Notice: The authors and publisher have made every effort to ensure that the patient care recommended herein, including choice of drugs and drug dosages, is in accord with the accepted standard and practice at the time of publication. However, since research and regulation constantly change clinical standards, the reader is urged to check the product information sheet included in the package of each drug, which includes recommended doses, warnings, and contraindications. This is particularly important with new or infrequently used drugs. Any treatment regimen, particularly one involving medication, involves inherent risk that must be weighed on a case-by-case basis against the benefits anticipated. The reader is cautioned that the purpose of this book is to inform and enlighten; the information contained herein is not intended as, and should not be employed as, a substitute for individual diagnosis and treatment.

DEDICATION

The editors of Ingle's *ENDODONTICS* are proud to dedicate this edition to two of the most inspired and beloved teachers and practitioners of endodontics during our generation: Dr. Dudley H. Glick and Dr. Alfred L. Frank. True gentlemen, world famous, innovators, and the closest of friends. So close, Al and Dudley were often referred to as Al Glick and Dudley Frank. Both practiced in Beverly Hills, both with a bevy of famous patients, they could have been long time competitors. Instead, they were inseparable - Damon and Pythias - professionally, academically, and socially. Their wives, Ellie Glick and Teri Frank, are the very best of friends. Between them they have eight sons.

Both were born, raised and educated in Ohio; they served with honor and decoration in World War II and following the war Dudley and Al were both graduated in dentistry from the University of Southern California. As predoctoral dental students they were infamous for their unusual interest in endodontics, in a school famous for its restorative dentistry. Upon graduation they both started general practices in the Los Angeles area and were soon noted for their superb restorative dentistry. They joined the endodontic faculty at USC and when word of their endodontic skills spread, referrals started to pour in. After consulting a number of endodontic friends, they "took the leap," and announced they were limiting themselves to endodontics, among the first really fulltime endodontists in Southern California.

They were the last of the "self-trained" endodontists. Self trained, that is, by taking every postgraduate endodontic course and attending available meetings, and visiting professionally with the nation's best known endodontists; first on the West Coast and then nationwide.

Over the years they became the endodontist's endodontists. If we, ourselves, needed root canal treatment, we would travel cross country to have either Al or Dudley perform the treatment. There was never a fee! They were proud of the trust placed in them by other skilled professionals. In fact, dentists, physicians and the clergy were rarely charged in their offices. That was the strongest belief in professional courtesy. And everyone else paid the same fee, whether you were Cary Grant, Nancy Regan, Mae West or Joe the plumber. Except teachers who received a reduced fee.

As they gained in renown, both Al and Dudley, were inundated with requests to speak to national and foreign audiences. No one made and retained so many devoted friends around the world. Their homes in Beverly Hills became a haven for the famous and students alike, sometimes for weeks at a time, as young people came to learn from the masters.

They never ceased their dedication to teaching, at USC, at UCLA, at Loma Linda, and at Cedars-Sinai Hospital. Both Dudley and Al were honored over and over by societies and universities alike.

They became famous locally, nationally internationally, yet remained the same modest, generous, considerate, literally lovable gentlemen they always were, brimming with integrity and honesty. This is what endeared them to those of us fortunate to have been their friends and disciples, students, employees and patients. We only wish the entire specialty profession had had the same opportunity.

Dr. Dudley H. Glick

Dr. Alfred L. Frank

PREFACE TO THE FIRST EDITION OF ENDODONTICS 1965 “PULL AND BE DAMNED ROAD”

This book was begun at Sne-oosh Beach, a quiet retreat overlooking Puget Sound and the San Juan Islands. At Sne-oosh it is possible to escape from complex civilization, and concentrate on the job at hand—writing an endodontic text.

Hard by Sne-oosh is an old Indian trail called PULL AND BE DAMNED ROAD. One could hardly imagine a more fitting location while writing a text on the pulpless tooth than

nearby PULL AND BE DAMNED ROAD, for “Pull and be damned” could well be the motto of the dental profession from its inception.

PULL AND BE DAMNED ROAD goes down to the shores of Skagit Bay, an inside passage of the gentle Pacific leading ominously to DECEPTION PASS. This delusive inlet, which so easily deceived the early explorers, reminds us of how our profession has practiced self-deception over the years. Unfortunately, many pass into the “pull and be damned” deceptive phase of dental practice, never to return.

Inside DECEPTION PASS, however, lies HOPE ISLAND, our symbol of the future. HOPE we must have, coupled with resolve. HOPE that the future of dentistry will noticeably improve. HOPE that an enlightened profession will be guided by the concept of retention and rehabilitation of the dental apparatus. HOPE for the rejection of “oral amputation.”

In this new text we hope to inspire dentists to consider root canal treatment as an integral part of their practice. We discuss in great detail the operative aspects of endodontic therapy: cavity preparation, canal débridement and filling. We leave to others the detailed discussion of anti-infectives, local anesthesia, oral microbiology,

although these subjects are dealt with in this text, brief and to the point. We have spent, however, an unusual amount of space and time in developing the chapter on DIFFERENTIAL DIAGNOSIS OF ORAL AND PERIORAL PAIN, so necessary in arriving at a proper diagnosis. Diagnosis of pain is falling more and more in the province of endodontics. Proper diagnosis is the discipline that separates the really competent dentist from the merely mechanical. So a great deal of thought and talent has gone into developing the four background chapters on normal and pathologic pulp and periapical tissues.

Snee-oosh Beach is no Walden Pond, nor are we Thoreau for that matter. But we may learn from Walden. "Simplify, Simplify!" was Thoreau's text, and simplification we have taken to heart. We have removed the "mumbo-jumbo" from endodontic treatment, a significant factor that discouraged dentists from including endodontics in their practice.

We have attempted to present the subject, not only in a simplified form, but in a systematic manner leading to success, pleasure and profit. We have attempted to remove the mystery and retain the basic core of the subject. We only hope this text succeeds in bringing some order out of the present chaos.

John I. Ingle
Seattle, Washington
1964

PREFACE

“PULL AND BE DAMNED ROAD”

REVISITED

The original sign for Pull and be Damned Road has been pilfered so many times the authorities have had to place a new sign over 20 feet above the ground. (Courtesy of Dr. James Stephens.)

Over 40 years ago the preface to the first edition of *Endodontics* featured “Pull And Be Damned Road.” Nothing from the first edition left such a lasting impression as that saying. Even today, “old timers” come up to me at meetings to reminisce about this preface. They may not remember the details of endodontic cavity preparation or the chapter on pain first expressed in that edition. Those features have become an integral part of any endodontic practice. But they do remember “Pull and Be Damned Road.” And for good reason.

Forty years ago it was more prevalent to extract teeth than to save them by root canal therapy. A plea was made in this preface to trust endodontic treatment and to reverse this trend toward “oral amputation.” Gradually this became a fact, as endodontics spurred ahead and full dentures declined.

And this brings to mind an incident I long have savored. I was a speaker at the Hinman Dental Meeting in Atlanta. Joining me as a headliner was Dr. Will Menninger, head of the famous Menninger Psychiatric Clinic, then based in Topeka, Kansas. Dr. Menninger and his brother Karl were unquestionably the world’s most famous psychiatrists. Dr. Will had been a brigadier general in World War II, head of all the army’s psychiatrists. In 1948 he was the first psychiatrist on the cover of *TIME* magazine. It was an honor for me to be on the same program with him, and I eagerly attended his first lecture that preceded mine.

When I began my lecture, there was Dr. Menninger seated in the front row. I considered it professional courtesy on his part, but I did notice him taking notes.

The Hinman had a format wherein each lecturer would repeat his same lecture the next day. I didn't attend Dr. Menninger's second lecture but he attended mine. There he was again, seated in the front row. I was flattered beyond measure. At the end of the lecture I asked him why his sudden interest in endodontics. His reply was startling.

"Dr. Ingle," he said, "I was so impressed with your lecture, but I was also terribly embarrassed. On behalf of my profession I must apologize to you for my past behavior. When I think of how many patients I have recommended that they have their teeth extracted, I am appalled at the destruction I have caused. I had no idea. Now I find these teeth could have been saved and their abscesses healed. You have no idea how thankful I am to you, for directing me from my past behavior." Spoken like a psychiatrist!

We've come a long way since those days, a time of wholesale extractions. But we face a new challenge today; not wholesale extractions but **selective extractions**; for the sole purpose of placing an implant. Once again, dentists are urging patients to have teeth extracted, ignoring the fact that a healthy root is far preferable to a mechanical implant; less costly, less painful, less time consuming, and above all, more biological.

Now I'm not saying implants are unhealthy or less successful. What I am expressing is my concern that many salvable teeth are being sacrificed on the altar of insatiability. Back to pull and be damned. I'm not against implants! As a matter of fact, implant therapy is now being taught in a number of endodontic post doctoral programs. The thesis being, however, that teeth that cannot or should not be saved by endodontics may well be extracted and replaced by an implant rather than a bridge. And who better to place that implant than a well-trained endodontist who has just made that judgment?

The 6th edition of *Endodontics* is replete with new innovations and knowledge. Now, more than ever, it remains the "Bible of Endodontics" a name long applied by others to the previous editions.

I feel most comfortable as I "pass the torch" to the new editors, Leif Bakland and Craig Baumgartner. And I have a feeling the profession will come to its senses; veering off "Pull and Be Damned Road" and onto the "Road Best Traveled."

John I. Ingle
December 2007

ACKNOWLEDGEMENTS

Once again, I am particularly indebted to my wife Joyce and my son Geoffrey, who were so helpful in manuscript preparation and computer utilization. And speaking of computers, I am especially indebted to my computer “maven”, Lynda Arnett, who frequently spent hours “setting me straight and bailing me out” of trouble.

Being isolated in a city without a school of dentistry presents a problem in literature search. Dr. Robert Bravin of El Cajon CA, who has a nearly complete library of the *Journal of Endodontics*, was especially helpful in providing back issues of JOE. In addition, I received a great deal of help from the dental school library at the University of Southern California and Chief Librarian, Professor Frank Mason, as well as Librarian John Glueckert. And at the University of Washington, in the Department of Dental Health Sciences, Dr. Peter Milgrom, chairman, and Janessa M. Stream Graves, Research Coordinator, were most helpful with trends and statistics. I received similar help from Jill Cochran at the American Association of Endodontists.

Finally, I must acknowledge the advice and counseling I received from my dear friend the late Dr. Dudley Glick. But most of all, I acknowledge, with pride and admiration, my coeditors, Dr. Leif K. Bakland and Dr J. Craig Baumgartner. They have carried the major load in producing this edition of *Endodontics*, tireless hours, hundreds of emails, phone calls and faxes. I leave this text in the good hands of these skilled and highly knowledgeable individuals.

John I. Ingle

A textbook with the scope and format of this, the 6th edition of *Ingle's Endodontics*, would not be possible but for the tremendous effort by numerous individuals. Each contributor to this book devoted considerable time to research, preparation, and writing. To them I express much gratitude for their efforts, but also for putting up with my deadline prodding. My hope is that this collaborative effort makes them as proud as it makes me.

Editing manuscripts from around the world (Europe, Asia, and the Americas) would be impossible but for the expert secretarial support provided by Luci Denger and Shannon Kalkanour in the Department of Endodontics at Loma Linda University. These capable coworkers skillfully completed in a timely fashion all the requests for changes, corrections, formatting and interactions with authors and publisher. To both Luci and Shannon – your contributions are most appreciated.

Anyone who takes on the job of editing a major text book knows that it will have an impact on the “day job” that each of us has. Were it not for an understanding dean, Dr. Charles Goodacre, and a cooperative department faculty, Drs. Mahmoud Torabinejad, Robert Handysides, and David Jaramillo, there would neither be the time nor the energy to complete this task. To them I say a heartfelt “Thank you.”

This grand textbook is not the result of any single individual, a fact that is true with regards to the editing as well as the writing and publishing. This was truly a team effort by John I. Ingle, J. Craig Baumgartner and me. We were in contact with each other, often daily, and I appreciate so many aspects of that interaction. John continues to teach me grammar and style, and Craig has a way of seeing through problems with humor and clarity. John and Craig, you have truly enriched my life.

Producing a textbook is more than writing – to reach you, the reader, it needs to be assembled, printed and distributed. My appreciation for making this possible goes to:

Brian Decker, who enthusiastically supported the notion of a textbook dedicated to the specialty of endodontics; Tricia Bindner, who served as production manager and who prodded when necessary and was always available for help and advice; and the support staff at BC Decker. Thank you all.

Looking back at the past several months of intense effort and the setting aside of other activities, it is clear to me that one person in my life made it possible, namely my wife Grete. Understanding when pressures mounted, re-assuring when doubts occurred, Grete unfailingly supported my efforts. Without her selfless partnership, my work could not have been completed on time. From my heart, thank you Grete.

Leif K. Bakland

I want to acknowledge and thank my dear wife Teddi, for her loving support of my academic endeavors. In addition, I especially want to thank John Ingle for the honor of being asked to participate in the editing of the 6th edition of *Ingle's Endodontics*. Also thanks to our co-editor, Leif Bakland, for his enthusiastic encouragement on virtually a daily basis during the long process of editing a text of this enormity. And finally a hearty thanks to all the contributors for their expertise and the tireless effort required to make this text the very best it can be.

J. Craig Baumgartner

THE DISCIPLINE OF ENDODONTICS

CHAPTER 1

MODERN ENDODONTIC THERAPY: PAST, PRESENT AND FUTURE

JOHN I. INGLE, HAROLD C. SLAVKIN

Because I'll have you know, Sancho, that a mouth without teeth is like a mill without its stone and you must value a tooth more than a diamond.

Miguel de Cervantes, Don Quixote

"Through shifting times there passed—those little bands of struggling beings who someday would be men. They survived through plasticity,—through a growing capacity to recognize, in changing times, that today is different than yesterday, and tomorrow from today. Many—most without doubt—were conservative creatures. These died by dry, unanticipated stream beds, or numbed and froze in unanticipated storms. Those, quite obviously, were not your ancestors. It was the others—the witty, sensitive, the flexible, the ones who could recognize a changing environment—these were the ones to assemble a new and most remarkable genetic package: Ourselves."

Robert Ardrey, The Territorial Imperative

Change

It was Benjamin Franklin (not Mark Twain) who said, "The only two certainties in life are death and taxes." Change has been the one constant of history. The challenge is not to avoid change, but to manage it. But change can be "for better or for worse."

Fortunately, or unfortunately, we have experienced both in endodontics. The disappointment in root canal filling materials such as silver points, numerous intracanal disinfectants, and several sealers is an example of the failures we have endured. The move from film to digital radiographs, more profound local anesthetics,

standardization of endodontic instruments, and new instrument alloys with novel geometric designs are only a few of the advances over the years. There are now many exciting developments to improve the quality and the output of our endeavors; some of them will be "winners" and some will be losers. Time and experimentation will determine which is which.

In Chapter 2, Dr. James Gutmann presents an historical chronicle of endodontics, so there is no need to repeat it here. But it might be interesting (as well as educational) to follow through on two early changes in endodontics that still affect us today—nomenclature and instrument design and standardization.

NOMENCLATURE

During World War II, Dr. Balint Orban was asked by the federal government to solve the problem of high altitude toothache being suffered by a number of Army Air Corps Pilots. This experience renewed his interest in pulp pathology. Dr. Orban, a famous physician, psychiatrist, dentist, periodontist, author and a superb histopathologist, was then asked to modernize endodontic nomenclature, which he did.¹

He first tackled the pulpal conditions and defined the various stages of pulpitis, wisely basing a classification on the symptoms of pulpalgia facing any dentist diagnosing painful toothache. He matched these symptoms with what he knew was happening pathologically in the pulp. They ranged from *reversible* incipient pulpalgia, through *irreversible* advanced pulpalgia with its excruciating pain, to the painless *necrosis* of the pulp. "Reversible" pulps can be saved, but most really painful pulps are inflamed and/or infected beyond redemption.

Before this time we spoke of “hyperemia of the pulp” with no proof that hyperemia occurred. It was not until 1965 that Beveridge and Brown² followed by Van Hassel³ demonstrated changes in intrapulpal pressures that were related to a number of clinical variables, including inflammation.

Orban also changed the nomenclature for *periapical* disease, basing it on his classification of *periodontitis* for periodontal disease. “Inflammation of the periodontium anywhere is periodontitis” he would say. “It’s **apical periodontitis** at the apex of the tooth – just as it is **marginal periodontitis** at the alveolar crest”.⁴ Before Orban, we spoke of pyorrhea and trench mouth or Vincent’s disease.

So changes in nomenclature, informed by critical observation, helped to form a background for an avalanche of research efforts that placed endodontics on a much more scientific footing.

INSTRUMENT DESIGN AND STANDARDIZATION

Until 1957, most endodontic instruments came in 6 sizes—1 through 6. There were *files* that were to be used in a push–pull rasping motion and **reamers** that were to be used in a rotary motion. There was no standardization within a size or between sizes, or among manufacturers. The design of most files and reamers was based on the original design developed by Kerr Co. in 1904, more than a half century before (Figure 1). Hence, the designation K files and K reamers. The only variation was the Swedish Hedström file shaped like a wood screw. And of course, there was also the ubiquitous broach that came in small, medium, and large sizes. Change was called for!

In 1957, a plea went out to the profession and the manufacturers to standardize endodontic instruments.⁵ It was answered by a Swiss company, and a study was undertaken to develop a standard that all manufacturers would adhere to and that would be accepted by the profession.

Figure 1 The original Kerr reamer, ca. 1904 (titled a broach at that time), is the origin of today’s K-style instruments. Reproduced with permission from Kerr Dental Manufacturing Co. 1904 catalog.

In 1958, a proposal was introduced to standardize the taper of instruments as well as the length. In addition, based on the metric system, a formula for a graduated increment in size from one instrument to the next was developed.^{6,7} The new numbering system allowed for numbers from 10 to 100 based on the tip diameter, #10 for a tip size of 0.1 mm to #100 for a tip size of 1.0 mm. The cutting blades were to extend up the shaft for 16 mm and the advance in taper was to be a gain of 0.3 mm, which figured out to be an increase of 0.01875 mm/mm (Figure 2). This figure soon became clumsy for manufacturing and was changed to 0.02 mm/mm. Hence these new standardized instruments came to be known as 0.02 instruments.

At first, most companies were unwilling to junk all their overage machines that produced instruments, while one Swiss company that backed the change began to capture the market. When the newly designed instruments were designated as the “International Standard” by the International Standards Organization, all the companies, worldwide, changed their manufacture to the new standard that remains the standard today.⁸

For a number of years there was not much movement in instrument design. And then it blossomed! Today there is a plethora of design changes as well as

Figure 2 Original recommendation for standardized instruments. The number of the instrument is determined by the diameter size at D1 in hundredths of millimeters. Diameter 2 (D2) is uniformly 0.32 mm greater than D1, a gain of 0.02 mm/1 mm of cutting blades.

size changes. The standard .02 taper instrument has now been joined by .04, .06, .08, even up to .12 mm/mm tapers. The original K style instruments have been joined by a colony of other designs; a few proved impractical and have disappeared from the market. Carbon steel gave way to stainless steel that is now being challenged by nickel/titanium, with probably more to come.

“Finger-powered” instruments, although they still have their place, are slowly being overtaken by electric-powered rotary instruments. According to an anonymous industry representative, in 1996 less than 1 million nickel–titanium (NiTi) rotary instruments were sold in the United States, compared to 20 million stainless steel instruments. In 8 years, by 2004, sales of NiTi rotary files had jumped from 1 million to 11.4 million, and by 2006 to 13.4 million. At the same time, 2004 and 2006, sales of stainless instruments reached a plateau of 23.5 and 24 million, respectively. With these two examples of **change** that has taken place in endodontics, it is obvious that there will be more in the future.

PRESENT STANDING OF ENDODONTICS

Speaking of change, what has been the impact on endodontics from the present rush toward implants? At a time when successful outcome in endodontics has vastly improved, when the stigma of painful root canal therapy is disappearing, when treatment time has been shortened, and when endodontic fees compare so favorably to implant and prosthetic fees, one wonders why this move toward implants. Conversations among endodontists often include comments about situations in which patients have been advised by general dentists or specialists, in for example, periodontics, that a tooth an endodontist might consider suitable for treatment should instead be replaced with an implant.

This has become a disturbing trend and the specialty of endodontics faces a challenge to educate both colleagues in dentistry and patients about the demonstrated benefits in maintaining the natural teeth. In Chapter 4, Dr. Mahmoud Torabinejad addresses this controversy that highlights the importance of involvement by the endodontic community. Such involvement also includes incorporating the area of implant dentistry into the scope of practice for endodontists. In Chapter 33, Drs. Jaime Lozada and Alejandro Kleinman describe the procedures involved in replacing a tooth that cannot be retained (e.g., due to a vertical root fracture); many endodontists are beginning to incorporate implant dentistry

in their practices. What then is the present standing of endodontics? With the profession? With the public? Let us look at some interesting facts.

