantly more leakage than AH Plus and Ketac-Endo.

Leakage of AH 26 and Diaket sealers was not significantly different from that of AH 26 and Ketac-Endo, which showed the least leakage, or from Apexit, which showed the most” (Table 3).

VITAPEX

Developed for its potential bactericidal and osteogenic activity, no mention was given to this material’s sealing ability in a report by Kawakami and associates.¹⁸⁷

Table 3 Mean Leakage Values and Standard Deviation for Each Tested Sealer. Reproduced with permission from Miletic I et al.¹⁸⁶

Sealer	Mean \pm SD Value (μL)
Ketac-Endo	0.357 \pm 0.082
AH Plus	0.378 \pm 0.076
AH26	0.390 \pm 0.071
Diaket	0.429 \pm 0.152
Apexit	0.490 \pm 0.137

Plastic- and Resin-Based Sealers

DIAKET

Although first introduced in the 1950s, little has been written about its sealing abilities. A report by Ozata et al.¹⁸⁸ in 1999 indicated that it had similar sealing abilities to Apexit, but better than Ketac-Endo when resisting dye penetration.

AH 26 (THERMASEAL)

This slow-setting resin sealer, when tested for tensile strength and bonding to dentin, performed better than Kerr Pulp Canal Sealer, SealApex, and

Ketac-Endo.¹⁸⁹ It was the precursor to the current product, AH Plus. When comparing AH Plus to Ketac-Endo and Fill Canal, De Almeida et al.¹⁹⁰ found it to be superior in dye-leakage resistance. Recently, Wuerch et al.¹⁹¹ studied the effect of intracanal medicaments, chlorhexidine gel, and calcium hydroxide on the sealing ability of AH Plus. Using the “fluid conductance model” (Figure 20), they found that neither impeded the apical seal when using AH Plus as a sealer.

McMichen et al.¹⁹² investigated several properties, including solubility, regarding AH Plus versus Tubliseal, Kerr Pulp Canal Sealer EWT, Roth 801, Apexit, and Endion. Using weight change of the roots in water over a 3-month period, they found AH Plus to be the least soluble. Another study by Schafer and Zandbiglari¹⁹³ addressed solubility by comparing the weight loss of ring molds filled with eight different sealers immersed in water. AH Plus had the least weight loss, with SealApex and Ketac-Endo showing the most weight loss. Eldeniz et al.¹⁹⁴ compared the shear bond strength to dentin with AH Plus, Diaket, and Endo-Rez and found AH Plus to be superior to both.

KETAC-ENDO

Ketac-Endo is a glass ionomer cement with properties similar in behavior to resin or plastic sealers. It has been discontinued but is discussed here because it has

Figure 20 Schematic illustrating the device developed by Dr. David Pashley at Medical College of Georgia and used to measure fluid flow around root canal fillings. The root cemented to a block of Plexiglas penetrated by an 18-gauge stainless steel tube, the entire system filled with water at a hydrostatic pressure of 20cm H₂O. Reproduced with permission from Wuerch RM, Apicella MJ, Mines P et al.¹⁸⁸

Bonding of endodontic sealers to gutta-percha and dentin

Figure 21 Bonding of endodontic sealers to gutta-percha and dentin. Reproduced with permission from Tagger M, Tagger E, Tjan AHL et al.²⁰²

been included in so many studies. Although somewhat difficult to remove from the canal, it is possible to do so.¹⁹⁵ Regarding microleakage, Ketac-Endo did not perform as well as Roth's 801 and AH 26 in a study by Rohde et al.¹⁹⁶. Another study by Dalat and Onai¹⁹⁷ confirmed these findings when comparing Ketac-Endo to AH 26. However, a report by Wu et al.¹⁹⁸ found the opposite, that is, "AH 26 leaked more than Ketac-Endo." When testing the antibacterial properties of five sealers including Ketac-Endo, Cobankara et al.¹⁹⁹ found that Ketac-Endo had less antibacterial effect against *E. faecalis* than did AH Plus, SealApex, and Sultan (Roeko-Seal) had none at all.