DEFINITION OF ENDODONTICS

First, we had better define endodontics—what is endodontology or what encompasses the practice of endodontics? The best definition may be modified from the definition by the American Association of Endodontists.⁹

“Endodontics is that branch of dentistry that is concerned with the morphology, physiology and pathology of the human dental pulp and periradicular tissues. Its study and practice encompass the basic clinical sciences including biology of the normal pulp; the etiology, diagnosis, prevention and treatment of diseases and injuries of the pulp; and associated periradicular conditions.

The scope of endodontics includes, but is not limited to, the differential diagnosis and the treatment of oral pain of pulpal or periradicular origin; vital pulp therapy, such as pulp capping and pulpotomy; nonsurgical treatment of root canal systems with or without periradicular pathosis of pulpal origin and the obturation of these root canal systems; selective surgical removal of pathological tissues resulting from pulpal pathosis; repair procedures related to such surgical removal of pathological tissues; intentional replantation and replantation of avulsed teeth; surgical removal of tooth structure, such as root-end resection and root-end filling; hemisection, bicuspidization and root resection; endodontic implants; bleaching of discolored dentin and enamel; retreatment of teeth previously treated endodontically; and treatment procedures related to coronal restorations by means of post and/or cores involving the root canal space.

The endodontic specialist is responsible for the advancement of endodontic knowledge through research; the transmission of information concerning the most recent advances in biologically acceptable procedures and materials; and the education of the public as to the importance of endodontics in keeping the dentition in a physiologically functional state for the maintenance of oral and systemic health.”

To this one might add: the diagnosis of extraoral referred pain; the management of traumatic injuries to the teeth; the biopsy of pathological tissue, and the growing recognition of pathological conditions

between the maxillary posterior teeth and the maxillary sinus.

RECENT ATTITUDES TOWARD DENTISTRY AND ENDODONTIC THERAPY

Increasingly, the term “root canal” has become fashionable and generally known. In conversation, people proudly proclaim that they have had a “root canal.” The stigmata of fear and pain are fast disappearing.

Another impressive factor in the acceptance of endodontics is television. Countless advertisements emphasize a beautiful smile—not just toothpaste advertisements, but commercials in every field, from Buicks to beer. At the same time, the constant barrage of denture adhesives and cleanser advertisements produces a chilling effect. The public sees the problems that develop from the loss of teeth. Obvious missing teeth are anathema.

There is no question that the public’s acceptance of endodontic treatment is on the rise. In 1969, for example, the American Dental Association (ADA) estimated that 6 million teeth were treated endodontically each year. By 1990, the ADA reported 20,754,000 endodontic procedures, or 2.1% of all dental procedures. By 1999, they reported that total endodontic activity had increased to 21,932,800 procedures, but now accounted for only 1.7% of the total dental procedures that numbered 1 billion 250,000 procedures.^{10,11}

This upward trend was also documented by the Public Affairs Committee of the AAE. Reporting on the surveys of the general public made by the Opinion Research Institute in 1984 and 1986, the Committee noted that 28% of 1,000 telephone respondents reported that they had had root canal therapy by 1986, an increase of 5% points over the 23% reported in 1984.¹² Also, in 1986, 62% said that they would choose root canal therapy over extraction, an increase of 10% points over the 52% in 1984. More than half the respondents (53%) believed that an endodontically treated tooth would last a lifetime.¹²

Twenty years later, in 2006, the AAE was reporting similar positive figures.¹³ On the other hand, 63% of the respondents described root canal therapy as “painful.” It turned out, however, that the respondents who had had root canal therapy were 6 times more likely to describe the procedure as “painless” than the cohort who had never had root canal treatment.¹³ In other words, patients have been shown to anticipate more pain than they will actually experience during endodontic treatment.¹⁴ Clearly, the profession has a mission to continue educating the public

to reverse its image of endodontics and promote the value of an endodontically treated tooth.

The rate of the use of endodontic services similar to the rate in the United States (28%) was reported from Norway also, where 27% of an older age group (66–75 years) had had root canal therapy, as had 12% of a younger age group (26–35 years). Incidentally, 100% of the root-filled teeth in the younger group were still present 10–17 years later, a remarkable achievement.¹⁵

The growth in endodontic services is also reflected in the sales of endodontic equipments, supplies, and instruments. In 1984, according to an anonymous industry representative, endodontics was a \$20 million market, growing at a rate of 4% per year.¹⁶ By 1997, 13 years later, the endodontic market, through dental dealer retail stores alone, was \$72 million, up from \$65.6 million in 1996, a growth of nearly 10%. One must add to these sales another 10% to account for mail order/telephone sales, a grand total of nearly \$80 million in 1997. Worldwide sales were probably double this figure!¹⁷ In the year 2005, it was revealed that total endodontic sales exceeded \$200 million in the USA alone and \$400 million worldwide.

Future of Endodontics as a Speciality

Every 4 years the American Dental Association Survey Center publishes a review of all aspects of dentistry including a report entitled “The Economics of Endodontics”. In this report, the Survey Center covers endodontic services and utilization, growth of the specialty, location of endodontists, characteristics of endodontists, finances, referrals, and “A Look at the Future.” The latest report was published in 2003 covering the years through 1999 with a few references in the years 2000 and 2001.¹⁰ Portions of the report were published in the *Journal of Endodontics* in 2006.¹¹

The report paints a rather pleasant picture of the present but voices some concerns about the distant future. Some concerns had not developed by 1999, such as the impact implants would have on the practice of endodontics. The report also predicted that the population of the United States would not reach 300 million until 2010 when in reality this figure was reached in October of 2006. On the whole, however, their concerns for the future bear review and attention.

One changing relationship arising is between the specialty and general practitioners. For instance, the ratio between general dentists and endodontists is dropping; in 1982, there were 50.3 possible referring general dentists to each endodontist. But by 2002, the

Figure 3 Ratio of general practitioners to endodontists, 1982–2002. Source: American Dental Association Survey Center, 1982–2002 Distribution of dentists in the United States by region and state.

ratio was down to 34.5 and falling (Figure 3). Although general dentists perform about 75% of all endodontic procedures, they still refer 25% to endodontists; whether this will change is open to speculation.

The number of endodontists has grown at a faster rate than any other dental specialty. Between 1982 and 2002 “the number of professionally active endodontists had increased by 85%.” In contrast, “[g]eneral practitioners grew at a rate of 33% from 1982 to 2002.”^{10,11} In 1989, there were 2,500 endodontic specialists in the United States.¹⁸ By the year 2003, the number had risen to 4258 practicing endodontists.¹⁹ Between 1982 and 2003, the number of endodontists grew 107.9%, faster than any other specialty, well exceeding the rate of the growth of general practi-

tioners (38.4%).²⁰ By November of 2006, according to the AAE, the specialty had grown to 4,859 endodontist members (personal communication, AAE).

There is no question that the greatest share of endodontic procedures is carried out by America’s general practitioners (Table 1). On the other hand, the specialty of endodontics is growing as well. For example, only 5% of those patients who had had root canal therapy in 1986 were treated by a specialist.¹² By 1999, however, endodontists were providing 4.4 million procedures, which was 20.3% of the 21.9 million total endodontic procedures provided by all dentists, endodontists included (see Table 1).¹⁰

In 1999, there were over 1 billion dental services rendered. Only 1.7% of these procedures were endodontic. It is interesting to note, however, that while

Table 1 Distribution of Endodontic Procedures by Specialty, 1990 and 1999

Type of Dentist	1990		1999	
General practitioners	15,758,100	76.1%	16,493,200	75.2%
Endodontists	3,860,700	18.6%	4,459,900	20.3%
Pediatric dentists	942,200	4.5%	721,300	3.3%
Oral and maxillofacial surgeons	108,800	0.5%	188,900	0.9%
Orthodontic and dentofacial	0	0.0%	0	0.0%
Orthopedists				
Periodontists	31,800	0.2%	50,700	0.2%
Prosthodontists	25,400	0.1%	18,800	0.1%
Total	20,754,000	100.0%	21,932,800	100.0%

Source: American Dental Association Survey Center, 1990 and 1999 Surveys of Dental Services Rendered.

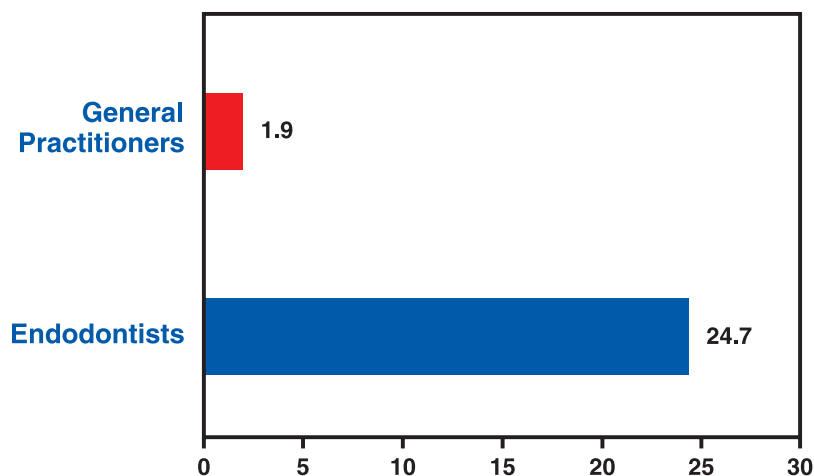

Figure 4 Total root canal treatments per week per dentist, 1999. Source: American Dental Association Survey Center. 1999 Survey of Dental Services Rendered.

<2% of the total services were endodontic, 15% of the total dental expenditures in 1999 went for endodontic treatment at a cost of 8.2 billion dollars.¹⁰

On a *per capita* basis, 6% of the total population received endodontic services in 1999. On the other hand, 9% of all dental patients received some form of endodontic treatment. In this same vein, general practitioners performed 16.5 million root canal procedures in 1999 compared to 4.5 million by endodontic specialists (see Table 1). However, endodontists performed 24.7 procedures a week compared to only 1.9 by gen-

eral practitioners (Figure 4). The average number of endodontic procedures in 1999 by a general practitioner (94.6) versus each endodontic specialist (1263.3) is striking (Figure 5).¹⁰

It is interesting to note the differences in the type of procedures performed by specialists versus general dentists. Endodontists performed 61.9% of the molar root canal treatments and general practitioners did 29.6% of the molars—less than half. The remainder was probably done by oral surgeons. By the same token, general dentists did 20.1% of the anterior root canal procedures

Figure 5 Root canal treatments per dentist, 1999. Source: American Dental Association, Survey Center. 1999 Survey of Dental Services Rendered.

Table 2 Endodontic Procedures Completed by General Practitioners and Endodontists, 1999

and 9.8% of the pulp cappings, whereas the specialists treated only half as many anterior teeth and performed only 0.4% of the pulp cappings (Table 2).^{10,11} Molar endodontics fairly well defines the difference in endodontic treatment performed between general dentists and endodontists.

Another consideration by the ADA survey group concerned amalgam versus resin restorations being placed, particularly in the posterior teeth. They pointed

out the age old record of amalgams protecting the pulp over long periods of time. In the year 2000, the jury was still out on the life span of posterior resins, so they were speculating on how failing resins in the future would impact the amount of endodontics to be done. They pointed out that amalgam restorations had declined from 100 million to 80 million between 1990 and 1999, a 20% decline, whereas resin restorations increased from 47.7 million in 1990 to 85.8 million in 1999, an 80% increase (Figure 6).¹⁰

Failing resins impacting an increase in endodontics may not be predictable at this time, whereas the age of patients in the future is predictable. Most root canal treatment is performed for patients between the ages of 25 and 64, particularly molar endodontics, done mostly by endodontists (Figure 7). Unfortunately, projected future change in the US population shows a severe drop off in the very age groups most prone to endodontic therapy (Figure 8). So this population shift may reduce the number of patients seeking endodontic services; at the same time the number of referring general dentists is decreasing.^{10,11} It is possible that the aging population (<64) will provide an increasing pool of patients needing endodontic services.

The present good news is that in the years 1997–1998, endodontists enjoyed an average net income of \$230,000, second only to oral surgeons, a surprising figure considering average gross

endodontist billings of \$491,550 (Figure 9). Only general practitioners and pediatric dentists reported lower billings. The reason is endodontic office expenses were exceptionally low—\$237,320, lowest of all dentists. The average endodontic office

employs only 5.6 nondentist staff (Figure 10).¹⁰ But remember, these figures, even though they are the latest available, are nearly 10 years old.

In spite of many encouraging figures for the present practice of endodontics, the future may not be as

Figure 10 Average Practice Expenses per Owner, 1992 and 1997/1998. Source: American Dental Association Survey Center. 1993 Survey of Dental Practice Specialists in Private Practice and 1998/1999 Survey of Dental Practice.

“rosy.” For example, the rate of dental caries is declining precipitously, and to a great extent, pulpal disease, leading to endodontic treatment, is driven by the index of dental caries.

Early in the 1970s, only 28% of the permanent teeth of American children were caries-free. Then, in 1988, the National Institute of Dental and Craniofacial Research (NIDCR) proudly announced that half of all children in the United States aged 5–17 years had no decay in their permanent teeth. None!²¹ Then again, between 1999 and 2002 the National Health and Nutrition Examination Survey (NHANES) reported that 62% of children and adolescents aged 6–19 years were caries-free in their permanent teeth.²² And as reported in the NHANES between 1974 and 1994, the number of decayed-missing-filled (DMF) permanent teeth in the children, not caries-free (aged 6–18) decreased from 4.44 to 1.90 (57.2%). The number of DMF permanent surfaces also decreased, from 8.64 to 3.56 (58.8%) during this period.²³ In the year 2003, however, tooth decay was rising, reported as 78% of adolescents, perhaps indicating an emerging problem for older children consuming “junk food” and sugary drinks.²⁴

As far as older adults are concerned, the NIDCR reported a remarkable decline in edentulism as well, particularly in the middle-aged, a group in which “total tooth loss has been practically eliminated.”²⁵ Indeed, during the 1999–2002 survey, adults older than 20 years retained an average of 24 of 28 natural teeth, and only 8% were edentulous.²² The elderly (age 65 and older), however, “are still in serious trouble,” root caries and periodontal disease being the primary offenders.²⁵ A recent study of 398 elderly women showed 36.4% were edentulous and 80.7% of the dentate women had periodontal disease.²⁶ It is likely that endodontists will share a greater part of the burden, carrying for our aging population. In addition, as the growing immigrant population in the United States becomes more affluent, it will increasingly seek care.

All of these encouraging figures suggest greater preventive measures and higher use of dental services by the public. Part of the improvement can be credited to a healthier economy and lifestyle, part to the national water supply and dentifrice fluoridation programs, part to the dental profession’s efforts, and part to dental insurance. A research has shown that third-party payment has increased the dental use and has improved oral health.^{27–29} By 1995, the ADA estimated that 63% of all US citizens were covered by a private insurance program and another 5.3% by public assistance. The remaining 31.4% were not covered by any insurance program.³⁰

Regardless, costs are high: in 2003, 43.1% of dental expenditures were paid by private insurance and 48.2%

were paid out of pocket. Government programs such as Medicaid and Medicare paid the remaining 8.2%.³⁰ However, for endodontics in particular, approximately 70% of patients were covered by a private insurance program.³¹

In providing these burgeoning services, the dental profession has fared well financially. From 1986 to 1995, the net income of dentists increased by 30.7%.³² In 2003, the ADA reported that dentists annually averaged \$177,340 net, a 31% increase from 1986 (when adjusted for 2003 dollars).³³

Dental expenditures by the public have also increased, from \$3.4 billion in 1967 to \$10 billion in 1977, to \$25.3 billion in 1987, to \$47.5 billion in 1996, and to \$67 billion in 2003.³⁰ The expenditure for dental services has increased by 509% from 1975 to 2005.³⁴ After all this expenditure and care, one is hard-pressed to explain why 15.1 million workdays are lost annually because of dental pain.³⁵

ENDODONTICS CASE PRESENTATION

All of these improvements notwithstanding, many patients still must be convinced that root canal therapy is an intelligent, practical solution to an age-old problem—the loss of teeth. The “case for endodontic treatment” must be presented to the patient in a straightforward manner. The patient with the correct “oral image” will be anxious to proceed with therapy.

“Is this tooth worth saving, doctor?” This sentiment is voiced more often than not by the patient who has been informed that his or her tooth will require endodontic therapy. Superficially, this appears to be a simple question that requires a direct, uncomplicated answer. It should not be interpreted as a hostile or as a challenge to the treatment recommendations presented for the retention of the tooth. Psychologically, however, this initial question is a prelude to a Pandora’s box of additional queries that disclose doubts, fears, apprehensions, and economic considerations: for example, “Is it painful?” “Will this tooth have to be extracted later?” “How long will this tooth last?” “Is it a dead tooth?” “Will it turn black?” and “How much will it cost?”

Following the first question, the dentist should anticipate such a series of questions. These may be avoided, however, by including the answers to anticipated questions in the presentation. In turn, the dentist will gain a decided psychological advantage. By this apparent insight into his or her problems, the patient is assured that the dentist is cognizant of the very questions the patient was about to raise or possibly was too reticent to ask.

Most of the patient's fear and doubts can be allayed by giving a concise answer to each question.

In today's world, the patient may have been offered the choice between saving the tooth by root canal treatment and extracting the tooth and replacing it with an implant. Unless the tooth is hopeless, the dedicated dentist, one who believes in root canal therapy, should be able to make a positive case for retaining the tooth.

To answer patients' questions, the ADA has produced two inexpensive pamphlets entitled: *Root Canal Treatment—Following up on your dentist's recommendations* and *Understanding Root Canal Treatment*^{*}. The AAE also publishes a number of pamphlets for patients: the *Your Guide To* series: *Endodontic Treatment*, *Dental Symptoms*, *Cracked Teeth*, *Endodontic Retreatment*, *Endodontic Surgery*, *Endodontic Post-Treatment Care*, and *Dental Symptoms*[†]. Although this approach is somewhat impersonal, it is a tangible reference, particularly when the patient returns home and tries to explain to an interested spouse what endodontic therapy involves.

Based on previous experiences in the office, the average patient has sufficient confidence in the dentist's ability to help. The patient is ready to accept the professional knowledge and advice offered but likes to have some part in evaluating the reasonableness of treatment. The professional person and the staff must spend time and thought necessary to understand the patient's initial resistance, which is sometimes based on false assumptions and beliefs in matters dealing with pulpless teeth. However, once the patient is secure in the thought that this is the correct treatment, most of the fears and apprehensions related to unfamiliarity with endodontic therapy will be dissipated.

A dental appointment is still associated with fear in the minds of many people (Figure 11).^{36–38} The mere thought of treating the “nerve” of a tooth implies pain. Patients require reassurance, supported by all available psychological and therapeutic methods of relaxation and pain control. The patient must be reassured that endodontic therapy need not be painful and usually requires no more than a local anesthetic.

All too often we hear negative remarks about root canal therapy: “Trying to do anything positive in Tacoma is akin to getting a *root canal* without Novocain.” Or, “Whew! What you just heard was a collective

Figure 11 Rash (possibly hives) occurred in this terrified patient who was merely sitting in the dental chair prior to root canal treatment. The patient's apprehension was allayed by sympathetic management, allowing successful completion in a four canal molar. Courtesy of Dr. Norbert Hertl.

sigh of relief following 7 months of agonizing root canal”—remarks made following President Clinton's “confession” on television. In contrast to these commonly heard excoriations, LeClaire et al.³⁸ reported that 43.9% of endodontic patients reported a decrease in fearfulness after having root canal therapy. Furthermore, 96.3% said that “they would have root canal therapy again to save a tooth”. It should be explained to the concerned patient that root canal therapy is a specialized form of dental procedure designed to retain a tooth safely and comfortably. The tooth, when properly treated and restored, can be retained as long as any other tooth. It is not a “dead tooth” as long as the roots of the tooth are embedded in healthy surrounding tissues. Although teeth do not turn “black” following root canal therapy, a slight change in color owing to reduced translucency may occur. Discoloration associated with pulp necrosis and leakage around restorations can be managed successfully (see Chapter 38). Most often, retention of the tooth and bleaching, veneering, or crowning (Figure 12) are preferable to extraction and/or an implant and replacement with a prosthetic appliance.¹²

There is a little doubt that economic considerations play an important role (and for some a supreme role) in the final decision. Some patients “think financially,” and even though they are able to afford treatment, they allow financial considerations to govern decisions that should logically be made on a physiological basis only. It is necessary to point out to these people the financial advantage of retaining a tooth by endodontic therapy rather than by extraction and prosthetic or implant replacement. In addition, it

should be mentioned in all honesty that any vital tooth prepared for a bridge abutment might eventually become a possible candidate for future endodontic therapy.

Also, the patient who says “Pull it out” should be informed of the problems that will arise if a space is left unfilled, that is, tilting, reduced masticatory efficiency, future periodontal problems, root caries, and cosmetic effects. Another commonly heard statement by the patient is, “It’s only a back tooth, anyway,” or “If it were a front tooth I would save it, but no one sees it in back.” This patient thinks cosmetically. The disadvantages of the loss of any tooth, let alone a posterior one, so essential for mastication, must be explained.

Fortunately, today’s patient is becoming more sophisticated, too “tooth conscious” to permit indiscriminate extraction without asking whether there is an alternative. Extraction contributes to a crippling aberration from the normal dentition. There is no doubt that a normally functioning, endodontically treated, and well-restored natural tooth is vastly superior to the best prosthetic or implant replacement.

INDICATIONS

The indications for endodontic therapy are legion. Every tooth, from central incisor to third molar, is a potential candidate for treatment. Far too often the expedient measure of extracting a pulpless tooth is a short-sighted attempt at solving a dental problem. Endodontic therapy, on the other hand, extends to the dentist and the patient the opportunity to save teeth.

The concept of retaining every possible tooth, and even the healthy roots of periodontally involved teeth, is based on the even distribution of the forces of mastication. The final success of any extensive restorative procedure depends on the root surface area attached through the periodontal ligaments to the alveolar bone. Like the proverbial “horseshoe nail,” root-filled teeth may often be the salvation of an otherwise hopeless case.

To carry this concept one step further, the importance of retaining even endodontically treated *roots*, over which a full denture may be constructed, the so-called *overdenture*, is recognized.³⁹ On some occasions, attachments may be added to these roots to provide additional retention for the denture above (Figure 13). At other times, the treated roots are

Figure 13 Four locator overdenture attachments (Zest anchors) ensure adequate retention for mandibular full denture. Courtesy of Dr. A.L. Schneider.

Figure 14 Dramatic demonstration of alveolar bone remaining around retained canines, but badly resorbed under maxillary full and mandibular partial dentures. Courtesy of Drs. J.L. Lord and S.Teel.

merely left in place on the assumption that the alveolar process will be retained around roots, and there will not be the usual ridge resorption so commonly seen under full or even partial dentures (Figure 14).

Modern dentistry incorporates endodontics as an integral part of restorative and prosthetic treatment. Any tooth with pulpal involvement, provided that it has adequate periodontal support, can be a candidate for root canal treatment. Even severely broken-down teeth and potential and actual abutment teeth can be candidates for the tooth-saving procedures of endodontics, provided all options with benefits and disadvantages are explained to the patient.

One of the greatest services rendered by the profession is the retention of the first permanent molar (Figure 15). In contrast, the long-range consequences

Figure 15 **A**, Pulpless first molar following failure of pulpotomy. Note two periapical lesions and complete loss of intraradicular bone. Draining sinus track opposite furcation is also present. **B**, Completion of endodontic treatment without surgery. **C**, Two-year recall radiograph. Total healing was complete in 6 months. New carious lesions now involve each interproximal surface.

Figure 16 Extrusion, recession (arrow), tipping, malocclusion, rotation, and gingival cemental caries are only a few of the long-range consequences following early extraction of a permanent first molar.

of breaking the continuity of either arch are also well known (Figure 16). Root canal therapy often provides the only opportunity for saving first molars with pulp involvement.

In addition to saving molars for children, saving posterior teeth for adults is also highly desirable. Retaining a root-filled terminal molar, for example, means saving two teeth—the molar's opposite tooth as well (Figure 17A). Moreover, root canal treatment may save an abutment tooth of an existing fixed prosthesis. The gain is doubled if the salvaged abutment is also the terminal posterior tooth in the arch and has a viable opponent (see Figure 17B).

Another candidate for endodontic therapy is the adolescent who arrives in the office with a grossly

Figure 17 A, Terminal molar retained by endodontic treatment saves opposing molar as well. Courtesy of Dr. L. Stephen Buchanan. **B**, Fixed partial denture possible only because abutment teeth are saved by root canal treatment. Courtesy of Dr. Norbert Hertl.

damaged dentition and is faced with multiple extractions and dentures (Figure 18). Many of these children are mortified by their appearance. It is gratifying to see the blossoming personality when an esthetic improvement has been achieved. The end result in these cases would not be possible without root canal therapy (Figure 19).

A growing area in which endodontics plays an important role is dental trauma (see Chapter 36). Advances have been made in the understanding of dental trauma, and endodontics as a discipline has played an important role in developing treatment approaches. This is understandable considering the importance that the pulp plays in traumatic dental injuries.

Figure 19 A, Obvious pulp involvement of incisors shown in Figure 18. **B**, Root canal treatment of these incisors makes possible post restoration followed by cosmetic provisional crowns.

CONSIDERATIONS PRIOR TO ENDODONTIC THERAPY

Although it is true that root canal treatment can be performed on virtually any tooth in the mouth, there are some important considerations that must be evaluated prior to recommending root canal treatment. Some of these were delineated by Dr. Ed Beveridge (personal communication, June 1971):

1. Is the tooth needed or important? Does it have an opponent? Could it some day serve as an abutment for prosthesis?
2. Is the tooth salvageable, or is it so badly damaged it cannot be restored?
3. Is the entire dentition so completely broken down it would be virtually impossible to restore?
4. Is the tooth serving esthetically, or would the patient be better served by its extraction and a more cosmetic replacement?
5. Is the tooth so severely involved periodontally that it would be lost soon for this reason?
6. Is the practitioner capable of performing the needed endodontic procedures?

Endodontists wish that patients are referred to them before procedural mishaps, such as root perforations, occur; if a mishap does occur during treatment by a general dentist, the patient is entitled to be given the option of care by a specialist.

AGE AND HEALTH AS CONSIDERATIONS

Age need not be a determinant in endodontic therapy. Simple and complex dental procedures are routinely performed on deciduous teeth in young children and on permanent teeth in patients well into their nineties. The same holds true for endodontic procedures. It should be noted, however, that complete removal of the pulp in young immature teeth should be avoided if possible. The procedures for pulp preservation are more desirable and are fully discussed in Chapter 34.

Health consideration must be evaluated for endodontics as it would for any other dental procedures. Most often, root canal therapy will be preferable to extraction. In severe cases of heart disease, diabetes, or radiation necrosis, root canal treatment is far less traumatic than extraction, for example.⁴⁰ Even in patients with terminal cancer, leukemia, or AIDS, endodontics is often preferred over extraction. Pregnancy, particularly in the second trimester, is usually a safe time for treatment. In all of these situations, however, endodontic surgery is likely to be as traumatic as extraction.

STATUS OF THE ORAL CONDITION

Pulpally involved teeth may simultaneously have periodontal lesions and be associated with other dental problems such as rampant decay, orthodontic misalignment, root resorption, and/or a history of

traumatic injuries. Often the treatment of such teeth requires a team effort of dental specialists along with the patient's general dentist.

The presence of *periodontal lesions* must be evaluated with respect to the correct diagnosis: Is the lesion of periodontal or endodontic origin, or is it

a combined situation? The answer to this question will determine the treatment approach and the outcome; generally, lesions of endodontic origin will respond satisfactorily to endodontic treatment alone (Figure 20), whereas those of periodontal origin will not be affected simply by endodontic

Figure 20 **A**, Mandibular molar with furcal bone loss (arrow) from endodontic infection and not from periodontal disease. **B**, Root canal treatment completed with no periodontal intervention. **C**, One-year control shows recovery of furcal lesion by endodontic treatment alone.

procedures (Figure 21).⁴¹ Combined lesions—those that develop as a result of both pulpal infection and periodontal disease—respond to a combined treat-

ment approach in which endodontic intervention precedes, or is done simultaneously with, periodontal treatment (Figure 22).⁴² Even teeth with apparently

hopeless root support can be saved by endodontic treatment and root amputation (Figure 23).

Today many teeth with necrotic pulps, once condemned to extraction, are saved by root

canal therapy, as are teeth with large periapical lesions or apical cysts (Figure 24),⁴³⁻⁴⁷ teeth with perforations or internal or cervical resorption (Figure 25). Teeth badly fractured by trauma

Figure 26 Maxillary incisors fractured into the pulp and also cariously involved. Endodontics can play an important role in the management of such situations.

(Figure 26), and pulpally involved teeth with tortuous or apparently obstructed canals or instruments separated within, teeth with flaring open

apices (Figure 27), teeth that are hopelessly discolored (Figure 28), and traumatically injured teeth.

Most of these complicated dental situations can be managed, often by a team approach involving various specialists along with the patient's general dentist. In all instances, the anticipated outcome must be discussed with the patient who should decide which treatment option to choose.

Controversies in Endodontics

There have been a number of controversies in endodontics, some solved, some abandoned, some remaining. Dr. Mahmoud Torabinejad will address some in Chapter 4. One controversy that comes to mind is the theory of focal infection and selective localization. This is also covered in Chapter 7. Another is the problem of flare-ups that will be thoroughly discussed in Chapter 21.

There are two controversies, however, that deserve our present and continued attention. The first deals with the efficacy of single-appointment therapy, and the second is the determination of where the apical terminus of the root canal should be, both for cleaning and shaping and for obturating the canal. A good deal of research and cognition has been expended in their behalf, but no universal agreements have been reached.

SINGLE-APPOINTMENT THERAPY

Single-appointment root canal therapy has become a common practice. When questioned, however, most general dentists reply that they reserve one-appointment treatment for vital pulp cases and immediate periapical surgery cases. In 1982, only 12.8% of dentists queried thought that necrotic teeth would be successfully treated

Figure 27 **A**, Flaring apex of incompletely formed root follows pulpal death caused by impact trauma at an early age. **B**, Obturation of “blunderbuss” canal is accomplished by retrofilling from a surgical approach. Historically, this was a common procedure. Today, such teeth are managed more conservatively without surgery. Ingle JI. Dental Digest 1956;62:410.

Figure 28 “Before” **A** and “after” **B**, photos demonstrating results of one internal bleaching treatment with Superoxol. The patient, a young medical student, recognized that the discolored tooth was off-putting and was overjoyed with the result. This is also an historical illustration; today, bleaching agents such as Superoxol are not used due to the risk of cervical resorption.

in one appointment.⁴⁸ On the other hand, endodontists have been treating patients in one-appointment visits for some time. At one time, 86% of the directors of postgraduate endodontic programs, when surveyed, reported that nonsurgical one-visit treatment was part of their program.⁴⁹ Today it is universal.

What are the advantages and disadvantages of single-visit endodontics?

Advantages:

1. Immediate familiarity with the internal anatomy, canal shape, and contour facilitates obturation

2. No risk of bacterial leakage beyond a temporary coronal seal between appointments
3. Reduction of clinic time
4. Patient convenience—no additional appointment or travel
5. Low cost

Perceived Disadvantages:

1. No easy access to the apical canal if there is a flare-up
2. Clinician fatigue with extended one-appointment operating time
3. Patient fatigue and discomfort with extended operating time
4. No opportunity to place an intracanal disinfectant (other than allowing NaOCl to disinfect during treatment)

What has held back one-appointment endodontics? The major consideration has been the concern about postoperative pain and failure.

POSTOPERATIVE PAIN

The fear that patients will probably develop postoperative pain and that the canal has been irretrievably sealed has probably been the greatest deterrent to single-visit therapy. Yet the literature shows no real difference in pain experienced by patients treated with multiple appointments.^{48–65} In spite of this evidence, 40% of the endodontic course directors surveyed were of the opinion that necrotic cases treated in one visit have more flare-ups.⁴⁸ The University of Iowa group,⁵⁰ however, found this not to be true—3.2 flare-ups for two-appointment cases versus 2.6 for one-treatment cases. Nor did Galberry find this to be true in Louisiana,⁵⁷ nor did Nakamuta and Nagasawa⁵⁸ in Japan, who had only 7.5% pain incidence after treating 106 infected cases in single appointments. More to the point, the symptoms experienced by the Japanese patients were not flare-ups, but mild pain, and needed no drugs or emergency treatment.

Oliet⁵⁶ reported that only 3% of his cohort of 264 patients receiving single-appointment treatment had severe pain, compared with 2.4% of the 123 patients treated in two visits. Wolch's⁵² records of over 2,000 cases treated at a single appointment showed that <1% of patients indicated any severe reaction. Pekruhn⁵⁵ reported no statistically significant difference between his two groups. Mulhern et al.⁵⁹ reported no significant difference in the incidence of pain between 30 single-rooted teeth with necrotic pulps treated in one appointment and 30 similar teeth treated in three appointments. At the University of Oklahoma, how-

ever, Roane et al.⁶⁰ found a “two to one higher frequency of pain following multiple visit treatment when compared to those completed in one visit.” More recent reports from Brazil,⁶¹ and Fava^{62–64}, from the Netherlands found no difference in the incidence of pain between one- and two-visit cases, and Trope⁶⁵ reported no flare-ups in one-appointment cases with no apical lesions.

However, retreatment of failed cases with apical periodontitis made the difference. These cases suffered a 13.6% flare-up rate.⁶⁵ One might expect pain from any case, as reported by Harrison et al.⁶⁶ Of 229 patients treated twice, 55.5% had no interappointment pain, 28.8% had slight pain, and 15.7% had moderate to severe pain. Eleazer and Eleazer⁶⁷ compared the flare-up rate between one and two appointments in treating necrotic canal molars. In the two-visit cohort, there was a 16% flare-up rate, whereas in the one-visit group, there was only a 3% flare-up experience, which proved to be significant. Ørstavik et al.⁶⁸ also reported fewer flare-ups following single-appointment therapy. And even more recently, 2006, Al-Negrish and Hababbeh⁶⁹ reported from Jordan on 112 cases of asymptomatic, necrotic pulp central incisors, half treated in one appointment and half treated in two appointments. “. . . more flare-ups occurred in the two appointment group 13.8% than in the single visit group 9.2%. Flare-ups occurred after 2 days and after 7 days, 5.2% and 1.8% respectively.” They further stated, “This should draw the attention of dentists not to over-react to early postobturation symptoms by immediately initiating root canal retreatment or extracting the involved tooth.” In light of these studies, neither pain nor flare-ups appear to be valid reasons to avoid single-appointment root canal therapy.

SUCCESS VERSUS FAILURE

If pain is not a deterrent, how about fear of failure? Pekruhn⁷⁰ has published a definitive evaluation of single-visit endodontics. From the clinics of the Arabian–American Oil Company, he reported a 1-year recall of 925 root-filled teeth of 1,140 possible cases. His failure rate was 5.2%, very comparable to many multiple-visit studies. Pekruhn was surprised to learn that his rate of failure was higher (15.3%) in teeth with periradicular lesions that had had no prior access opening. If this type of case had been previously opened, the incidence of failure would drop to 6.5%. The highest failure rate (16.6%) was in endodontic retreatment cases. Symptomatic cases were twice as likely to fail as were asymptomatic cases (10.6% versus 5.0%).

A Japanese study followed *one-visit cases* for as long as 40 months and reported an 86% success rate.⁵⁸ Oliet⁵⁶ again found no statistical significance between his two groups. The majority of the postgraduate directors of endodontics also felt that the chance of successful healing was equal for either type of therapy.⁴⁹ The original investigators in this field, Fox et al.,⁵¹ Wolch,⁵² Soltanoff,⁵³ and Ether et al.,⁵⁴ were convinced that single-visit root canal therapy could be just as successful as multiple-visit therapy. None, however, treated the acutely infected or abscess case in a single visit.

In marked contrast to these positive reports, Sjögren and his associates in Sweden sounded a word of caution.⁷¹ At a *single appointment*, they cleaned and obturated 55 single-rooted teeth with apical periodontitis. All of the teeth were initially infected. After cleaning and irrigating with sodium hypochlorite and just before obturation, they cultured the canals. Using advanced *anaerobic* bacteriologic techniques, they found that 22 (40%) of the 55 canals tested positive and the other 33 (60%) tested negative. Periapical healing was then followed for 5 years. Complete periapical healing occurred in 94% of the 33 cases that yielded *negative* cultures! But in those 22 cases in which the canals tested positive prior to root canal filling, “the success rate of healing had *fallen to just 68%*,” a statistically significant difference.⁷¹ In other words, if a canal is still infected at the time of filling at a single dental appointment, there may be a 26% greater chance of failure than if the canal is disinfected. Their conclusions emphasized the importance of eliminating bacteria from the canal system before obturation, and this objective could not be achieved reliably without an effective intracanal medicament. This is one limited study, but it was done carefully and provided the evidence correlating the presence of bacteria to longer-term outcomes.

Ørstavik colleagues⁷² faced up to this problem and studied 23 teeth with apical periodontitis, all but one infected initially. At the end of each sitting, apical dentin samples were cultured anaerobically. No chemical irrigants were used during cleaning and shaping, and at the end of the first appointment, 14 of the 23 canals were still infected. At an earlier time, Ingle and Zeldow,^{73,74} using aerobic culturing, found much the same. Ørstavik et al.⁷² then sealed calcium hydroxide in the canal. In 1 week, at the start of the second appointment, only one root canal had sufficient numbers of bacteria “for quantification”—the calcium hydroxide was that effective! They also found “a tendency for teeth causing symptoms to harbor more bacteria than symptomless teeth.”

In a follow-up study, Trope et al.⁷⁵ treated teeth with apical periodontitis, with and without calcium hydroxide, in one or two visits. They reached a number of conclusions that are as follows:

1. “[C]alcium hydroxide disinfection after chemomechanical cleaning will result in negative cultures in most cases.”
2. “[I]nstrumentation and irrigation alone decrease the number of bacteria in the canal 1000-fold; however the canals cannot be rendered free of bacteria by this method alone.”
3. “[T]he additional disinfecting action of calcium hydroxide before obturation resulted in a 10% increase in healing rates. This difference should be considered clinically important.”

In another 52-week comparative study in North Carolina of the “periapical healing of infected roots [in dogs] obturated in one step or with prior calcium hydroxide disinfection,” the researchers concluded that “Ca(OH)₂ disinfection before obturation of infected root canals results in significantly less periapical inflammation than obturation alone.”⁷⁶

One has to ask, therefore, wouldn’t it be better to extend one more appointment, properly medicate the canal between appointments, and improve the patient’s chances by filling a bacteria-free canal? Unfortunately, there is a widely held but anecdotal opinion that current chemomechanical cleaning techniques are superior, predictably removing the entire bacterial flora. If this is so, single-visit treatment of necrotic pulp cases would definitely be indicated. However, research has yet to be published to corroborate these opinions. Until then, it may be more prudent to use an intracanal medicament such as calcium hydroxide or povidone iodine within a multiple-visit regimen, for cases in which a mature bacterial flora is present within the canal system prior to treatment.

Although single appointments would be very appropriate in *cases with vital pulps*, on the other hand, for symptomatic teeth with necrotic pulps and apical periodontitis and for failed cases requiring retreatment, there may be a risk of lower success rates in the long term. To date, the evidence for recommending either one- or multiple-visit endodontics is not consistent. The prudent practitioner needs to make decisions carefully as new evidence becomes available.

Wolch⁵² said it best: “In the treatment of any disease, a cure can only be affected if the cause is removed. Since endodontic diseases originate from an infected or affected pulp, it is axiomatic that the

root canal must be thoroughly and carefully debrided and obturated” (personal communication, 1983).

DETERMINATION OF THE APICAL TERMINUS AND CLEANING THE APICAL PATENCY

The second controversy to be discussed surrounds the determination of an accurate *working length*, one of the most critical steps of endodontic therapy. The cleaning, shaping, and obturation of the root canal system cannot be accomplished accurately unless the working length is determined precisely.⁷⁷⁻⁷⁹ And if the working length is to be established slightly short of the apical foramen, what of that tiny space that lies beyond the constriction—the *apical patency area*? What if this space contains toxic debris and harmful bacteria that could prevent future healing and repair? Simon⁸⁰ has stressed the need for clarification and consistency in the use of terms relating to working length determination. Working length (Figure 29) is defined in the endodontic glossary as “the distance from the coronal reference point to the point at which canal preparation and obturation should terminate.”⁸¹

The *anatomic apex* is the tip or the end of the root determined morphologically, whereas the *radiographic apex* is the tip or the end of the root determined radiographically.⁸¹ Root morphology and radiographic

Figure 29 Care should be exercised to establish the position of the foramen. Hopefully, it appears at the apex **A** and 0.5–1.0 mm is simply subtracted from the tooth length as a “safety factor.” The lateral exit of the canal **B** is sometimes seen in the radiograph or discovered by instrument placement and re-examined radiographically. Today, electronic apex locators are important instruments for determining the apical exit of root canals. Reproduced with permission from Serene T, Krasny R, Ziegler P, et al. *Principles of Preclinical Endodontics*. Dubuque, IA: Kendall/Hunt Publishing; 1974.

distortion may cause the location of the radiographic apex to vary from the anatomic apex.

The *apical foramen* is the main apical opening (entrance/exit) of the root canal. It is frequently eccentrically located well away from the anatomic or the radiographic apex⁸²⁻⁸⁴ (Figure 30). Palmer⁸⁴ investigation showed that this deviation occurred in 68–80% of the teeth in his study.

An accessory foramen is an orifice on the surface of the root communicating with a lateral or an accessory canal.⁸¹ They may exist as a single foramen or as multiple foramina.