ROEKO-SEAL AUTOMIX

This silicone-based material, a relatively new sealer, was compared clinically with other cases obturated with Grossman's sealer and evaluated up to 12 months after treatment.²⁰⁰ No difference in success rates was noted. Lucena-Martin and associates²⁰¹ compared leakage to black ink between Roeko-Seal, Top Seal, and Endomethasone and found no significant differences between them. When compared with the more commonly used AH Plus and Ketac-Endo, Cobankara et al.²⁰² found Roeko-Seal to have better resistance to leakage than both of the others when subjected to fluid filtration. Using fluid filtration, Wu et al.²⁰³ compared the leakage in root canal fillings in extracted teeth filled vertically and laterally

using gutta-percha and Roeko-Seal, Kerr Pulp Canal Sealer. They found that Roeko-Seal leaked less than Kerr Sealer.

SEALER 26

This epoxy-based resin has been shown to have better adherence to dentin than zinc oxide-based sealers, when used with and without laser application.²⁰⁴ Apparently its bond strength ability is its main advantage. Tagger et al.²⁰⁵ showed it to bond more strongly to gutta-percha and dentin than did eight other well-known sealers (Figure 21).

Methacrylate Resin Sealers

ENDO-REZ

This urethane-based resin sealer was compared to AH Plus by Kardon et al.,²⁰⁶ assessing the differences in sealing ability by the fluid filtration method. Their results indicated that Endo-Rez was not as effective at sealing the apex as AH Plus when using a single cone or warm vertical condensation. However, another study found more apical leakage with Grossman's sealer than with Endo-Rez in either single cone or lateral compaction methods of obturation.²⁰⁷ Two more recent studies by the same group showed the sealing ability of Endo-Rez to be enhanced by the use of a self-etching adhesive.^{208,209}

EPIPHANY

This recently developed curable resin composite sealer was analyzed in 2005 in a previously mentioned study using an SEM to compare the ultrastructural quality of its apical seal (combined with Resilon) with that of gutta-percha and AH Plus.¹¹⁴ Neither sealer achieved a complete apical seal as previously mentioned. An *in vitro* study by Tunga and Bodrumlu²¹⁰ addressed leakage allowed via fluid transport in human anterior teeth after instrumentation, smear layer removal, and obturation with either laterally compacted gutta-percha and AH 26 or AH Plus sealers or Epiphany sealer and Resilon. Teeth filled with AH 26 and gutta-percha exhibited the most leakage, while the least leakage was observed with Epiphany and Resilon. Biggs and associates²¹¹ compared the sealing abilities of gutta-percha/Roth 801 and gutta-percha/AH Plus to Resilon/Epiphany and found no differences in sealing abilities. Because of the rising popularity of the Resilon/Epiphany combination for obturating canals, much remains to be seen regarding the future performance of Epiphany as a sealer.

FIBREFILL

Another methacrylate resin sealer, its shear bond strength was analyzed by Gogos et al.²¹² and compared Endion, calciobiotic root canal sealer (CRCS), and Topseal (an epoxy resin). Fibrefill was found to have the bond strength of these four sealers. The apical leakage associated with Fibrefill with and without the presence of a smear layer was compared to that of CRCS in a study in Greece.²¹³ The findings indicated that Fibrefill leaked significantly less than CRCS with or without a smear layer, but especially without the smear layer.

METASEAL

MetaSEAL (Parkell, Edgewood, NY) is the latest resin root canal sealer. MetaSEAL is the endodontic version of 4-Meta, a long-standing restorative sealer. Its self-etch formula hybridizes the dentin wall of the canal to prevent leakage. It bonds to both Resilon and gutta-percha. Belli et al.²¹⁴ compared MetaSEAL with Epiphany/Real Seal and AH Plus with gutta-percha and found less leakage with MetaSEAL after 1 week, but no difference among the sealer groups at 4- and 12-weeks time periods.