The *apical constriction* (minor apical diameter) (Figure 31) is the apical portion of the root canal having the narrowest diameter. This position may vary but is usually 0.5–1.0 mm short of the center of the apical foramen.⁸¹⁻⁸³ The *minor diameter* widens apically toward the foramen (*major diameter*) and assumes a funnel shape. This is the area of “apical patency” that will be discussed later.

Figure 30 The apical foramen, some distance from the radiographic apex, stresses the importance of finding the actual orifice by electric apex locator (EAL). D, Dentin; C, Cementum. Reproduced with permission from Skillen WG. *J Am Dent Assoc* 1930;17:2082.

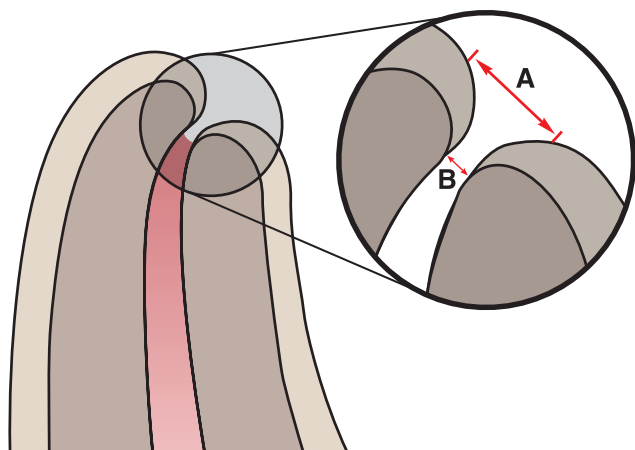

Figure 31 Diagrammatic view of the root apex. The importance of differentiating between the *minor diameter B* and the *major diameter (radiographic apex) A* is apparent. Courtesy of Dr. Stephen Weeks.

The apical third is the most studied region of the root canal.^{82,83,85-90} Dummer⁸³ and his associates reported many variations in the apical constriction.

In 6% of cases, the constriction may be blocked by the cementum.

The *cementodentinal junction* is the region where the dentin and the cementum are united, the point at which the cemental surface terminates at or near the apex of the tooth.⁸¹ It must be pointed out, however, that the cementodentinal junction is a histological landmark that cannot be located clinically or radiographically. Langeland⁹¹ has reported that the cementodentinal junction does not always coincide with the apical constriction. The location of the cementodentinal junction also ranges from 0.5 to 3.0 mm short of the apical constriction.^{81-88, 92-96}

Therefore, it is generally accepted that the apical constriction is most frequently located 0.5–1.0 mm short of the apical foramen, but with variations. These variations may be revealed by the patient's reaction to an overextended instrument or by an electric apex locator (EAL).

Now to complicate matters further, Brynolf⁹⁷ (Figure 32) has pointed out that the apical constriction may disappear completely when apical disease destroys, by resorption, the entire apical structure.

Figure 32 Brynolf's interpretation of the normal and resorbed *lamina dura*. *Left*, Radiographic appearance of the normal lamina dura under magnification. *Center*, Loss of lamina dura at the apex along with inflammatory resorption as a result of the necrotic tissue in the canal (C). *A*, apical soft tissue; *B*, bone trabeculae; *C*, root canal; *F*, foramen; *L*, PDL; *M*, medullary space. *Right*, Necropsy of specimen detailed in *Center*. Reproduced with permission from Brynolf I, *Odontologisk Revy* 1967;18 Suppl 11:27.

Figure 33 Weine's recommendations for determining the working length based on radiographic evidence of root/bone resorption. **A**, If no root or bone resorption is evident, preparation should terminate 1.0 mm from the apical foramen. **B**, If bone resorption is apparent but there is no root resorption, shorten the working length by 1.5 mm. **C**, If both root and bone resorption are apparent, shorten the length by 2.0 mm. Courtesy of Dr. Franklin Weine.

Weine⁹⁸ (Figure 33) faced this complication early on and recommended a compromise based on the radiographic evidence. If in the radiograph there appears to be a normal periodontal ligament width, that is, no bone or tooth resorption is evident, the working length should terminate 1.0 mm, “safety allowance,” from the apical foramen. If there appears to be bony resorption but no apparent tooth resorption, the working length should be shortened by 1.5 mm. On the other hand, if both bone and tooth resorption is apparent radiographically, the length of the tooth measurement should be shortened by 2.0 mm. This should “draw back” the point of apical constriction far enough in the canal to establish an apical stop. Enlarging instruments and obturation should not proceed beyond this point. In 1922, Davis⁹⁹ was the “first to suggest that careful treatment of the apical tissue was a requirement for success in root canal treatment.”¹⁰⁰

Weine's recommendation, however, is not infallible! Take the case exhibited by Brynolf (see Figure 32) in which the entire apical structure has been destroyed. In these cases and in youngsters where the canal is wide open, the so-called “blunderbuss” canal, the primary filling point will have to be adjusted—cut back—until it fits tightly at the apex and exhibits “tugback.”

Another variation involves canal preparation following the so-called partial pulpectomy. Nygaard-Ostby showed in the case of pulpectomy of a vital, yet inflamed, pulp that it was wise to retain a portion of the pulp at the apex to assure periapical healing.¹⁰¹ Careful cleaning, shaping, and obturation to this pulpal “stump” allow this tiny segment of tissue to continue producing dentin and cementum (Figure 34).

In marked contrast, three endodontic programs in the United States, in 1997, were teaching “penetration of the foramen, to or beyond the radiographic apex.”¹⁰² Schilder^{103–105} declared “his aim was to debride and to fill to the apex...” He further admitted

Figure 34 Partial pulpectomy. Observation period of 6 months. Only slight accumulation of lymphocytes adjacent to the plug of dentin particles and remnants of Kloropercha (DF at top). Cell-rich fibrous connective tissue occupies the residual pulp canal. Large deposits of hard tissue (H) along the walls. Reproduced with permission from Hörstad P, Nygaard-Østby B. *Oral Surg Oral Path Oral Med Oral Radiol Endod* 1978;46:275.

Figure 35 Overextension of root canal instrument, beyond the minor diameter to the radiographic apex, traumatizes periodontal soft tissue and may deposit toxic canal debris and bacteria periapically.

that “his procedure in most cases involved instrumentation beyond the root canal limit, inside the adjacent periodontal ligament” (Figure 35).

In addition to the concern with the extent of the working length measurement, one must also be concerned with the breadth of preparation in the apical one-third of the canal. Initially it was thought that cleansing with a No. 25 instrument was adequate in most cases. Today, however, with the advent of the nickel–titanium rotary instruments, it is not unusual to use a No. 60 or a LightSpeed instrument in an attempt to thoroughly clean and shape the apical preparation. This not only removes most of the packed tissue, dentin filings, and bacteria from the region but also provides room for a thorough irrigation with NaOCl and EDTA to remove the smear layer as well.¹⁰⁶ The importance of thoroughly cleansing and disinfecting this area was emphasized by Baumgartner and Falkler¹⁰⁷ when they disclosed the presence of 50 different strains of bacteria in the apical 5.0 mm of infected root canals, 68% of which were strict anaerobes. If these bacteria, along with

tissue debris, are forced into the apical tissue, inflammation, if not infection, will be the result. Al-Omari and Dummer¹⁰⁸ found that this occurred 81% of the time particularly with linear filing as in the step-back technique. Hartwell et al.¹⁰⁹ found much the same; that linear filing with K files produced significantly more debris and irrigant extrusion than with rotary file preparation. So how can this be prevented or at least minimized?

APICAL PATENCY AND ITS PREPARATION

“Apical patency is leaving the apical foramen accessible, free from dentin chips, pulp fragments, and other debris,” as well as bacteria.¹¹⁰ In an excellent review of the subject entitled *The Importance of Apical Patency and Cleaning the Apical Foramen in Root Canal Preparation*, Sousa¹¹⁰ points out that maintaining apical patency does not necessarily clean the foramen but avoids apical blockage by dentin chips and debris, thus retaining true working length. “The apical foramen should be instrumented to be cleaned.” In 1997, a survey of 53 university endodontic departments revealed that 50% were teaching “the concept of patency to their undergraduates or graduates or both.”¹⁰² Far earlier, Buchanan and Ruddle^{111,112} were advocates of maintaining apical patency, depending to a great extent on NaOCl presence and irrigation to clean the apical foramen space. Patency files passing through the NaOCl tend to be sterile.¹¹³ Both Buchanan and Ruddle prefer to recapitulate, beyond the working length, to the foramen with a No. 10 or No. 15 0.02 file after each enlarging instrument is used. They also suggest that fresh NaOCl is to be left in the canal for another 5 min or so. Sousa¹¹⁰ also recommends using a file, one or two sizes beyond the last enlarging instrument to clean the remaining space to the foramen. Remember the 50 strains of bacteria that may be lurking there!

So what does this all “boil down to?” It boils down to success versus failure, healing versus disease. In the final analysis, where should the preparation and the obturation terminate? As far as preparation is concerned, a good case has been made that the apical constriction, 0.5–1.0 mm short of the apical foramen, is the best point for termination. This should be followed by maintaining apical patency and then cleaning and disinfecting the tiny area to the apical foramen.

As far as obturation is concerned, “[I]n terms of percentage rates of success, metaanalysis showed that obturation 0 to 1.0 mm short of the apex (group A) was better than obturation 1 to 3 mm short of the apex (group B); both [groups] were superior to obturation beyond the apex (group C).”¹¹⁴ “This

finding is not surprising; it has been shown that obturating materials in periradicular tissues are an irritant and they adversely impact healing”.¹⁰⁰

Modern endodontics, therefore, extends from efforts to save the pulp—pulp capping—to implants. To be proficient as a specialist, one must be knowledgeable as well as skillful. That should not be asking too much! After all we are dealing with the smallest organ in the body.

A case for change has been made in this chapter; change that has affected our past, change that is presently occurring, and changes that will undoubtedly affect our future. But we may be in for a big surprise. Already underway, our scientists are plotting to grow human teeth in the laboratory that could then be implanted in place of their diseased or damaged precursors. Who is to say they will not succeed? At least we should start considering the possibility.

Anticipating the Future

The opportunities for oral health care in the twenty-first century are enormous. Perhaps foremost is the realization of comprehensive oral health care, and this will require health literacy, health promotion, risk assessment, and advances in disease and disorder prevention. The profession still faces an enormous backlog of dental disease and must make every effort and employ all our skills and knowledge to improve the nation’s oral health. “More than 51 million school hours are lost each year because of dental illness. Dental disease is the single most common chronic childhood disease—five times more common than asthma.”¹¹⁵

The twenty-first century also promises remarkable advances and transformations by the convergence of six major determinants, any one of which might be sufficient to profoundly transform well-being and quality of life for many, many millions of people:

1. The biological and biotechnological revolutions
2. A major redistribution and increase in global population
3. Changing demographics in industrialized as well as developing nations
4. Changing patterns of diseases and disorders, including the emergence and re-emergence of infectious diseases (often with unique pathogens), and changes in the organization and the management of health care
5. Instant global communication systems through the Internet, cable, satellite, and wireless technologies

6. A continuing exponential rate of growth in information technology, especially driven by bioinformatics and nanotechnology that will advance computer speed, memory, and complexity.

These global six determinants are already changing the way we live now and they will continue to have profound implications for the future of health care, oral health care, endodontics and well-being of all people.¹¹⁵

The Past and Present as Prologue for the Future

The intellectual activity and contributions from the eighteenth, nineteenth, and twentieth centuries have provided the foundations for present-day science and technology. Moreover, more has been learned and implemented in the last 100 years than in the past 5,000 years. The rate and magnitude of scientific discovery, the fuel for the engine of technology, continues to accelerate. The convergence of the biological and digital revolutions with clinical dentistry and medicine is changing and transforming diagnostics, treatment planning, procedures, techniques, therapeutics, biomaterials, and predictable outcomes of therapy.^{116–134} We have come a long way since Pasteur, Koch, Ehrlich, and Vannevar Bush established the foundations for the emerging fields of microbiology, immunology, and computer sciences during the last century. In tandem, dental and medical education were transformed vis-à-vis the Flexner and Gies Reports from the 1920s in America, and today we are anticipating another level of major transformation in health professional education.¹³⁵

The seeds were sown for the convergence of chemistry, physics, and biology into molecular biology, as well as the convergence of Charles Darwin’s theories of evolution with fruit fly genetics, population genetics and DNA sequencing of 38,000-year-old bones of Neanderthal into the synthesis of evolutionary biology. These enormous efforts have produced a foundation that enabled the Human Genome Project to be completed by October 2004 and further to acquire a molecular genetic data base for many viral, bacterial, yeast, plant, invertebrate, vertebrate, primate, and human genomes.^{136–139} These efforts further established the foundations for bioinformatics, tissue engineering, nanobiotechnology, stem cell biology, and

tissue and organ regenerations.^{116–134} Our future perspective is filled with enthusiasm.

Transforming Advances

Three transforming advances will be highlighted: (1) saliva as a diagnostic and informative fluid, (2) tissue engineering, and (3) tooth regeneration.

SALIVA AS A DIAGNOSTIC AND INFORMATIVE FLUID

During the last decade, enormous progress has been made in identifying informative biomarkers found in saliva, and also in identifying oral buccal epithelial cells from which DNA can be extracted for human genomic studies and diagnostics.

Today, saliva is being used to harvest oral buccal epithelial cells and to thereby isolate genomic DNA representing 23,000 human genes and to be able to ascertain single nucleotide polymorphisms informative for complex human diseases. Beyond genomics, saliva is also informative for biomarkers that indicate viral infections such as measles, mumps, rubella, hepatitis A and B and, of course, HIV-1 and -2. Direct antigen detection is also available for influenza A and B, streptococcus group A (*N*-acetylglucosamine), salivary estradiol, several breast cancer biomarkers (e.g., CA-15, epidermal growth factor receptor (EGFR), cathepsin-D and Waf 1), zinc-binding cystic fibrosis antigen, and several markers for type 2 diabetes. Beyond the hundreds of different types of oral bacteria species as well as yeast organisms, many hormones and drugs such as aldosterone, cortisol, estrogens, insulin, melatonin, progesterone, testosterone, carbamazepine, lithium, methadone, phenytoin antipyrine, threohilline, caffeine, cocaine, continine, ethanol, marijuana, and various opiates are now identified and measured in saliva. And the list continues with the addition of informative messenger RNAs (so-called “transcriptome” representing human saliva).

Further, miniature devices for “point-of-care” are being developed for salivary diagnostics using microfluidics, microcapillary electrophoresis, and other nanobiotechnology advances.

TISSUE ENGINEERING

As clinicians, it is our opportunity to translate the fundamental discoveries of science and technology, as are now rapidly occurring in stem cell biology, molecular biology, genomics, functional genomics,

and biomaterials/biotechnology/information technology, into concrete advancements for our patients and communities. This approach provides a bridge over which clinicians can traverse to learn how to apply scientific advances in tissue engineering and regeneration to their clinical practices.

The convergence between stem cells and biotechnology has made it possible to envision the design and fabrication of biological tissues applicable to a large number of human diseases and disorders. Three decades ago, the first tissue engineering proof of principle was established with bone marrow transplantation for myelogenous leukemia. Less than 10 years ago, the first cartilage tissue engineering product was approved by the FDA and is being used for a variety of knee applications.

Tissue engineering is a contemporary field of biomedical therapy focused at developing and improving procedures and complementary biomaterials for the design and fabrication of new tissues to replace damaged tissues and is based upon the principles of cell biology, developmental biology, molecular biology, and bioengineering. Tissue engineering is presently focused on tissue replacements such as bone, cementum, dentin and enamel as well as periodontal ligament, oral mucosa, muscle and nerves. Recent progress has literally been astonishing.^{116–136, 139–143}

TOOTH REGENERATION

The prospects for tooth regeneration are enormously promising.¹⁴⁴ During the past 50 years, a foundation has been provided for understanding the evolution, developmental biology, histogenesis and differentiation, and extracellular matrix-mediated biomineralization of vertebrate tooth organs. Based upon the knowledge of biological principles, it is becoming readily feasible to design and fabricate tooth organs in the not too distant future.¹⁴⁴

Is the knowledge base and techniques presently available sufficient to design and fabricate tooth organs for tooth replacement applications in clinical dentistry? Does the knowledge gained from experimental embryology, autotransplantation of teeth, human genetics, adult stem cell biology, and the identification of human and mouse morphoregulatory genes for tooth morphogenesis lead to biomimetic designs and fabrication for tooth regeneration?

The answer to these questions would appear to be affirmative. For example, the National Institutes of Health recently released a Request for Applications to establish Centers for Excellence in Regenerative Medicine with tooth organ regeneration being one of the suggested models. It is becoming readily apparent that despite

many of the recent clinical advances in mechanical solutions to tooth restoration and dental implants, or the advancements of autotransplantation of human teeth for tooth replacement, the twenty-first century provides a number of unique opportunities to enable biological solutions to biological problems including tooth organ regeneration. The recent convergence of the human genome completion,^{136–138} scientific advances toward understanding the molecular regulation of tooth morphogenesis,¹⁴⁴ stem cell biology,^{125,126,140,141} nanotechnology, and biotechnology offer unprecedented opportunities to realize tooth regeneration. One of the next critical steps will be to apply the knowledge of molecular regulation of tooth morphogenesis to manipulate adult stem cells in becoming odontogenic phenotypes.

Significant progresses have been made in stem cell biological research, which has advanced our understanding in the area of hematopoiesis, tissue engineering (e.g., bone, cartilage, and muscle), and biomaterials. Recently, studies have shown that adult stem cells have a much higher degree of developmental potential than previously thought, and this has prompted considerations to explore the potential of stem cell-mediated muscle, bone, cartilage, and dentin regeneration.

Stem cells are truly remarkable. They have the potential to grow into an array of specialized cells and hold great promise for treating medical and dental conditions, such as missing teeth. Conventionally, these pluripotent cells are divided into embryonic and adult stem cells. The difference is mainly in the number of types of differentiated cells that can be produced by the stem cell. When exploring the potential of stem cell-mediated tissue regeneration, recent studies have focused on the application of adult bone marrow because it is readily accessible and contains both hematopoietic and stromal fibroblast stem cells.^{120–129} Systemically injected mouse bone marrow-derived cells have given rise to muscle, cartilage, bone, liver, heart, brain, lung alveolar epithelium, intestine, and, of course, hematocytes. Although most of these animal studies now serve as precursors for future human clinical trials in treating certain medical and dental conditions, the basic scientific principles learned from these current analyses have certainly advanced our understanding of the biological regulation of tissue engineering. In contrast to previous paradigms, postnatal stem cells have a much greater potential when it comes to tissue regeneration.

To date, there is no study demonstrating bone marrow-mediated tooth regeneration. This might be attributed to an as yet incomplete understanding of proper manipulation of adult somatic stem cells and

several other confounding issues. The knowledge of molecular regulation of tooth morphogenesis will significantly enhance the focus on the importance of signaling pathways when studies begin to explore the regulatory issues of progenitor cell differentiation.^{144–147} Accordingly, as studies begin to discover the precise molecular regulation of stem cell proliferation and differentiation, bone marrow-derived progenitors hold great promise in tooth regeneration.¹¹⁶

Meanwhile, odontogenic stem cells have been identified, isolated, and tested from adult dental pulp tissue.^{117,130,133,148} After being transplanted into immunocompromised mice, dental pulp stem cells regenerate dentin-like tissue; curiously, the quantity of regenerated dentin tissue appears to far exceed the dentin tissue generated *in situ* during the lifetime of a particular tooth organ. Thus, odontogenic stem cells isolated from adult dental pulp can serve as a resource to regenerate large amount of dentin tissue that can be used in tooth repair.

Collectively, a new paradigm is emerging, which suggests an understanding of common mechanisms that are critical in regulating the fate of stem cells. These discoveries also reveal several signaling networks that underlie the specific regulatory properties of tooth morphogenesis. Indeed, there remain many questions and technical obstacles before stem cells will be used to regenerate teeth. However, there are several significant lines of evidence to consider, which are as follows:

1. Enamel organ epithelia and dental papilla mesenchymal tissues contain stem cells during postnatal stages of life
2. Late cap stage and bell stage tooth organs contain stem cells
3. Odontogenic adult stem cells respond to mechanical as well as chemical “signals”.
4. Presumably, adult bone marrow as well as dental pulp tissues contain “odontogenic” stem cells
5. Epithelial–mesenchymal interactions are prerequisite for tooth regeneration.

The authors express “guarded enthusiasm,” yet there is a little doubt that adult stem cell-mediated tooth regeneration will be realized in the not too distant future. The advances in basic, translational, and pre-phase 1 clinical trials are impressive. In tandem, the changing demographics within industrial nations indicate an increasing societal demand for “body parts” to address the quality of life issues for aging populations. The prospects for tooth regeneration could be realized in the next few decades and could be rapidly utilized to improve the quality of human life in many nations around the world.

CHAPTER 2

HISTORY OF ENDODONTICS

JAMES L. GUTMANN

Endodontics is the branch of dentistry concerned with the morphology, physiology, and pathology of the human dental pulp and periapical tissues. Its study and practice encompass the basic clinical sciences including biology of the normal pulp; the etiology, diagnosis, prevention and treatment of diseases and injuries of the pulp; and associated periapical conditions.¹ However, while this represents the contemporary definition of endodontics, the true codification for the art and science of this discipline really did not occur until its recognition as a specialty and in fact it was not even until the first part of the twentieth century that the concept of “endodontics” began to take shape.

In the latter part of the nineteenth and the first part of the twentieth century, endodontics was referred to as root canal therapy or pathodontia.² Dr. Harry B. Johnston, of Atlanta, Georgia, a well-known lecturer and clinician in the early twentieth century coined the term endodontics from the Greek word “*en*,” meaning in or within, and “*odous*,” meaning tooth: the process of working within the tooth. In 1928, his practice was identified as the first practice to be “limited to endodontics.”

In 1943 when a group of distinguished dental professionals met in Chicago to form an association of dental practitioners interested in root canal therapy, they used the term “endodontics” and called the organization the American Association of Endodontics. They envisioned endodontics as becoming a special area of dental practice. In an editorial that appeared in the first issue of the *Journal of Endodontia* in 1946, Dr. Balint Orban highlighted the need for the pursuit of quality within this emerging specialty.³ “Today after much work and thought, things are looking brighter. The ‘Endodontist’ is not anymore a rebel against the ruling of ‘science’ but a recognized specialist of dentistry. The technique has been refined to such a degree that it gives standing to the dentist even in the eyes of the medical profession, and safety to the patient. Since root canal treatment has

been elevated to the status of a specialty, those who intend to do this work must adequately prepare themselves for it.”

The founding fathers of the American Association of Endodontists (AAE) responded to the call from three distinguished individuals as follows.⁴ “On a call from Dr. W. Clyde Davis of Lincoln, Nebraska, Dr. John H. Hoppers of Chicago and Dr. Louis I. Grossman of Philadelphia, a group of nineteen dentists whose names follow, met [on February 25] in Dining Room 4 at the Palmer House in Chicago for the purpose of organizing a society for the study of root canal therapy, with Dr. Hoppers in the chair. The following were present: Dr. Charles M. White, Dr. G. L. Girardot, Dr. George C. Sharp, Dr. Saul Levy, Dr. Truman B. DeWitt, Dr. Douglas A. Meinig, Dr. T. C. Starshak, Dr. Henry Kahn, Dr. Sophia Bolotny, Dr. John H. Hoppers, Dr. Harry B. Johnston, Dr. Edgar D. Coolidge, Dr. S.D. Green, Dr. Paul T. Dawson, Dr. George W. Meinig, Dr. J. W. Ritter, Dr. Vincent B. Milas, Dr. Arthur R. Sample and Dr. Clyde Davis.”

By 1963, more than 200 dentists were limiting their practice to endodontics.⁵

Because of the remarkable growth and development of endodontics during the previous 25 years, and because of the untiring efforts of leaders in the AAE, the American Dental Association recognized “endodontists” as a special area of dentistry in 1963. The first examination and certification of diplomates occurred 2 years later in 1965.⁴ As of this publication, there are about 6,600 members of the AAE and over 1300 certified diplomates.

In order to understand and appreciate the evolution of this dental specialty, a brief review of its historical roots is indicated. Because most of the elements of this evolution come from a rather diverse range of sources, the present codification of the definition and scope of this specialty will be used as a framework for this investigation.

The present definition of endodontics has been consolidated to focus on two areas¹:

1. Morphology, physiology, and pathology of the human dental pulp and periapical tissues.
2. Etiology, diagnosis, prevention, and treatment of disease of the pulp and associated periapical conditions.

The present scope of endodontics has been distilled into the following outline, one that will be followed in this historical pursuit.

- Differential diagnosis and treatment of oral pain of pulpal and/or periapical origin, or referred pain.
- Vital pulp therapy (pulp capping, pulpotomy, apexogenesis, and apexification).
- Non-surgical treatment of root canal systems with or without periapical pathosis of pulpal origin, including obturation of these systems.
- Selective surgical removal of periapical pathosis resulting from the extension of pulpal pathosis including tooth structures: root-end resection, hemisection, bicuspidization, root resection, and root-end filling.
- Root repair procedures related to pathologic or odontiatrogenic pathosis/damage.
- Intentional replantation and replantation of avulsed teeth and management of other traumatic tooth injuries (luxations).
- Interrelationships between pulpal and periodontal disease.

- Endodontic endosseous implants (diodontic tooth implants).
- Bleaching of discolored dentin and enamel.
- Revision of previously treated root canal systems—both non-surgical and surgical.
- Coronal restorative procedures involving the root canal space and coronal access openings.

Definition

MORPHOLOGY, PHYSIOLOGY, AND PATHOLOGY OF THE HUMAN DENTAL PULP AND PERIAPICAL TISSUES

The dental pulp is the most unique organ and its relationship with both the tissues that it produces, dentin, and the associated surrounding tissues, enamel, cementum, periodontal ligament, and supporting bone is most interesting and challenging in terms of clinical assessments, diagnoses, and treatments. The study of the dental pulp, the adjacent dentin, and supporting oral structures has a long history of “discoveries and developments,” and the history of endodontics would not be complete without first having an appreciation for the evolution of this chronology, as it reflects a true, global flavor. Table 1 provides a concise and impressive listing of the chronology of discoveries in

Table 1 Chronology of Discoveries in Pulpodentinal Histology

Author (place of activity)	Nationality	Year	Original Description
Van Leeuwenhoek (Delft) ³²⁹	The Netherlands	1675	“Transparent pipes” in the tooth bone
Malpighi (Bologna) ³³⁰	Italy	1686	“Substantia tubulosa” equal to dentine
De la Hire (Paris) ³³¹	France	1699	“Infinity of small fibrils,” enamel rods
Hunter (London) ³³²	Great Britain	1771	Madder refractive, avascular, different from other bones
Purkinje (Breslau) ³³³	Germany	1835	Accurate description of tooth structures
Fränkel (Breslau) ³³⁴	Germany	1835	Tubular dentine, contour lines
Raschkow (Breslau) ³³⁵	Germany	1835	Cellular secretion theory of dentine; pulp innervation plexus (<i>eponym</i>)
Retzius (Stockholm) ³³⁶	Sweden	1836	Tubular canal system in dentine
Müller (Berlin) ³³⁷	Germany	1837	“Hollow fibrils in tubular tooth substance”
Linderer and Linderer (Berlin) ³³⁸	Germany	1837	First (German) dental text including histology
Tomes (London) ³³⁹	Great Britain	1838	Granular layer of dentine (<i>eponym</i>)
Schwann (Louvain) ³⁴⁰	Belgium	1839	Cellular theory of vegetable and animal; “ivory cells with fibrous processes” in pig; nerve cells (<i>eponym</i>)
Nasmyth (London) ³⁴¹	Great Britain	1839	“Baccated fibrils” in dentine; pulp ossification theory

pulpodentinal histology (see the references cited in Table 1 for information on these early publications).⁶ For today's student of pulpal histology and oral biology, this table represents an amazing codification of developments that have influenced current thought historically and provided contemporary clinical directives. Further information on the extensive contributions to the study of the entire oral biological complex of pertinence to endodontics can be found in the treatise on our pioneers in oral biology by Kremenak and Squier.⁷ The true aficionado of pulp histology is directed to the most current publication on this topic⁸ (Figure 1).

Extensive treatises on tooth morphology have existed for over 100 years,⁹ with the major works in this area attributed to Hess¹⁰ who made vulcanite corrosion preparations of almost 3000 permanent teeth. Additional

historical contributions can be found in the studies of Barrett,¹¹ Pucci and Reig,¹² Skillen,¹³ and Wheeler.¹⁴ On the basis of the data recorded in these studies, Grossman¹⁵ raised the following question; "One may well ask at this point if root canal work is justified in view of the complexity of the canals, since by no method can all the minute ramifications be filled." In rhetorical response to this query, Grossman indicated that Thomas¹⁶ studied a large number of serial sections of root apices and found "that many canals seen in the apical region in individual sections, both ground and decalcified, do not communicate directly with the pulp. Many of them are imbedded vessels, their loopings being plainly demonstrated in serial sections. Sometimes such loopings arise from, and terminate in, the pulpal wall."

Kronfeld¹⁷ responded more succinctly to Grossman's question in the following manner: "Microscopic findings

Figure 1 Photos of dental pulps that had either been diseased or challenged with various toxic chemicals, such as arsenic or phenoltannin that were used in pulp therapy in the late 1800s. This study represented one of the first extensive evaluations of pulp tissue in response to caries or medicinal treatment. Note the inflammation, presence of calcified material and fibrosis. From Witzel A. *Die Antiseptische Behandlung der Pulpkrankheiten des Zahnes*. Berlin: Commissionsverlag Von C. Ash & Sons; 1879. (See Table 3)

on extracted teeth with clinically well-filled, uninfected main canals prove that nature takes care of the remaining unfilled lateral branches and apical ramifications. All these fine canals contain living tissue that remains vital after the pulp has been removed from the main canal and forms cementum that eventually may completely obliterate the lateral canals.”

ETIOLOGY, DIAGNOSIS, PREVENTION, AND TREATMENT OF DISEASE OF THE PULP AND ASSOCIATED PERIAPICAL CONDITIONS

This portion of the definition of endodontics will be addressed primarily under the scope of the specialty. However, it is interesting to note how some of the historical thought processes impacted over time on the development of endodontics as a science and an art.¹

Coolidge¹⁸ gave us the first codification of endodontics as a science in as much as he based this discipline on the concept of “therapeutics.” He defined therapeutics as a science devoted to the restoration and maintenance of health. It was the application of remedies for the relief of suffering, the control of disease, and the restoration of adequate body function. He further defined it as used in dentistry and as based on a rational treatment of disease that encompasses the disciplines of the biological sciences of chemistry, physiology, pathology, bacteriology, pharmacology, and psychology, as well as upon clinical experience. Furthermore, “it is very obvious that rational therapeutics could not be practiced without a fundamental knowledge of the etiology and pathology of disease combined with a familiarity with the pharmacological action of drugs.... Just because improvement in a given case is observed after administration of a certain remedy, it is not sufficient evidence to prove the progress was in response to the remedy. However when a series of many cases of similar pathology show favorable response to the same remedy, one of the factors in rational therapeutics has been established.”

Coolidge goes on to address the historical issue, that therapeutists have been looked upon as having superhuman powers, often with a mysterious or magical control over physical conditions. “The primitive belief that a deity or a demon is responsible for the cause of

disease has been carried down through the ages, and occasional evidences of that belief are still found in the newspaper reports of sacrifice for atonement and persecution of persons suspected of witchcraft.... Not only are such practices to be found in the so-called backward countries, but in our own country, in isolated sections. Talismans and charms have not entirely been put aside even though great progress has been made in therapeutic procedure.”

In his discussion of therapeutics and with a focus on pharmacology, Coolidge identifies an issue that is still prevalent and of concern today, including the use of N2 and its multiple variations, that are referred to as RC2B paste. “It has always been the desire of the therapist to find a drug with sufficient germicidal power to destroy microorganisms without damage to the human body cells. So far no drug has been developed that entirely meets such requirements, since some damage to tissue cells is caused by all drugs that have germicidal properties.... There are so very few conditions where drugs can be given the credit for the cure that alleviative treatment remains a very necessary part of therapeutics.... The promotion of beneficial reactions, the control of harmful reactions, the aid to organs and functions that have lost some of their efficiency, through disease or accident, and...very important factors in therapeutics.”

Coolidge then focuses specifically on dental therapeutics: “... as in general therapeutics, curative treatment depends upon the correct interpretation of the symptoms of disease and the determination of their cause.... It is necessary to study each individual case in order to find what factors appear to be the most important in the etiology of the dental disease, and then to make an intelligent effort to remove or correct the disease.”

Dr. Robert L. Levy of the College of Physicians and Surgeons of Columbia University calls attention to two important essentials of therapeutics¹⁹: “The therapist should always be sure the remedy used will at least do no harm. His intentions are to help Nature, but a remedy may hinder rather than help in spite of good intentions. In the management of patients, confidence is the great factor in successful treatment. To establish confidence, scientific training alone is not sufficient, but thorough training in the principles of therapeutics, combined with intellect and character that make up personality are all essential.”

The issues of science do no harm, and rational therapeutics and all they espouse were to come crashing down on the dental professional in the early 1900s in the form of the focal infection theory. Apparently, the microbial populations in the oral cavity and the devastation that they rendered to patients globally in

¹In the ensuing discussion, the reader is encouraged to substitute the word endodontics or endodontist for therapeutics or therapist where indicated to get the full flavor of content as it relates to the basis for the evolution for contemporary endodontics.

the form of caries and periodontal disease failed to gain the attention of the dentist who was concerned with restorations and esthetics. It took an earth-shaking presentation on the part of a British physician to bring the dental profession to its knees.

William Hunter²⁰ was a physician on staff at the Charing Cross Hospital in London, England in 1910. The focus of his interest in medicine was in the area of anemia and the sepsis producing such. He characterized the surgeon as having antisepsis, and Hunter felt that, although areas of surgery were immersed in antisepsis, the practice of medicine was often lapse and that “septic suppurations unfortunately occurred... as complications of various medical diseases.” He ranked sepsis in medicine as “the most prevalent and potent infective disease in the body,” focusing on the movement of staphylococcal and streptococcal organisms throughout the body, compromising specific regions or organ systems. When applying these principles to oral medicine, the physician was immune to the potential disease processes occurring in the oral cavity, regarding it as “matter of teeth and dentistry,” with which he cannot deal. Hunter referred to these oral conditions as “oral sepsis,” a topic he had lectured 10 years prior to his indictment. He claimed that all members of the medical profession had the responsibility to address “oral sepsis.” “The matter of oral sepsis is, therefore, of urgent importance in relation to the whole multifarious and widespread group of affections—medical, surgical, and dental—caused by the actual presence or toxic action of pyogenic organisms (staphylococci and streptococci).” Hunter focused both on teeth and on supporting structures as being the seats of sepsis, especially in the poor patients who could not afford dental treatment.²⁰ “It is in poor patients that these septic conditions are most common. They have had ‘no care’ of their mouths; their fate is the relatively happier one of having their septic roots lying exposed in all their nakedness surrounded with tarter, overgrown it may be by foul, septic fungating gums. This sepsis is relatively open and above-board; it stares one in the face when it is looked for.” Although displaying respect for the mechanical skills of the dentist, he voiced his contempt for the lack of awareness of the seat of oral sepsis, citing it as surgical malpractice.

In his presentation, Hunter cited systematic disease processes that he attributed to oral sepsis, such as gastritis, anemia, ulcers, colitis, and nephritis. He claimed that this “evil was so common and widespread that it is impossible to deal adequately with....” Needless to say, the dental profession would soon respond to this vehement indictment and succumb to the dictates of the medical profession.

In 1912, Rhein²¹ was the first to respond intelligently to William Hunter’s vicious attack on American dentistry. In doing so, Rhein directed the blame for the lack of concern for oral sepsis to the physicians. “It has been unfortunate that the insidious nature of this grave evil has been ignored by medical men for so many years. This apparent indifference of the physician to oral sepsis has unquestionably had an important bearing on the reckless indifference shown by so many dentists to the presence of septic foci in the alveolus.” Additionally, he cites the low fees and the complaints of the dentists that they “cannot get paid for the time needed to remove pulps properly and to seal root canals aseptically,” as causes for indifference on the part of the dentist.

In describing the presence of chronic apical periodontitis with a maxillary lateral incisor, Rhein labels it as a source of “septic poisoning,” which many practicing dentists were treating with the approach of letting “sleeping dogs lie.” In addition, he supports Hunter’s accusation of the poor crown and bridge prostheses and chides the dental profession to realize that Hunter’s observations are true. “If such be the facts, then let us acknowledge them honestly, and in attempting to drag ourselves from this quicksand of dishonor, let us not forget that instead of criticism we owe Dr. Hunter a debt of gratitude.” Rhein urged the dentists to forget the “antique methods of preserving dead pulp tissue, and become familiar with a scientific method of obtaining strictly aseptic conditions.”

In 1913, Logan²² responded to overwhelming concepts of oral sepsis, addressing the treatment of chronic dentoalveolar abscesses, without extraction, to prevent the spread of sepsis. Hartzell,²³ in 1914, provided a discourse on oral bacteria, their role in secondary infections, and principles underlying their transmutation and their paths of entrance to the vital organs.

At the Panama Pacific Dental Congress in 1915, Buckley²⁴ echoed the words of Ulrich²⁵ that “... every tip of a devitalized tooth whether the root canal has been properly or improperly filled becomes a *locus resistancii minorii*.” In doing so, Buckley admitted that the removal of focal infection is appropriate but not to the extent of wholesale, unwarranted extraction²⁴: “... the majority of teeth this involved, may be therapeutically or surgically treated so that they will not be a menace to the health of the individual.”

During this time, Rosenow^{26–29} and Billings³⁰ were rapidly clarifying and espousing the concept of focal infection and elective localization. They felt that bacteria had a predisposition to lodge in specific areas, producing a disease process remote from the original site of infection. Rosenow, working in an

In teeth of 15 monkeys:

1. *S. viridans* sealed in pulp cavities
2. Radiolucent areas developed in 27 of 54 teeth
3. Cultures of *S. viridans* recovered in 77% of teeth

RESULTS:

"Gross and histologic examination of the viscera, alimentary tract, joints and nervous system showed no changes that could be related in any way to the infection produced in the teeth."

GENVERT

Figure 2 A study done in monkeys by Genvert H. et al. in 1941 as cited by Grossman L. Root Canal Therapy. 4th ed. Philadelphia: Lea & Febiger; 1955 that disputed the focal infection theory. Genvert had inoculated the periapical tissues creating a focus of infection at the root end of a number of teeth, but could not determine any systemic involvement resulting from such foci of infection.

area of immature bacteriology without thorough radiographic diagnosis and using extracted teeth dropped into tubes of media, secured mixed cultures of organisms from which he isolated *Streptococcus viridans*. He was concerned about this strain as being the organism of systemic infection. However, in 1917, Meyer³¹ criticized the culturing of extracted teeth as a diagnostic technique and called attention to the possibility of culturing normal mouth organisms that contaminated the tooth during extraction. Grossman³² pointed out that it was disconcerting, but true that practically every investigation dealing with the pulpless tooth made prior to 1936 was invalid (Figure 2). In 1928, Holman³³ reviewed the literature critically and commented on the theory of elective localization. "The specificity of the bacteria has not been proved and the theory of elective localization is so open to misinterpretation and so limited in its practical application that it cannot be considered as a help in the solution to the problem. A certain general

bacterial adaptation to environment is conceded by everyone, but the factors on the side of the host are more variable and far more important."

However, the theories of focal infection and elective localization, when coupled, were to have a devastating effect on the dental profession, as not only pulpless teeth but also teeth with any possibility of chronic inflammation or infection, along with the surrounding periodontium, were considered as the primary source of systemic disease.

In 1918, Peak,³⁴ in a common sense approach to this problem, stated that all focal infection is not of dental origin and that even though the medical profession has indicted the dental profession "...we (dentists) are alive to the prevalence and importance of oral focal infection, and that we can be relied on to intelligently and conscientiously handle our end of the work." Even with this low key approach, Peak chose to land a "salvo" in the lap of the medical profession. "The ruthless extraction of teeth, as demanded by some of

the physicians, is a crime against the patient, and indictment against the physician and the surgeon, and a sad commentary on the co-operation and understanding existing between the medical and dental professions.”

Even Rosenow²⁷ deplored the thoughtless extraction of teeth; however, he did feel it necessary in the presence of systemic disease. “No one deplores more than I the ruthless extraction of teeth that has been practiced in some instances as a result of the work on focal infection. Vital teeth free from pyorrhea should never be extracted except as it becomes necessary for restorative work. The extraction of pulpless teeth seems to me to be indicated, regardless of the appearance of the radiograms, in cases of serious systemic diseases for which no other focus can be found.” However, Rosenow²⁹ did not limit his directives to pulpless teeth. “Teeth, especially multi-rooted teeth, with deep fillings or caps, which manifest evidence of infection of the pulp, with or without pulp stones, and even symptomless teeth which react positively to vitality test and that have deep fillings, may be the source of systemic effects and may need to be removed.” Even with these teeth, he felt “devitalization . . . and the filling of root canal . . . should cease.”

Throughout the first half of the twentieth century, teeth and the seat of potential focal infection they represent have been implicated in multiple disease processes throughout the body, such as eye disease, arthritis, tonsillitis, stomach ulcers, cholecystitis, myositis, diabetes, and many more nondescript unexplained vague systemic conditions.³⁵⁻⁴² While there was an overwhelming tendency to radically eliminate the teeth in the hope of resolving these medical problems, some astute investigators attempted to dispel this irrational, irresponsible course of treatment. As a physician, Hatton⁴³ was one of the most vocal and sensible. “In all humbleness and as a physician, may I say a word to the physicians of this audience? The mouth and teeth, because of their position, are easily examined, yet the determination of the nature and extent of oral infection is a highly technical problem. It is true that any one can acquire much information from the study of dental roentgenograms, but to presume to arrive at a definite conclusion, solely from their examination, is a type of folly that no good physician would be guilty of in the study of any other part of the body. May I suggest that pulpless teeth are not dead teeth, that though the pulps are gone they are still embedded in a highly vascular fibrous membrane, and that the question of nutrition of hard parts of a tooth is still an open question, and that treatment and filling of

the pulp canal can be accomplished even after infection has occurred.”