The Smear Layer and Apical Leakage

The question of the presence of the smear layer and its effect on apical seal continues to be addressed. Yamada et al.²¹⁵ have extolled the virtue of its removal and how it promotes a better apical seal with the filling material via dentinal tubule penetration. Cobankara and associates²¹⁶ studied the effects of the presence or the absence of the smear layer on root fracture resistance *in vitro* and found no difference whether it was present or absent. They also found no difference whether AH 26 or Ketac-Endo was used as a sealer.

An SEM study compared intact smear layers in prepared canals and those with removed smear layers and the ability of AH Plus, Apexit, and Roth 811 to penetrate dentinal tubules.²¹⁷ The authors found that the presence of a smear layer obstructed all sealers from penetration; however, all three sealers penetrated the tubules with the removal of the smear layer (Figure 22). They concluded that the “smear layer plays an important role in sealer penetration into the dentinal tubules, as well as in the potential clinical implications.”

Eldeniz et al.²¹⁸ tested the shear bond strength of Diaket, AH Plus, and Endo-Rez with and without the presence of a smear layer. AH Plus was found to have the highest shear bond strength of any of these in either condition, and higher with no smear layer. Another study evaluated the effects of final irrigants on apical leakage in smear layer-free canals using fluid filtration measurements.²¹⁹ Although the authors used only one sealer (Roth 801), whether the final irrigant was 70% isopropyl alcohol, NaOCl, or Peridex, no significant difference was noted for sealer penetration or microleakage. Additional investigations are needed, using current sealers, to study the effects of the presence or the absence of the smear layer on sealer penetration and microleakage in filled canals.

Lasers and Apical Microleakage

The advent of laser use in dentistry has expanded its applications in hard tissue, specifically to include intracanal use. Kimura et al.²²⁰ evaluated the amount of apical leakage *in vitro* after root canal preparation using Er:YAG laser irradiation versus a control group without irradiation. They found no significant difference in the amount of leakage between the two groups. Another *in vitro* investigation by Goy et al.²²¹ involved instrumented teeth that were lasered with

Figure 22 Appearance of experimental groups: **A**, Smear layer covering the root canal walls. **B**, Smear layer-free root canal walls. **C**, Smear layer inhibited Apexit from penetrating dentinal tubules. **D**, Area between root canal walls and maximum penetration depth in smear layer-free root canal walls for AH Plus; **E**, Apexit; and **F**, Roth 811. Reproduced with permission from Kokkas AB, Boutsoukis AC, Vassiliadis LP et al.²¹³

Nd:YAG irradiation, followed by black ink application in one group and without black ink as a control. The canals were filled and then evaluated by stereoscopy or SEM. They concluded that laser irradiation following black ink application increased smear layer removal and significantly reduced apical leakage after obturation.

Similar findings were reported by Park et al.²²² They also used Nd:YAG laser following rotary instru-

mentation or hand instrumentation, with teeth likewise instrumented, without irradiation. All teeth were sealed with Kerr Pulp Canal Sealer and gutta-percha. They concluded that laser irradiation immediately following canal preparation reduced apical leakage after obturation.

More studies on the effect of laser irradiation will certainly be forthcoming. It appears that lasers are at least nondetrimental to preparation and obturation,

Figure 23 Furcal accessory canal and lateral canal, mesial root filled by vertical compaction of warm gutta-percha. Reproduced with permission from West JD.

and at most, appear to somewhat enhance them. See Chapter 26E, “Endodontics Instruments and Armamentarium,” for more information on the use of lasers in endodontics.