An additional theory which emerged from the conflagrations of focal infection was the “hollow tube” theory. In their classic paper in 1931, Rickert and Dixon⁴⁴ demonstrated “halos of irritation” around the open ends of implanted platinum and steel hypodermic needles. For them, this finding “gave rather convincing evidence that the circulatory elements diffusing out of the openings of these tubes were not well tolerated by the vital tissues,” and this was analogous to what occurs in the pulpless tooth. Therefore, root canal systems required a tight seal to prevent the irritation and inflammation of the periradicular tissues. In addition, the material used to fill the root canal or apical foramen could not irritate the tissues, and caution was expressed as to the use of these materials in root surgery, especially copper amalgam. While the need to prevent localized tissue irritation is valid, the hollow tube theory as promulgated by Rickert and Dixon was effectively disproved by Goldman and Pearson,⁴⁵ Torneck,^{46,47} and Phillips⁴⁸ in the 1960s.

Focal infection is not dead, although its tenets have been severely dissembled over the years. There exist today professionals who will espouse one or more aspects of the focal infection theory when a diagnosis cannot be made or successful treatment achieved. The quality and success of both non-surgical and surgical endodontics in contemporary practice, the control of microbiologic populations, and the present day etiology for endodontic therapy have all had a tremendous impact on lessening the intensity of the focal infection concept, and dispelling it as scientifically unsound.

Scope

DIFFERENTIAL DIAGNOSIS AND TREATMENT OF ORAL PAIN OF PULPAL AND/OR PERIAPICAL ORIGIN

Long before the beginning of the twentieth century, dental practitioners came to an agreement that the causes of pulpal injury are many and varied, and they were grouped as physical, chemical, and bacterial. Fish⁴⁹ in 1932 indicated that just cutting the dentinal fibrils, as in a cavity preparation, caused some degeneration of the elements of the pulp. Further and more deleterious damage was identified as being due to excessive heat generation during cavity preparation or the polishing of a restoration.¹⁵ For completeness,

Table 2 Differential Diagnosis of Inflammatory Diseases of the Pulp

The Pulp	The Periodontal Membrane
The pain is not always localized. Often difficult to locate	The pain is always localized. Easily located
The pain is sharp, lancinating, intermittent and throbbing.	The pain is dull, steady, and continuous. It is not affected by position of body or time of day
Usually worse during fatigue and at night when in reclining position	The tooth is not affected by thermal changes or chemical irritants
The pulp is very sensitive to thermal changes and other irritants	In early stages, pressure relieves and later intensifies the pain
The tooth is not tender to percussion	The tooth is raised in its socket and strikes first in occlusion
The tooth does not seem elongated and does not interfere in occlusion	A sound unfilled tooth often develops periodontal pain
The tooth usually shows extensive caries or a large restoration	The regional lymph nodes are usually enlarged and tender to palpation
The regional lymph nodes in the submaxillary area are not affected	Body temperature is usually increased
Body temperature is not affected	

Adapted from Prinz H⁵³.

The use of the term "periodontal membrane" was in vogue and used as such since the mid-1800s, as opposed to periodontal ligament. Even today, among periodontists, there is disagreement as to whether it is a membrane or ligament; however the perspective may be based on how the structure is viewed, that is, histologically or functionally.

even the potential for pressurized changes encountered at high altitudes was identified as a cause of pulpal problems in 1937.⁵⁰ While the possibility of "aerodontalgia" was of concern in the late 1930s and 1940s, Ritchey and Orban⁵¹ indicated that high altitude itself would not cause pain in a tooth with a normal pulp. Kennon⁵² observed that 65% of the aerodontalgic teeth had been restored with a period of 12 months or less prior to the onset of pain at high altitudes, but had been asymptomatic at ground level. This finding lent further support for the potential of immediate pulpal damage or degenerative changes that may occur following restorative dental procedures.

Regarding pulpal diagnosis and a reliable determination for such, Hermann Prinz⁵³ provided us with a detailed differential diagnostic scheme in 1937 (Table 2) to determine the difference between pulp and periapical pain. Codified pulp testing techniques in the 1800s to make this type of determination were almost non-existent. In the early 1900s, the following tests were considered essential, as was a documented record of such, including an adamant dictate that "judgment must be exercised in the interpretation of the diagnostic symptoms".⁵⁴

- Roentgenograms (in particular, bitewings for children's and young adult's teeth).
- Transillumination (noting the color changes between a tooth with a vital and non-vital pulp in addition to the labial and lingual soft tissues).
- Thermal vitality tests (use of ice or hot water).
- Electric pulp tester (the stalwart was the Burton pulp vitalometer) (Figure 3).
- Percussion and palpation.
- Mobility additional tests added by Grossman.¹⁵

- Test cavity additional tests added by Grossman.¹⁵
- Anesthetic test additional tests added by Grossman.¹⁵

In the early to mid-1900s, Grossman provided the dental community with a concise listing of diseases of the dental pulp and periapical tissues and diagnostic states.¹⁵ These delineations and demarcations were carried forth well into the late 1900s in many countries and, while histopathologically sound, created confusion from a clinical diagnostic standpoint.

Diseases of the Pulp

The diseases of the pulp according to Grossman¹⁵ are the following:

1. Pulpitis: (a) acute serous, (b) acute suppurative, (c) chronic ulcerative, (d) chronic hypertrophic.
2. Pulp degenerations: (a) calcific, (b) fibrous, (c) atrophic, (d) fatty.
3. Necrosis or gangrene of pulp.

Diseases of the Periapical Tissues

The diseases of the periapical tissues according to Grossman¹⁵ are the following:

1. Acute apical periodontitis
2. Acute alveolar abscess
3. Chronic alveolar abscess
4. Subacute alveolar abscess
5. Granuloma
6. Cyst

With regard to these diagnostic states, two important issues were brought forth to the dental community that may still linger as controversial in some sectors even today: (1) are there bacteria in granulomas and (2) is the granuloma pathosis or a defense reaction? Kronfeld¹⁷

Figure 3 Burton vitalometer with attachments for determining the vitality of the pulp and transilluminator for further diagnostic use. From Coolidge ED. *Endodontia—The Clinical Pathology and Treatment of the Dental Pulp and Pulpless Teeth*. Philadelphia; Lea & Febiger: 1950.

in 1939 stated “While the bacteriologic method is a sensitive means for determining whether bacteria are present in a pulpless tooth, the histological method is useful in determining the location from which bacteria were obtained. For example, a tooth with a granuloma

may have an infected root canal but a sterile periapical tissue . . . The presence of bacteria can easily be demonstrated in smears from the root canal of an untreated pulpless tooth. It is not quite so simple to answer the questions as to whether or not bacteria are present in

granulomas and radicular cysts, for the findings vary with the bacteriological technique used. A few investigators have reported bacteria in all granulomas. The majority of recent observers, however, agree that granulomas and cysts are found sterile in quite a large percentage of cases.”

With regard to the second question, Schour stated⁵⁵ “...the formation of a granuloma is indicative of a defense reaction on the part of the periapical tissue. It may occur in the absence of infection. It has been shown that a granuloma may develop as a result of chemical or traumatic injury following removal of a vital pulp. Furthermore, although bacterial infection may stimulate the tissues to form a granuloma, the granuloma may persist even after removal of the infection.”

VITAL PULP THERAPY (PULP CAPPING, PULPOTOMY, APEXOGENESIS, AND APEXIFICATION)

Phillip Pfaff, a German dentist to Frederick the Great, has been identified as being the first to mention pulp capping. He tailored a piece of metal, gold or lead, to “... *die Figur einer halben Hulse von einer Erbse, deren unterster Theil eine Vertiefung haben soll*” (...the shape of half a peapod, so that the lower surface should have a concavity) (Figure 4). In that way, the metal would be prevented from contacting the living, and therefore, sensible pulp.⁵⁶ Since then a multitude of publications have either extolled the

virtues of pulp capping in retaining pulpal vitality, or they have damned it as being unreliable in the maintaining pulpal vitality, instead contributing to the development of significant pulpal calcification and increasing the difficulty of a root canal procedure, or has outright “killed” the dental pulp. To this dilemma, a careful delineation of when to cap and when not to cap was given to us in 1883 by W. E. Harding of Shrewsbury, England, as he astutely differentiated between capping of an accidental exposure and a carious exposure.⁵⁷ “In the ‘good old days,’ the treatment of an exposed pulp was the extraction of the tooth, but that mode of procedure has long been exploded by the progress of Dental Science.

The first question the dental surgeon of today asks himself is not,—Can I save the tooth, but can I save the pulp? This, gentlemen, has not added much to our labour and anxieties, but is also contributed much to our professional usefulness to mankind.

We all know how easily and successfully a case of accidental exposure can be treated. My usual plan is to swab out the cavity with carbolic acid, which will arrest the bleeding, then place of the point of exposure a small piece of court plaster, or blotting of Fletcher’s artificial dentine. This can be applied in a more plastic state than the phosphate fillings, and unlike oxychloride of zinc it is non-irritant and easily removed if necessary. When this has hardened the permanent filling may be proceeded with at the same sitting.

Figure 4 Frontispiece and Title page from Pfaff’s original publication. (From author’s collection).

The reason these cases are so easily dealt with is that the pulp is quite healthy, and if covered with a non-conductor at once, so as to exclude the germs of micro-organisms, it will heal by first intention.

But in those cases where the exposure results from caries the difficulties are vastly greater, as the pulp is almost sure to be inflamed, and probably suppurating. My experiences of these cases treated by capping is the reverse of satisfactory, the percentage of successful cases being small, and on this point I hope some of the gentlemen present will give us the benefit of experience.

The first point to determine is the condition of the pulp. The history of the case is often deceptive, for the cavity is in such a position as not to be exposed to the impact of food it may not have given much pain, and yet be suppurating; but in the odour we have a certain means of diagnosis. If that peculiar phosphatic odour is present, I very much doubt the possibility of saving the pulp, and think any attempt at capping will result in its death, and eventually in a chronic abscess; in such cases the destruction of the pulp is, I think, by far the best treatment. Should capping be determined upon, the application to the exposed surface of iodoform and eucalyptus oil has generally proved the most successful. It may then be covered with artificial dentine—and in these cases it is always safer to put in a temporary filling for a few weeks, which can be removed in case of pain. Hill's gutta percha over the artificial dentine answers very well."

The historical presentation by Harding highlights many key issues in the pulp capping controversy that has existed for decades. Firstly, the need to eliminate bacteria was highlighted, although it was not really taken into serious consideration regarding pulpal health until the publication by Kakehashi et al. in 1965.⁵⁸ Secondly, the need to establish a pulpal diagnosis was the key to choosing the right treatment; however, Harding could only identify two parameters, those being odor and the possibility of suppuration, for which the latter was guesswork at best. Thirdly, as with Harding, Seltzer and Bender discouraged the use of pulp capping on cariously exposed teeth.⁵⁹ As opposed to Harding, however, these latter authors were able to provide histological justification for their position.

While the contemporary use of pulp capping has been questioned, recent studies have endorsed this procedure in teeth with incompletely formed roots and exposed pulps. In particular, studies by Cvek and others have reported a high degree of success with pulp capping and partial pulpotomy in cases of teeth with traumatic pulp exposures of varying sizes and mature or immature root development (apexogenesis).^{60,61}

Along with pulp capping, partial or full pulpotomies are considered within the realm of vital pulp therapy. Pulpotomies differ from pulp capping in the amount of tissue that is removed. From an historical viewpoint, it is possible that investigators and clinicians intermingled these procedures in their reports. However, a partial or full pulpotomy has been used with high degrees of success for carious, mechanical, and traumatic exposures of the pulp primarily in the presence of immature root development.

According to Hess, early attempts to preserve the vitality of an amputated pulp were made by Bodecker (1886), Preiswerk (1900), and Fisher¹⁵ (1912). In 1924, Leonard reported highly satisfactory results following pulpotomy in selected cases, using his techniques for over 20 years.⁶² A few years later, Neuwirth experimented on teeth of dogs, the pulp of which had been amputated coronally and covered with non-irritating agents, including dentin dust. He found no pathological changes in any of the specimens examined.¹⁵ His findings were confirmed by Hellner in 1930 and noted that dentin shavings dropped upon pulp tissue from the bur also produced a regional pulp calcification.¹⁵ Similar findings were recorded by Pribyl in 1931.¹⁵ On the other hand, Rebel observed secondary reparative dentin formation following pulpotomy but interpreted the presence of the osteoid due to metaplasia of the pulp.⁶³

In 1933, Gottlieb, Orban, and Stein⁶⁴ obtained apical calcification in every case when, experimenting on animals, they incorporated up to 50% of dentin dust in an oxyphosphate cement and used it on contact with amputated pulp. In 1934, Loewenstein reported from 60 to 70% success in a series of 37 cases of pulp amputation,¹⁵ while Novikoff in 1935 reported 16 cases of pulpotomy in children with age ranging from 7 to 10 years with only one failure.⁶⁵ In 1938, Hess, who had considerable experience with performing pulpotomies, reported that about 80% of cases showed complete walling off of the pulp stump with a calcific barrier.¹⁵ Finally in 1938, Teuscher and Zander⁶⁶ provided us with experimental results on the use of a paste of calcium hydroxide to cover amputated pulps. Histological sections of selected cases showed formation of secondary reparative dentin over the pulp stump and maintenance of pulpal vitality. The actual reported technique of pulpotomy using calcium hydroxide was described by Zander and Law in 1942,⁶⁷ and histological evidence of repair with formation of a new layer of odontoblasts and a secondary irregular dentin barrier has been given by Zander and Glass in 1949.⁶⁸

Figure 5 "Exposure eight weeks after capping with Ca(OH)_2 . **A**, Site of exposure; **B**, Dentin walls; **C**, Remnant of necrotic area; **D**, Zone of demarcation and primitive dentin; **E**, New dentin barrier; **F**, Continuous odontoblastic layer and **G**, vital pulp." From Grossman L. Root Canal Therapy. 2nd ed. Philadelphia: Lea & Febiger; 1950.

Historically, the most effective capping material has been calcium hydroxide (Figure 5). The earliest reference to this material is attributed to Nygren in 1838.⁶⁹

The development of this material for routine use clinically, with substantial histologic data, is attributed to Hermann in 1930⁷⁰ and Zander in 1939.⁷¹ Eastlick⁷² recommended it for use with exposed pulps in teeth with immature apices in 1943 as Granath⁷³ did in 1959 for apexification procedures. The use of calcium hydroxide for apexification was popularized in the early 1960s by Dr. Alfred L. Frank in his presentation at the AAE meeting in 1964, and his detailed applications that became known as the "Frank Technique" were published in 1966.⁷⁴ Heithersay⁷⁵ has provided a rather extensive treatise on the wide range of applications for calcium hydroxide.

NON-SURGICAL TREATMENT OF ROOT CANAL SYSTEMS WITH OR WITHOUT PERIAPICAL PATHOSIS OF PULPAL ORIGIN, INCLUDING OBTURATION OF THESE SYSTEMS

The need for non-surgical root canal procedures and tooth retention was necessitated by the presence of the proverbial "toothache," a malady that has plagued man from time immemorial (Figure 6). Historically, many innovative

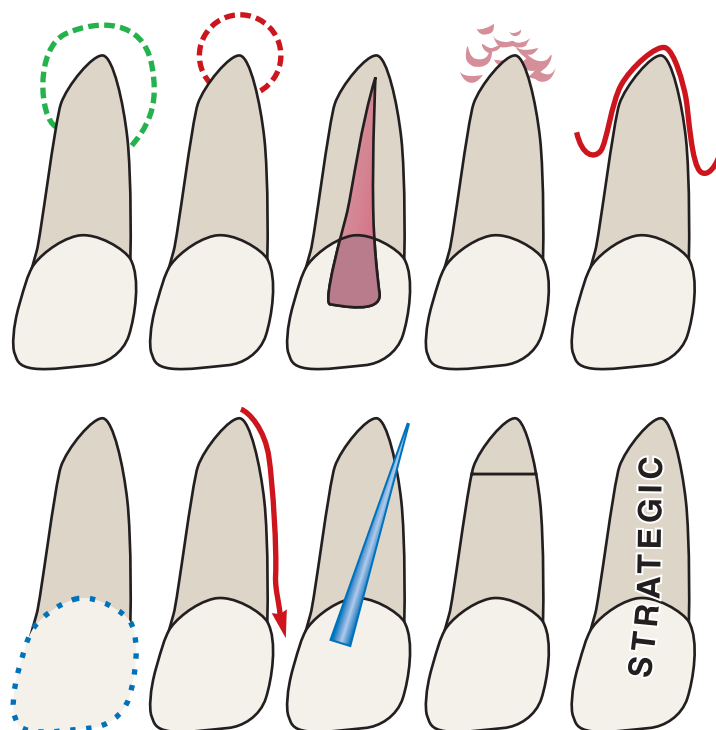

Figure 6 "Local contraindications to endodontic treatment" as cited by Grossman. 1, Large area of rarefaction; 2, cyst; 3, obstruction to apical foramen; 4, erosion of root apex; 5, loss of alveolar bone; 6, loss of crown preventing sterile field; 7, fistula discharging through gingival crevice; 8, lateral perforation; 9, fracture of root with death of pulp; 10, non-strategic tooth functionally and esthetically." From Grossman L. Root Canal Therapy. 2nd ed. Philadelphia: Lea & Febiger; 1950.

cures have been attempted with a wide range of fascinating outcomes.

Cure of the Toothache

As recorded in medical history, toothache has been the scourge of the ages. Many unusual remedies have been described; it is quite evident that necessity, instinct, and mere chance have taught civilizations the means to usual and unusual “cures.” On Egyptian tablets, in Hebrew books, and from Chinese, Greek, and Roman medical writings are recorded descriptions and causes of this scourge. The Ebers papyrus⁷⁶ written about 1500 BC, contained the recipe for a medicament for “curing the gnawing of the blood in the tooth.” The ingredients to be used included the following:

- The fruit of the Gebu plant—one thirty-second part
- Onion—one sixty-fourth part
- Cake—one sixteenth part
- Dough—one eighth part
- Anest plant—one thirty-second part
- Water—one-half part

This was left to stand and then chewed for 4 days.

Archigenes of Apamea (a Syrian city), who lived in Rome in the latter part of the first century, was well known as a physician and operator and distinguished himself with his daring trepanations.⁷³ He recommended various remedies for odontalgia, including a mouthwash made by boiling gallnuts and hallicacabum in vinegar and a concoction of roasted earthworms and spikenard ointment mixed with crushed eggs of spiders. His principal statement regarding dentistry was that odontalgia, in certain cases, was related to a disease in the anterior part of the tooth.

From the Middle Ages are recorded accounts of many “improved” methods of relieving the aching tooth. There was still a strong belief during this time that tooth decay was caused by presence of tooth “worms.” The priest and physician Andrew Boorde,⁷⁷ who achieved fame in the late fifteenth century, described his own unique “deworming technique”:

“And if it (toothache) do come by worms, make a candle of wax with Henbane seeds and light it and let the perfume of the candle enter into the tooth and gape over a dish of cold water and then you may take the worms out of the water and kill them on your nail.”

Abulcasis (1050–1122), known as abir-al-Qasim Khalaf ibi (Abbas al-Zahrowi), controlled toothaches through the use of cautery. He inserted a red-hot needle into the pulp through a tube which was designed to protect the surrounding structures⁷⁸; Guy de Chauliac, a famous medieval surgeon, used a mixture of camphor, sulfur, myrrh, and asafetida as a filling material to cure toothache caused by worms.⁷⁹ In the later Middle Ages, French anatomist Ambrose Paré (1517–1592) wrote⁷³ “Toothache is, of all others, the most atrocious pain that can torment a man, being followed by death. Erosion (caries) is the effect of an acute and acrid humor. To combat this, one must recourse to cauterization . . . By means of cauterization . . . one burns the nerve, thus rendering it incapable of again feeling or causing pain.”

The physician for the Imperial Baths at Calsbad, Johann Stephan Strabelbergen (1630), used oil of vitriol or a concoction made of a frog cooked in vinegar to kill worms in teeth. Lazzar Rivierre was the first to recommend a remedy that is still being used for toothache: placing a small piece of cotton moistened with oil of cloves in the cavity. He altered this with oil or camphor or oil or boxwood.⁷⁹ John Aubrey (1626–1697), in his book *Brief Lives*, reflects on bits of folklore designed to cure the toothache⁸⁰: “To cure the Tooth-ach, Take a new Nail, and make the Gum bleed with it, and then drive it into an Oak. This did Cure William Neal, Sir William Neal’s son, a very stout Gentleman, when he was almost Mad with the Pain, and had a mind to have Pistoll’d himself.”

A history of the remedies used to combat toothache would be incomplete if it did not include the suggestions of the “founder of modern dentistry,” Pierre Fauchard. Guerini translates from *Le Chirurgien Dentiste*, written in 1728 by Fauchard⁷³

Figure 7 A & B. Frontispiece and Title page from Fauchard's original textbook. (From author's collection).

(Figure 7A,B): “Some pretend to cure toothache with an elixir of some special essence; others with plaster; others by means of prayers and signing of the cross; others with specifics for killing the worms which are supposed to gnaw the tooth and so cause pain; others pretend to be so clever that they can cure the most inveterate toothache by merely touching the tooth with a finger dipped into or washed with some rare and mysterious liquid; finally, they promise to cure every kind of toothache by scarifying the ears with a lancet or cauterizing them with a hot iron.”

Finally, Fauchard speaks of another remedy, assuring his readers that with this remedy many persons who have had almost all of their teeth decayed and who suffered very often from toothache have found great relief: “It consists of rinsing the mouth every morning and also before going to bed with a spoonful of one's own rinse (urine) immediately after it has been emitted, always provided the individual be not ill. One is to hold it in the mouth for some time and the practice ought to be continued. This remedy is

good, but undoubtedly not pleasant, except so far that it produced great relief. It is rather difficult in the beginning to accustom one's self to it. But what would not one do to secure his health and repose.”

Fauchard goes on to speak of trepanation of the teeth when they are worn away or decayed and causing pain. He begins by saying: “Most of the varieties of pain caused by the canines and the incisors when worn away, or decayed cease after the use of the trepan.” He uses the word trepan in a wide sense, meaning any instrument (even a needle or a pin) with which “one penetrates into the inner cavity of the teeth.”

In 1756, L. B. Lenter, a German, wrote a pamphlet in which he recommended electricity as a means of curing toothache.⁷³ Other writers recommended the use of a magnet as an alternative. In 1770, Thomas Berdmore⁸¹ published his *Treatise on the Disorders and Deformities of the Teeth and Gums*. In it, he addressed various causes of toothache and its cure. When the toothache was caused by “obstructions and inflammation of the nerves and

vascular parts of the tooth,” the treatment indicated was “counter-impression” and sedatives—primarily to divert the mind from the “disordered nerve.” In practice, the burning of the ear with a hot iron was performed to serve as a “counter-impression.” To Berdmore, however, this treatment was unacceptable.

In his book published in 1794, Ranieri Gerbi, a professor at the University of Pisa, recommended a very singular cure for a violent toothache.⁷³ Under the name *circulio anteodontalgicis* [*sic*] he described an insect living habitually in the flowers of the *Cardi-sus spinosimus* that could be used as a remedy for a toothache. Other medical practitioners of this era in other countries described similar procedures using different types of insects.

Throughout the history, dental “scientists” were still pursuing the elusive “tooth worm.” While no scientific accounts actually exist which support its presence, the

Chinese dentists, especially, are said to understand how to make superstitions pay. When a patient with the toothache presents himself, they (the dentists) were in the habit of making an incision into the gums “to let the worms out.” For this purpose, they used an instrument that had a hollow handle filled with artificial worms. When the incision was made, the operator, with a dexterous turn of the instrument, dropped the worms into the mouth. Generally, the excitement of the patient and the loss of blood caused at least a temporary relief. The worms were then collected, dried, and ready to be taken out of the next patient’s gum⁸² (Entrepreneurism at its finest!). In 1883, F. H. Balkwill of England in a bold exposé attempted to explain scientifically the causes of pain in teeth without pulps that exhibited “no evidence of pericemental irritation.”⁸³

Table 3 highlights a brief and concise listing of some of the major developments in the provision of “root

Table 3 Chronology of Important Developments in the “Roots” of Non-Surgical Endodontic Procedures to the Mid-Twentieth Century

Clinician/Investigator	Era or Year	Procedure, Technique, Instrument
Fauchard ²⁶⁷	18th century	Pulp extirpation, hole drilled into the tooth by file or drill held in a brace; roughened needle used to remove the pulp; cotton with essential oil placed; plug could be removed and replaced if pain present
Riviere ¹⁵	1725	Used oil of clove for toothache; later used lint placed in the cavity that had been dampened with oil of cinnamon, clove, camphor or turpentine
Pfaff ²⁶⁸	1756	Capping of the exposed pulp
Woofendale ³⁸³	1783	Destroyed the pulp with cautery to alleviate pain; no pulp canal cavity filling
Longbothom ³⁸⁴	1802	Recommended that root canals be filled when it was inadvisable to extract them
Hudson ¹⁵	1809	Filled pulp cavity with gold; anterior teeth only, canal treatment not mentioned
Fitch ¹⁵	1829	Formulas for toothache pills, opium, camphor, oil of clove and oil of cassia (from coarse cinnamon bark); laudanum (tincture of opium) also used
Koecker ³⁸⁵	1826	Established criteria for pulp capping
Maynard ³⁸⁶	1838	
Spooner ³⁸⁶	1836	
Burdell ³⁸⁶	1838	Condemned the use of arsenic for pulp destruction
Hill ³⁸⁶	1847	Gutta-percha, “Hill’s Stopping”
Arthur ³⁸⁶	1852	Described the making of barbed broaches with handles
Shadoan ³⁸⁷	1859	Used cobalt and creosote to destroy the nerve of the tooth
Barnum ³⁸⁶	1862	Developed the dental rubber dam
Chase ³⁸⁸	1866	Pulp mummification
Magitot ³⁸⁹ (see Figure 2-10)	1867	Suggested use of electric current for vitality testing
Bowman ¹⁵	1867	Popularized the use of gutta-percha for filling root canals; introduced a solution of chloroform and gutta-percha in 1883; also tried the use of shellac with gutta-percha for tackiness and adherence; Bowman was also the co-inventor of the dental rubber dam clamp forceps with C. F. Allen
Keep ¹⁵	1876	Oxychloride of zinc for capping and filling root canals
Witzel ³⁹⁰	1879	Introduced phenol (initially in 1873)
Brophy ¹⁵	1880	Used heat to evaluate the status of the pulp; traced sinus tracts; used test cavities to verify diagnosis
Allport ¹⁵	1882	Used arsenic for short periods (24 h) on the pulp; reported on sloughing of a portion of the pulp while maintaining the rest for the pulp for years
Mills ³⁹¹	1883	Pulp knocking, popularized the removal of the pulp was by driving a slender wooden peg into the canal with a sharp blow from a mallet; technique had been used by some clinicians for over 20 years
Perry ³²⁷	1883	Wrapped gutta-percha around a gold wire (roots of ThermaFil?); made gutta-percha points that were rolled in shellac (custom prepared cones?) and compacted them into the root canal
Evans ¹⁵	1886	Developed an instrument to dry and disinfect the root canal

Table 3 continued on page 52

Table 3 continued from page 51

Register ³⁹²	1888	Popularized Evans' technique of drying and sterilizing root canal with compressed air heated to 130°F
Rollins ³⁸⁶	1889	Rubber dam clamps
Miller ⁸² (see Figure 2-11)	1890	Foundations of dental bacteriology; demonstrated the presence of bacteria in dead pulp tissue and in infected canal; emphasis on antiseptics
Gramm ³⁹³	1890	Introduced copper points for filling root canals; later gold-plated them to prevent discoloration
Marshall ¹⁵	1891	Popularized the use of the electric pulp tester
Schreier ¹⁵	1883	Used sodium potassium alloy to destroy the pulp
Kirk ¹⁵	1892	Used sodium dioxide for cleaning of the root canal and bleaching of discolored teeth
Breuer ¹⁵	1893	"Ionization" treatment of pulpless teeth, empirical applications
Rollins ³⁸⁶		Added vermillion to gutta-percha
Callahan ³⁹⁴	1894	Used 40% sulfuric acid for the widening of root canals; claimed that the solution also removed pulp tissue and sterilized the canal
Brown ³⁹⁵	1894	Claimed to diagnosed the "strangulation of a tooth nerve"; also detailed the use of hot, cold and percussion as diagnostic tests
Stevens ¹⁵	1895	Marketed the wooden points for "pulp knocking"
Perry ³⁹⁶	1895	"Tempered" Swiss watch broaches for better applications in the root canal; also used chloro-percha technique
Rhein ³¹²	1897	Popularized the use of ionization treatment for pulpless teeth in the USA, empirical applications
Tomes ¹⁵	1897	Suggested paraffin for filling root canals
Rollins ³⁸⁶	1898	Motorized root canal drill
Kells ³⁹⁷	1899	Used x-rays for their diagnostic value; used first to assess root canal obturation
Gysi ¹⁵	1899	Introduced trio paste for pulp mummification
Harlan ³⁹⁸	1900	Used a solution of papain for digestion of dead pulp tissue
Price ³⁹⁹	1901	Identified the value of x-rays in root canal work and the diagnosis of a non-vital pulp
Buest ¹⁵	1901	Recommended that gutta-percha have a core of a silver wire to provide rigidity
Onderdonk ¹⁵	1901	Called for bacteriologic examination of the root canal prior to obturation
Klotz ⁴⁰⁰	1902	Detailed the use of a Morey nerve drill to enlarge the coronal orifice of the canal and enable the penetration of a nerve broach; identified need to know where root canal curvatures are located to prevent the formation of a "ledge" into the side of the canal
Myers ⁴⁰¹	1904	High pressure syringe for anesthetizing the pulp, "Myer Dental Obtunder" (intrapulpal anesthesia)
Vaughan ⁴⁰²	1906	Infiltration anesthesia for anesthetizing the pulp
Buckley ⁴⁰³	1906	Tricresol and formalin introduced
Prinz ⁴⁰⁴	1912	Recommended a high melting-point paraffin for filling root canals
Callahan ³⁹⁴	1914	Suggested a solution of varnish of chloroform and rosin for lining the root canals prior to obturation
Howe ¹⁵	1917	Recommend ammoniacal silver nitrate for silver impregnation of the pulp tissue remnants to render them inert and sterilize the canal
Skillen ⁴⁰⁶ and Thomas ¹⁶	1921	Detailed investigations into the development of the apices of teeth
Husband ⁴⁰⁷	1925	Suggested copper amalgam for filling root canals
Grove ¹⁵	1929	Made precision-fitting gold cones for obturation (canals were prepared with a special set of engine reamers)
Trebitsch ¹⁵	1929	Introduced silver cones for root canal fillings
Stewart ⁴⁰⁸	1930	Introduced a gold-tin amalgam for root canal filling
Jasper ¹⁹⁵	1933	Introduced silver points that had the same diameter and taper as the root canal instruments
Ross ⁴⁰⁹ and Grossman ⁴¹¹	1935, 1935, 1936	Introduced a stable, organic chlorine solution (azochloramid) for sterilization of root canals
Østby ⁴¹²	1944	Described in detail tissue reactions to root canal treatment procedures; described the "Østby Block Section" technique whereby the apical periodontium and root apex are removed intact following treatment procedures for the purpose of histological evaluation
Grossman ⁴¹³	1948	Introduced a penicillin suspension for root canals followed by a penicillin-streptomycin suspension; followed by a penicillin-streptomycin-bacitracin-sodium caprylate suspension (PBSC) in 1949
Kuttler ⁴¹⁴	1955	Defined the apical anatomy of the cemental-dentinal junction with regard to working length determination
Østby ⁴¹⁵	1961	Detailed description of the role of the blood clot in endodontic therapy
Sunada ⁴¹⁶	1962	Introduced the concept of the electronic apex locator

Figure 8 Root canal treatment procedures as described in 1936. **A**, "1, A plaster model of cuspid tooth enlarged 5 diameters. Outline drawn for opening into pulp chamber; 2 opening into pulp cavity but poor access to canal; 3, outline of desired opening to make a straight canal; 4, small file broach unable to pass curvature in canal; 5, small file broach bent at point to pass first curve; 6, small file broach bent and gently rotated to pass second curve. Repeated filing in and out from foramen gradually wears away the curves to compare with outline on model 3. **B**, "7, larger file broach slightly bent to continue enlarging canal to proper size for filling; 8, measuring wire inserted in canal and bent at right angles over incisal edge as measuring point; 9, root canal plugger No. 34 3 mm. shorter than measurement wire and inserted in canal to the bend; 10, plugger No. 34 carrying 3 mm piece of filling material (gutta-percha) into canal as far as the bend in plugger; 11, plugger No. 34 carrying second 3 mm. piece of filling material into place; 12, canal filled. (Berichten des IX. International Zahnörztekongresses Wien, Urban und Schwarzenberg, 1936.)" From Coolidge ED. *Endodontia—The Clinical Pathology and Treatment of the Dental Pulp and Pulpless Teeth*. Philadelphia; Lea & Febiger: 1950.

canal procedures and techniques" into the 1900s (Figure 8A,B). These developments laid the groundwork for the contemporary principles of root canal treatment. However, what may have impacted more on root canal therapy and its acceptance occurred in locations distant from each other in the mid-1900s. While in Montevideo, Uruguay, Dr. Francisco M. Pucci first pointed out the necessity for meticulous intracoronary preparation as the basis for ultimate success in intracanal preparation and obturation,⁸⁴ it was Dr. John I. Ingle in Seattle, Washington who gave us the standardized instruments to clean and shape canals properly⁸⁵ and Dr. Herbert S. Schilder in Boston, Massachusetts who provides us with many of the contemporary principles for successful canal obturation.⁸⁶

SELECTIVE SURGICAL REMOVAL OF PERIAPICAL PATHOSIS RESULTING FROM THE EXTENSION OF PULPAL PATHOSIS INCLUDING TOOTH STRUCTURES: ROOT-END RESECTION, HEMISECTION, BICUSPIDIZATION, ROOT RESECTION, ROOT-END FILLING

Surgical endodontic procedures have a long history of trial and error with multiple authors and clinicians claiming revolutionary techniques. Table 4 provides a brief and concise listing of developments in this realm up to the beginning of the 1900s.

For the first half of the twentieth century, the development of endodontic surgery can be

Table 4 Chronology of Important Developments in the "Roots" of Surgical Endodontic Procedures to 1900

Clinician/Investigator	Era or Year	Procedure, Technique, Instrument
Abulcasis ⁷⁹	11th century	Intentional replantation
Pare	1561	All provided detailed accounts of replantation citing multiple clinical situations; Hunter reached the conclusion that a vital periodontal ligament was a prerequisite for successful union of the tooth and the alveolus following replantation. Pfaff and Berdmore performed root-end resections and placed root-end fillings of wax, lead or gold
Fauchard ²⁶⁷	1712	
Pfaff ²⁶⁸	1756	
Berdmore ⁴¹⁷	1768	
Hunter ²⁶⁹	1778	

Table 4 continued on page 54

Table 4 continued from page 53

Heister ⁴¹⁸	1724	Managed chronic sinus tracts by opening them, cleaning them out or burning them out
Harris ⁴¹⁹	1839	Used a lancet or sharp bistoury-pointed knife to puncture a tumor of the gums to release the pus
Desirabode ⁴²⁰ and Magitot ⁴²¹	1843 and 1860–1870	Claims made as to being the first to perform root-end resection
Hullihen	1845	Surgical trephination through the soft tissue, bone, and into the pulp chamber to alleviate a congested pulp—“Hullihen Operation”
Bronson ⁴²²	1866	After applying carbolic acid to the gums, one perpendicular slit and one transverse slit was made in the overlying tissues and an engine drill was used to drill directly through to the end of the root to relieve congestion and effect a discharge of suppuration; this approach was labeled as “barbaric” by FY Clark; approach was also questioned by J. N. Farrar
Smith ⁴²³	1871	Used root-end resection to manage a tooth with a necrotic pulp and surrounding alveolar abscess
Farrar ⁴²⁴	1880	Performed a procedure on abscessed teeth referred to as an “apicotomy”
Martin	1881	Claimed by some to be the inventor of root-end resection to manage draining sinus tracts
Dunn ⁴²⁵	1884	Amputated “fangs” using a tubular saw to enter the jaws removing the diseased soft tissue and root end
Farrar ²²⁹	1884	Recommended the radical removal by amputation of any portion of roots of teeth that were of not further use
Black ²³⁰	1886	Recommended the amputation of the apex of the root of any teeth in the case of long-neglected abscess
Younger ²³³	1886	Reiterated Hunter’s opinion on the need for a vital periodontal ligament following replantation
Grayston ⁴²⁶	1887	Used cocaine anesthesia in the surgical management of an alveolar abscess
Fredel ²⁷⁴ and Sheff ²⁷⁵	1887 and 1890	Initiated animal experiments to address the role of the periodontal ligament (referred to as the periosteum) in the resorptive process (referred to as adsorption)
Rhein ²³¹	1890	Recommended complete root amputation as a radical cure for a chronic alveolar abscess
Ottolinguì ⁴²⁷	1892	Presented a succinct technique for the immediate filling of a root canal followed by the resection of the root apex
Rhein ³¹²	1897	Describe surgical treatment for the management of the alveolar abscess, including marsupialization
Partsch ^{428–430}	1895–1900	Credited with the methodical development of “Wurzelspitzenresektion” (root-end resection) first under chloroform anesthesia and later cocaine anesthesia; credited with packing the surgical cavity with iodoform gauze (Partsch I operation) and tissue reapproximation with suturing (Partsch II operation)

characterized as both progressive and regressive. While tremendous strides were being made by the European and American dental professionals in the enhancement and application of endodontic surgical techniques, in all areas of the oral cavity, the very roots of the focus of endodontics and its surgical component were being severely attacked from the ivory towers of the medical profession. William Hunter’s classical presentation “An address on the role of sepsis and antisepsis in medicine,” which was delivered to the Faculty of Medicine of McGill University in Montreal, in 1910, and published in London in 1911, initiated the conflagrations of “focal infection,” a concept whose burning embers are still smoldering in multiple bastions around the world.²⁰ Before this indictment, how-

ever, surgical advances and diversified applications marked the entry of endodontics into the twentieth century.

On the heels of Partsch’s achievements in the late 1800s and early 1900s (Figure 9), many European clinicians assumed the challenges of the *Wurzelspitzenresektion* procedure, and because of the clinical success attained, the concept of focal infection did not impact greatly on these surgical practices on the European Continent. German and Austrian authors such as Fischer, Mayhofer, Euler, Williger, Fryd, Kersting, Knoche, Witzel, Metz, and Hermann had a tremendous impact on the development of surgical endodontics. In 1908, Béal published a technique article on “*résection de l’apex*” (root-end resection) and, along with case reports, highlighted the

Figure 9 Semilunar incision on the buccal mucosa as promulgated by Partsch in the late 1800s. From Berger A. *The Principles and Techniques of Oral Surgery*. Brooklyn: Dental Items of Interest Publishing Co.; 1930.

development of endodontic surgery in France.⁸⁷ Roy in 1925⁸⁸ and La Cronique in 1927⁸⁹ are often credited with the classic articles in France that addressed “*le curettage apical*” and “*amputation de l’apex*.” Both authors clearly presented detailed surgical indications and techniques to manage “*lesions radiculaires*.” In 1930, Duclos⁹⁰ compared techniques of simple drainage in the case of a periradicular abscess with those of complete root-end resection. In 1934, he presented detailed methods on the management of the apical portion of the canal following resection, favoring a circular preparation in the long axis of the root for the placement of amalgam.⁹¹

Some of the first and most important publications in Eastern Europe were from Czechoslovakia in 1913 by Bažant⁹² entitled “*Resection radialis*,” in which the indications for root-end resection are clearly outlined and detailed, and by Šmelhaus in 1916, who reported on his extensive experiences with periradicular surgery.⁹³ Later investigations by Kostečka⁹⁴ discussing causes of failure and the psychological aspects of the surgical procedure for the patient, and a text by Měšťan in 1937, covering all aspects of periradicular surgery,⁹⁵ served as the benchmark for “*resekci kořenového hrotu*” (resection of the tip of the root) in Eastern Europe for the next 40 years.

The continued development of surgery on the European Continent led to the publication of some

significant and detailed articles, monographs, and texts devoted to extensive coverage of all surgical concepts, especially molar surgery. The first of these was by Faulhaber and Neumann⁹⁶ in 1912, entitled *Die chirurgische Behandlung der Wurzelhautrekrankungen*, in which the authors combined both theoretical concepts and clinical techniques. They provided an extensive description of surgical armamentarium, anatomical considerations, and specific techniques used to gain surgical access to various portions of the oral cavity and a description of the use of amalgam as a root-end filling material.

In 1915, Neumann⁹⁷ focused strictly on lower molar surgery in his monograph entitled *Die Wurzelspitzenresektion an den unteren Molaren*. As today, there was considerable concern over the inferior alveolar canal, mental foramen, and their vital contents. Neumann provides the first detailed anatomical description of the relationships of the mandibular roots to both osseous and neurovascular structures and related these to periradicular surgical procedures. A uniting and expansion of these surgical concepts occurred in a 1921 publication of Faulhaber and Neumann’s second edition of their 1912 text.⁹⁸ In 1926, Neumann published his *Atlas—der radikal chirurgischen Behandlung der Parodontosen*, which dealt primarily with the surgical management of periodontal disease.⁹⁹ However, he proposed a split thickness surgical flap, which in design is known as the modern day Oschenbein-Luebke flap used in root-end resection (Figure 10).