Filling Lateral and Accessory Canals

Historically, the question of the significance of filling lateral canals (Figure 23) has persisted for nearly four decades. Kitagawa²²³ espoused the greater lack of bacteria in dentin around lateral canals than in the main canal(s). In somewhat contradistinction, Fox et al.²²⁴ remarked that the periodontal ligament adjacent to occluded lateral canals remained noninflamed regardless of the pulpal condition and that due to instrumentation, the orifices to such canals were frequently blocked.

Weine's²²⁵ classic article in 1984 addressed the significance of filling lateral canals (a branch of the main canal coronal to the apical region) and accessory canals (going from the secondary branching of the canal) in the apical region. He refuted the assertion that vertically compacted gutta-percha and sealer close off more lateral canals than other methods of obturation. He also stated that lateral canals may

Figure 24 Gutta-percha replication of lateral grooves and depressions when the System B Fine heat plugger was inserted to a depth of 3mm (group C) from working length. Group A (not shown) had the System B Fine heat plugger inserted to a depth of 5mm from the WL, and group B (not shown) had the System B Fine heat plugger inserted to a depth of 4mm from the WL. Group C had statistically better movement of gutta-percha into the 1mm dentin depression than either group A or group B and better movement of gutta-percha into the 3mm dentin depression than group A. Group C also demonstrated statistically better movement of gutta-percha into the lateral grooves at 3mm from the WL than either group A or group B. Reproduced with permission from Bowman, CJ and Baumgartner, JC.²²³

cause pain during treatment and may even lead to failure if not adequately cleaned and sealed.

A study in 2001 by Goldberg et al.²²⁶ evaluated the ability of lateral compaction of gutta-percha and of five thermoplasticized gutta-percha filling techniques to obturate simulated (artificial) lateral canals. More lateral canals were filled with Ultrafil, ThermaFil, and System B plus Obtura II than with Obura II alone or with lateral compaction. Bowman and Baumgartner²²⁷ used a split tooth plastic model to evaluate the movement of gutta-percha into lateral grooves and depressions in the apical 7 mm, using System B Heat Source and Obtura II for backfill. Only when the System B plugger reached 3 mm from the apex, gutta-percha was observed in the lateral grooves (Figure 24).

Villegas et al.²²⁸ evaluated accessory canal obturations in vitro after using no irrigation, distilled water, sodium hypochlorite, or sodium hypochlorite in conjunction with ethylenediaminetetraacetic acid (EDTA). They measured gutta-percha penetration into accessory canals and concluded that sodium hypochlorite alone or in conjunction with EDTA in final irrigation may facilitate obturation material flow into accessory canals.

The importance of lateral and accessory canal obturation is still under investigation, and further studies would seem to be appropriate to continue to address this issue.²⁸

Coronal Protection of the Obturation

RATIONALE FOR A CORONAL SEAL

The importance of a coronal restoration placed over a canal obturation to prevent microleakage is emphasized by the findings of Torabinejad et al.²²⁹ They found that without a coronal protection seal of the canal obturation(s), it took only 19 days for *Staphylococcus* organisms placed in a coronal access cavity to reach the apex in half of their test cases and 42 days for the same percentage of *Proteus* samples. Alves et al.²³⁰ found that bacterial endotoxins could reach the apex of obturated canals in as little as 20 days if not protected by a coronal seal.

METHODS OF EVALUATING CORONAL LEAKAGE

Not surprisingly, techniques used to study coronal leakage are similar to those employed to evaluate apical microleakage. Wimonchit et al.²³¹ mention methods including vacuum dye penetration, fluid filtration, and passive dye penetration, with the vacuum dye method allowing significantly more penetration. Lyroudia et al.²³² have described the use of a 3D computer-assisted reconstruction of a tooth and a root canal in order to study coronal leakage.

TEMPORARY CORONAL CLOSURE MATERIALS

For the reasons mentioned above, canal obturations require protective seals. Restorative requirements may sometimes necessitate the use of temporary filling materials (cements) to accomplish this. The knowledge that *Streptococcus sanguis* bacteria are 500 times larger than aniline blue dye prompted Deveaux

et al.²³³ to study the ability of *S. sanguis* to penetrate 4 mm of Cavit, TERM, and IRM cements before and after thermocycling. Cavit and IRM succeeded in denying bacterial passage, but after thermocycling, 60% of the TERM fillings allowed bacterial penetration.

There are other reports that found favor with or conflicted with the above study. Some found Cavit to be among the best temporary filling materials regarding sealability (although quite soluble).^{234,235} Other studies concluded that it was inferior to IRM and ZOE.^{236,237} Acid-containing cements (zinc phosphate and polycarboxylate) did not fare as well against bacterial leakage. However, when dentinal walls were etched, KetacFil was adequate.²³⁸

Barthel et al.²³⁹ suggested that a double seal of IRM and glass ionomer cement may prevent bacterial penetration. When considering Amalgambond (Parkell) as an interim material, in a leakage study by Galvan and associates,²⁴⁰ it was found to outperform IRM and even C&B Metabond. In a more recent study involving methylene blue dye penetration, there was no significant difference in marginal leakage between Cavit, IRM, and Ultratemp Firm.²⁴¹ Cruz et al.²⁴² evaluated two lesser-known cements, Fermin and Canseal against Cavit and Caviton, and found that Fermin resisted methylene blue dye penetration better than the other cements.

PERMANENT CORONAL CLOSURE MATERIALS

It is disconcerting to find that with permanent filling materials and bases placed over endodontic access cavities, bacterial leakage still occurs.²⁴³ Even full coverage, the ultimate protection of endodontic accesses, is a restoration that can allow leakage to the obturation level.^{244,245} The latter of these two studies showed that both amalgam and composites can leak, even under a cast metal crown.

Today's restorative world includes materials such as Ketac-Fil glass ionomer, Herculite composite resin, and etchant agents including GLUMA. After thermocycling, Wilcox and Diaz-Arnold²⁴³ found that all of them leaked (Figure 25). However, Tjan et al.^{246,247} found that when using Amalgambond to line prepared dentin and enamel, a newly placed amalgam restoration was leakproof (Figure 26). In the same studies, teeth lined with Copalite did not fare as well and leaked to the pulpal level. Wolcott et al.²⁴⁸ found that a glass ionomer intraorifice barrier inhibited the leakage considerably more

Figure 25 Variations in leakage (arrow, extent of AgNO_3): r, restoration; b, base, g, gutta-percha. **A**, Specimen from group 3 (temporary stopping + glass ionomer) which showed the least microleakage, extending just into coronal portion of temporary stopping. **B**, AgNO_3 extends more than half way down the base-dentin interface in the group 3 (temporary stopping + glass ionomer) specimen. **C**, Leakage just to the junction of the base and gutta-percha (group 2, temporary stopping + composite resin). **D**, AgNO_3 penetration into the gutta-percha (group 4, zinc phosphate + composite resin). **E**, The worst specimen, group 1 (zinc phosphate + glass ionomer) shows complete penetration of the AgNO_3 along the gutta-percha. Reproduced with permission from Wilcox, LR and Diaz-Arnold, A.²³⁹

Figure 26 Comparative study in microleakage between resin adhesive and copal varnish. **A**, Amalgam (A) bonded to dentin (D) using Amalgambond demonstrating no microleakage. **B**, Amalgam (A) lined with Copalite shows extensive microleakage (**arrows**) (Courtesy, Drs. A. Tjan and D. Tan).

than when such was not used in permanent access closures.

A final word to be said about coronal closures regards loss of either temporary or permanent materials over an existing obturation. Magura et al.²⁴⁹ at Indiana recommended “retreatment of obturated canals that have been exposed to the oral cavity for at least 3 months.” Reinforcement of this statement comes from an *in vivo* monkey study by Madison and Wilcox,²⁵⁰ who showed that with coronal microleakage, saliva leaked down filled root canals when any of SealApex, AH 26, or ZOE sealers was used.

Influence of Post Space Preparation on Obturation

In order to provide better retention for a core buildup after root canal treatment, it is often necessary to include one or more posts (dowels) (see Chapter 39, “Restoration of Endodontically Treated Teeth”). The length of the space created to accommodate a post and its time of preparation (immediately following obturation or at a later time) are of concern, as they can affect the quality and the durability of the canal seal. A study by Bourgeois and Lemon²⁵⁸ in 1981 related that using a hot plugger

when making a post space was favorable. A follow-up study by Dickey et al.²⁵² suggested that if Peeso reamers or chloroform and K-files were used, gutta-percha removal should be delayed by 1 week to allow for setting of the sealer.

The classic literature dealing with the timing of post space preparation has differed regarding its importance. Mattison et al.²⁵³ showed that timing did not matter. More recently, studies have shown conflicting results, as one study with immediate post space preparation gave better results to minimize coronal leakage, while another study showed no difference between immediate and delayed preparation.^{254,255} Another study addressed post spaces made in canals obturated by different filling techniques, including silver points, lateral compaction, warm/vertical compaction, Ultrafil or Obtura and found no significant differences in amounts of leakage.²⁵⁶

Another issue with respect to post space preparation is that of minimal obturation length (or maximum post space depth). Goodacre and Spolnik²⁵⁷ recommend post length of at least the same or more as the height of the crown and that 4 to 5 mm of gutta-percha remains apical to the post to maintain an adequate seal. Abramovitz et al.²⁵⁸ more recently showed that less than 4 to 5 mm of gutta-percha provides an unreliable seal.

Figure 27 **A**, Sample of group 1 (immediate post preparation) shows no apical leakage. **B**, Sample from group 2 (one week delay) shows significant leakage. Reproduced with permission from Solano F, Hartwell G, and Appelstein, C.²⁵⁷

Some concern has been expressed about ThermoFil carriers and their potential impedance when creating a post space. Ravanshad and Torebinejad²⁵⁹ compared metal core ThermoFil obturations notched to fracture 5 to 6 mm from the apex to lateral and vertical compaction obturations with respect to coronal leakage. They found that the ThermoFil group had the highest degree of coronal dye penetration. When comparing ThermoFil plastic and metal carrier obturations following the manufacturer's instructions regarding post space preparation, there was very little differences in apical leakage according to Mattison.²⁶⁰

Another study compared the effects of immediate versus delayed post space preparation on the apical seal using AH Plus sealer and vertical compaction.²⁶¹ Post space depths were all done to allow 4 mm of apical gutta-percha to remain. Teeth in which the post space preparation was delayed for 1 week had significantly more apical leakage than those with immediate post space preparation (Figure 27).

Perhaps more convincing evidence of the importance of leaving a minimum amount of apical seal are the findings of Kvist et al.²⁶² in a clinical study of root canal failures. They found that cases involving post placement had a significantly higher percentage of failures related to apical fillings with less than 3 mm of length. A very thorough recent review of post placement in restoring endodontically treated teeth was provided by Schwartz and Robins²⁶³ and will be further elaborated in Chapter 40, "Restoration of Endodontically Treated Teeth."

Summary

Obturation of the radicular space, encompassing core filling materials and sealers, has undergone many, albeit slow, changes over several decades. Grossman's formula persists, but now, methacrylate sealers are also in use. Silver points have virtually disappeared from use, and a polycaprolactone-based material (Resilon) is challenging gutta-percha as the most common, long-standing core material. Newer backfill delivery systems are in use, including Calamus (Dentsply Tulsa Dental Specialties, Tulsa, OK) that has yet to be studied and compared to other current methods. Lasers are being introduced to enhance apical seals. The controversies over the significance of the smear layer and the efficacy of calcium hydroxide continue to be addressed. Future technology holds the promise of even better obturations.