Otto Hofer, from Vienna, provided a thorough review of surgical flap designs in his 1935 extensive treatise entitled “*Wurzelspitzenresektion und Zystenoperationen*,” a paper he presented in Prague in 1934.¹⁰⁰ Hofer provided detailed descriptions of anterior surgical entries according to Csernyei,^{101,102} Pichler,¹⁰³ and Wassmund,¹⁰⁴ which addressed not only root-end resection but also the Partsch I approach to soft tissue flap design and cyst management, as modified by the latter two clinicians into a “*periostalplastischen*” approach (split mucosa and periosteum). Once the cystic contents are removed and root ends managed, the flaps are split and layered into the osseous cavity with the anticipation of providing drainage and stimulating an internal to external granulation closure. While Pichler’s and Wassmund’s flap designs were “*periostalplastischen*” in concept, Csernyei’s approach was considered as “*osteoplastischen*” in nature, in which the bone and periosteum are elevated intact and separate from the mucosa. In Csernyei’s “*Operationsschema*,” which is a modified Partsch II procedure, a plate of bone is loosened

Figure 10 Neumann's depiction of a surgical flap in the attached gingiva that resembles the contemporary Oschenbein-Luebke flap. From Neumann R. Atlas—der radikal chirurgischen Behandlung der parodontosen. Berlin: Hermann Meusser; 1926.

intact, reflected, and replaced over the “*Wurzelspitzenresektion*” site. Csernyei's observations of healing with this flap design on dogs compared to Partsch's “semilunar” approach without regard to osseous integrity are quite interesting. Histological evaluations provided “a perfect ossification of the apical alveolus after 6 months” with the “*osteoplastischen*” method, whereas only scar tissue was formed with the Partsch technique. Contemporary endodontic surgery also cites scar tissue and healing by secondary intention as a disadvantage to the semilunar incision, especially when the incision overlies the osseous defect. Csernyei's flap design and osseous lid approach is presently in vogue for mandibular posterior teeth, having been further modified as a

“bony lid only,” and is espoused by Khoury as the “*Knochendeckelmethode*.”¹⁰⁵

In 1936, Karl Peter from the University of Erlangen published his landmark text entitled *Die Wurzelspitzenresektion der Molaren*, which has served as the formative text for all contemporary endodontic surgical concepts.¹⁰⁶ Peter's text clearly outlined indications, providing a thorough literature review and historical development of periradicular surgery. Surgical flap designs for posterior teeth were detailed, and anatomical relationships of osseous and neurovascular structures were highlighted. Peter classified the position of the inferior alveolar canal relative to the molar roots, in addition to providing descriptive relationships of the maxillary sinus and its size and position relative to the roots of maxillary teeth.

Concomitantly, Held¹⁰⁷ from Switzerland published an extensive paper on the surgical management of all teeth in the mouth. He provided detailed anatomical considerations, both soft tissue and hard tissue, along with surgical techniques, principals of postoperative management, and guidelines for post-treatment evaluation. By this time, there had been so much input into the evaluation of various soft tissue incisions and flap designs by the multitude of European clinicians that the specific approaches had been labeled as to their inventors, advocates, or modifiers.

Surgical management of the resected root end was also detailed at this time, with the development of specific root-end preparation techniques. In 1914, von Hippel described the vertical slot root-end preparation referred to as the “*Slitsmethoden*,” which was indicated to clean and seal the root canal when a post-core was present.¹⁰⁸ Ruud¹⁰⁹ modified this technique in 1947 adding retentive grooves, while Matsura¹¹⁰ brought this technique to contemporary endodontic surgery in 1962. In the mid-1930s, Schupfer,^{111,112} from the University of Innsbruck, detailed the transverse root-end preparation, which was perpetuated by Luks well into the 1970s.¹¹³ However, either of these root-end preparation techniques may have been practiced prior to von Hippel or Schupfer by Schuster in 1913, with a vertical slot along the facial aspect of the root.¹¹⁴ Variations in the techniques advocated for root-end preparation were necessitated by the difficulty encountered in gaining access to the resected root when only a small amount of bone or root was removed in the

Figure 11 Drawing by Tangerud depicting miniature handpiece for root-end preparation as opposed to a straight handpiece. From Tangerud BJ. Den retrograde rotbehandling ved alveotomi. *Nor Tannlægeforen Tid* 1939;49:170-175.

resection procedure. Tangerud¹¹⁵ noted this problem in 1939 and developed a small (2.5mm high and 4mm broad) handpiece to facilitate root-end preparation (Figure 11).

In 1939, Castenfeldt,¹¹⁶ from Stockholm, published a lengthy treatise on root-end filling and management of chronic apical periodontitis. He focused on residual infection in the resected dentinal tubules as being the major reason for surgical failure. A total seal of the root face with silver amalgam was recommended by removing all dentinal tubules at the resected root face (Figure 12). A bevel was cut in the dentin from the canal orifice to the cemental junction.

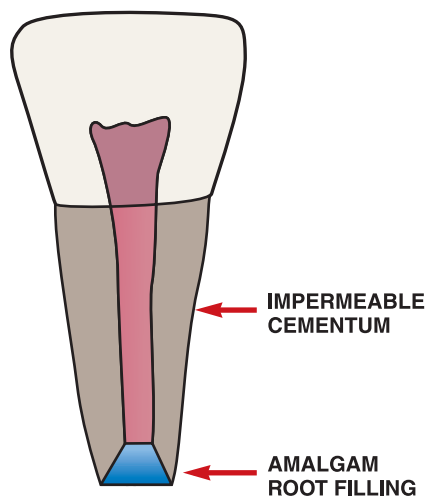

Figure 12 Complete covering of the resected root end as depicted by Castenfeldt. From Castenfeldt T. Om retrograd rotfyllning vid radikaloperation av kronisk apical parodontit. *Sven Tandlök Tidsskr* 1939;32:227-260.

In the United Kingdom in 1927, Fawn from London had strong feelings about the “infection” present in the apical portion of the root with a nonvital pulp.¹¹⁷ While Castenfeldt later indicated the need for a seal of the entire apical root face in these cases, Fawn felt that resection would remove the areas that harbor the bacteria. Fawn discussed the causes of failure of root-end resection and focused on diagnosis. In doing so, he identified a major problem that existed with the use of periradicular surgery and is still present today as the major cause of failure with surgical intervention. “For example, a great many men have grasped this operation as a means of avoiding an awkward situation. A tooth would be treated inadequately; after a lapse of time an abscess would develop. To cover up all possible reflection, root amputation is performed without proper diagnoses. Something of a surgical nature is done, which is eventually followed by failure.”

Ross from England had recommended Castenfeldt’s technique 4 years earlier for managing the exposed dentin.¹¹⁸ His rationale for the complete amalgam closure was that success was to be measured by the “complete seal of the dentin.” He frowned upon the use of silver nitrate to coat and impregnate the exposed dentinal tubules, which was a common practice in the United States at that time. “After removal of the apical third of the root, a rose head burr is inserted into the wound, and a cavity is cut into the exposed dentine in the root. As much dentine as possible is removed, and the root canal is then plugged with a solid coherent amalgam, which fills the canal and seals the end of the root. The operation should be done under strictly aseptic conditions, and the amalgam sterilized before being used...copper amalgam...has antiseptic properties, and further does not act as an irritant to the apical tissues.”

Histological evaluation of root-end resections commenced with the studies of Bauer,^{119,120} Euler,¹²¹ and Kronfeld¹²² in the 1920s. Cavina¹²³ from the Universities of Padua and Bologna in Italy published a lengthy paper on the indications, techniques, and results of “*l’amputazione degli apici delle radici dentali*” in 1930. In this paper, he was one of the first to discuss and relate to clinical procedures the histological findings of Bauer, Euler, and Kronfeld in the evaluation of healing of the periradicular tissues following surgery. Further studies at that time that addressed the healing of periradicular tissues and provided excellent histological data regarding the regeneration of the cementum and periodontal ligament were those of Gottlieb,^{7,124} Steinhardt,¹²⁵ Häupl,¹²⁶ Takács,¹²⁷ and Herbert.¹²⁸ As stated by Gottlieb, “When a root end is amputated, we expose

the surface of a transverse section of the root. The cavity caused by the operation is filled in with organized connective tissue and the root surface is embedded into this. As a rule, the wound caused by the operation heals . . . and it is likely that the exposed dentinal surface . . . may be covered, with or without resorption, by secondary cementum which may or may not unite with the surrounding bone; or the dentinal surface may be simply tolerated by the adjacent connective tissue, without having an influence of any consequence upon the environmental tissues.”

From 1925 to 1935, there was a keen focus on the process and longitudinal evaluation of “Wurzelspitzenresektion” from the Ludwig-Maximilian University in Munich. Multiple university dissertations under the primary direction of Professor P. P. Kranz addressed all aspects of root-end surgical procedures.^{129–134} Endodontic surgery on the European Continent had expanded, developed, and weathered the storm of focal infection that plagued the American dental profession. Not that the European community was immune to this concept, as focal infection was a serious focus of attention in the late 1930s and early 1940s relative to “Wurzelspitzenresektion.” Fischer¹³⁵ and Wassmund¹³⁶ from Germany, Kostečka¹³⁷ from Czechoslovakia, and Gaerny¹³⁸ from Switzerland published key articles addressing the concepts of focal infection, relating them to the practice of surgical endodontics. Although mixed feelings prevailed, the use of periapical surgery continued as a major component of dental practice in Europe.

During these four decades, the development of periapical surgical concepts and techniques flourished and vacillated in the Americas. Early reports by Moorehead¹³⁹ in 1903 and Schamberg¹⁴⁰ in 1906 focused on the use of the Partsch I approach to root-end resection in which the “roughened” (resorbed) and associated periodontal membrane was removed with a bur (fissure, round, or rosehead), the root edges smoothed, and the cavity packed with iodoform or carbolated gauze for drainage. The patient would return for multiple visits until complete granulation of the cavity was observed. Schamberg provided a detailed, diagrammatic description of the technique used for root-end resection, errors commonly encountered in these procedures. “The operation that I advocate consists of a rapid ablation of the diseased area including the end of the root by means of a swiftly running bur.” Ironically, the errors identified by Schamberg in resection are commonplace in contemporary surgical treatment. Schamberg also recommended root canal obturation subsequent to surgery, whereas Hartzell encouraged it prior to

root-end resection for technical reasons.^{141,142} “To succeed in this work, make the root-canal of the affected tooth as nearly sterile as possible, and fill it with chloro-percha and gutta-percha points . . . (prior to anesthesia and surgery). Always put in the root canal filling first, because if you cut off the root tip first it would be difficult to make a successful root filling; but if you fill the root canal first and then cut off the root tip, you will have a clean, oval surface.”

Hartzell’s technique for root-end resection was succinct, especially the procedure for locating the root tip. This approach was prompted by the high cost of radiographs that he felt precluded the advantage of the operation for many of his patients. “Now, you can judge where to make this opening by having explored your root canal with a slender instrument, and with the finger ends located the root end as nearly as you can, and then measured the depth of the root canal with your root canal plugger or broach. Then draw that out and lay it upon the tooth and estimate in the gum tissue about where the opening should be.”

He also emphasized the need for a smooth root end to prevent future irritation in the surgical site. Hartzell’s failures were “a trifle less than seven percent in three hundred and fifty-one cases treated in this way.”¹⁴¹ However, he only included teeth without “pyorrhea.”

Buckley^{143,144} indicated that surgical intervention was necessary for those teeth “where the medicinal treatment has failed.” “The success of the operation depended on the thoroughness of the procedure. A vertical incision was used over the tooth, or a circular incision was indicated with two or more teeth . . . a vertical incision is made about one-half of three-fourths of an inch in length, direct over the affected root . . . A bistoury (scalpel) is used for this purpose and care should be taken to make the incision as high as possible . . . so that it stops about on a line with the floor of the necrotic area.”

In designing a surgical tissue flap, Brophy,¹⁴⁵ in 1915, cautioned the surgeon not to impinge on the free gingival margin, in essence negating the use of a full mucoperiosteal flap. “In the management of such an abscess, as in the treatment of all of the infectious diseases involving the gum tissue, it is essential that the continuity of the border of the gum be not divided. A division of the tissues at this point may lead to a recession and exposure of the neck of the tooth . . .”

Bone chisels and mallets were used by Buckley¹⁴⁴ to resect the root, which was a recent suggestion by Schamberg.¹⁴⁰ It was essential to remove the apex to

the coronal depth of the periapical lesion. The root edges were smoothed and the cavity packed with iodoform gauze.

In 1913, Reid provided the dental literature with multiple articles on the trials and tribulations of root-end resection.^{146–148} Techniques of resection with several burs were elucidated after root canal obturation. "...I would first use a diamond shaped drill, passing it through the root and succeed this with a fissure bur, cutting both ways until the end is severed from its parent. Final smoothing of the roughened end left by the bur can best be done with a fine Arkansas stone." He also cites root-end resection as the panacea for the fractured instrument beyond the root apex. "In glancing over the contents of one of our leading dental journals recent issue I came across a short article on root amputation, recommending the operation as a recourse for the removal of broken broaches or drills left protruding through the apical foramen. I prophesy that but few dentists have escaped this perplexing calamity, and those who have happened to meet with such a misfortune may possibly find this suggestion a panacea for such subsequent difficulties." Even though an advocate of this technique, Reid questioned the long-term success of his "partial root amputations," as he doubted the regeneration of the periodontal ligament. "So far as my knowledge goes, there is no evidence that the membrane is ever renewed, and if such as a fact, I feel confident we can never hope to be able to save partially amputated roots for any great length of time...."

For 6 years, from 1915 to 1920, the dental literature was besieged with articles written on root-end resection.^{149–171} The use of the "crescent shaped" or semilunar incision was standard, as was sealing the gutta-percha at the root apex with a hot burnisher after resection on a root-filled tooth, or after resection and the pulling of a gutta-percha cone through the apical foramen. Zinc oxyphosphate was commonly used as a sealer with gutta-percha.

The placement of amalgam root-end fillings was becoming an acceptable procedure at that time. Garvin from Manitoba, Canada, "had the privilege" of seeing this technique performed by the Dean of the Dental School from Oslo, Norway, Dr. Immanuel Ottesen.¹⁷² "An incision was made, the soft tissues were retracted, the alveolar bone over the apex removed with a chisel, the end of the root amputated and the area curetted, an amalgam filling inserted in the apex, an antiseptic placed in the wound and the tissues sutured at the line of incision."

In a series of articles from 1916 to 1919, Lucas indicated that he first polished the resected root

end and then prepared a self-retentive cavity with a small bur in the root end for the placement of an amalgam.^{151,157,167} In cases of the mandibular teeth, he had the referring dentist fill the entire canal with copper amalgam prior to surgical resection because "it is practically impossible to fill the remaining end of the canal after the apical end of the root is cut off." However, he did not recommend the use of copper amalgam in the maxillary teeth due to the potential of staining of the root structure.

In 1917, Ivy¹⁵² and Howe¹⁵³ recommended the sealing of the apically resected tubules with silver nitrate. "By this means we believe the open tubuli of the bare root end are sealed, and any bacteria in them prevented from emerging."

In 1918, Prinz,¹⁵⁶ influenced significantly by Partsch and other European clinicians, presented a paper on the techniques of root-end resection. His procedures of incision, flap design, and management of presumed cystic lesions were reflections of the then advocated German techniques. His influence was to have a significant impact on the practice of endodontic surgery in the United States over the next 40 years (Figure 13).

In an attempt to disclose some of the problems perceived with the practice of root-end resection or apicoectomy and to highlight some personally advocated advantages of replantation, Edmund Kells, in 1918, lashed out at the perpetrators of sloppy techniques accompanying dramatic presentations of surgical expertise.¹⁵⁸ "It is undoubtedly safe to say that the operation of apicoectomy is quite 'the thing' nowadays, and is, in fact, a fad with many up-to-date operators. It is to be seen at clinics, in the 'movies,' and, taken all in all, is always most interesting to see, staged as it usually is with the accompanying dramatic accessories of *so called* asepsis. But, 'coming down from the clouds,' as it were, will the operation, as usually performed and as *invariably seen* by the writer, stand analysis, and how will it compare with the apparently neglected operation of replanting for the accomplishment of the same purpose?" Undoubtedly, Kells was influenced not only by the need for quality care and proper case management, but also by the pressures of the focal infection theory, which had gained significant momentum in the second decade of the twentieth century, and which was about to explode on the dental scene in the 1920s. After expounding on his technique of replantation, he arrives at two conclusions in his diatribe: "(1) The conditions to be found within the root-canal and beyond the root end must necessarily be and are infinitely better after replanting than after

Figure 13 Schematic drawing of cyst management according to Prinz. Left to right upper diagrams, access is gained with tissue flap retracted; Lower left, the cyst is removed and the root end is resected to the base of the cavity; Lower right, the cavity is packed with iodoform gauze to stabilize the flap internally. apicoectomy (2) That whenever a tooth or root can be extracted without injury to itself, there can be but one choice between the two operations.”

At that same time, Arthur Smith of Rochester, New York, reported on a survey of eight questions on root-end amputation sent to prominent clinicians and authorities at that time.¹⁶⁰ On April 22, 1918, Dr. Carl Grove responded to Dr. Smith’s first question thusly: (Question: Do you consider the root amputation in any case?) Dr. Grove’s response was as follows: (author’s entries in square brackets) “My dear doctor, As I am no longer a believer in apiectomy I do not think it is necessary for

me to answer your questions, but I shall endeavor to state briefly why I believe these operations are a failure. In my opinion the percentage of successful cases of root amputations [apical resections] is extremely small. I question very much if there is ever a normal regeneration of bone following these operations; at least I am convinced from the investigations I have made that an attachment of tissue to the root end never takes place, which is, I believe, the chief cause for the failures. I do not regard radiographs as being conclusive evidence, as it is not possible to disclose minute changes or disease tissue that may exist, neither is it possible to determine

by radiograph if there is a regeneration of bone in the rarefied area or if dense around the rarefied area has resulted from the activity of the osteoblasts in the deposit of osseous tissue in the cancellous portion of the bone. These results can be produced by the stimulating of the osteoblasts by the use of certain remedies. Trusting this will explain my position regarding the question, and answer your inquiry, I am Yours very truly, Carl J. Grove." [The full concept of regeneration as we know it was not detailed¹⁷³; however, the issue of attachment vis-à-vis Sharpey's fibers from the periodontal ligament into newly formed cementum does appear to be understood by Dr. Grove, along with bone regeneration.]

Controversies also existed at this time with the use of a chisel versus a bur to remove the root apex. Silverman was a major advocate of the chisel¹⁵⁹ as would be Mead in the 1930s and 1940s.¹⁷⁴ Silverman's rationale was as follows. Silverman referred to the chisel technique as "heat-less, quicker, cleaner and generally more convenient."

During this era, attention to surgical armamentarium was at its peak, with each surgeon or author advocating or inventing a "better mousetrap." However, one piece of equipment that was commonly used was the Killian headband, modified for root-end resection (Figure 14). This apparatus freed the operator to work in an unimpeded environment. Coupled with the "Schutzlaken" or surgical shield or drape as suggested by Witzel according to Partsch,¹⁷⁵ and demonstrated by Silverman in conjunction with the head band, the patient was "efficiently" treated in a "presumed" aseptic environment.¹⁵⁹

At the beginning of the third decade of the twentieth century, the full impact of the focal infection theory had caught up with periapical surgery. Proper diagnosis and asepsis were demanded and more often than not extractions were the treatment of choice. However, a few brave surgeons persisted, focusing the objections to periradicular surgery on its use by the unqualified dentist, rather than on the merits of the surgical procedure. "Faulty dental work is very often traceable to the routine slovenly habits of the dentist who has no more than superficial smattering of science and art."¹⁷¹

Technique articles in the 1920s by Berger,¹⁷⁶ Ruggier,¹⁷⁷ Moorehead,¹⁷⁸ Kay,¹⁷⁹ Beavis,¹⁸⁰ and Posner¹⁸¹ focused on similar techniques advocated from 1915 to 1920 with minor variations. Semilunar incisions were the *modus operandi* (Figures 15 and 16) although triangular flaps were beginning to appear; the use of the mallet and chisel to resect the apex was being replaced with the cross-cut fissure bur; root apices were cut to

Figure 14 Patient wearing a "Schutzlaken" or surgical drape and Killian head band as depicted by Silverman. From Silverman SL. The status of apicoectomy. J Nat Dent Assoc 1918;5:255-263.

the base of the osseous lesion favoring a transverse cut as opposed to an angular cut; silver nitrate on the resected root surface had both proponents and opponents; the use of a hot burnisher at the apex was used sparingly; if any clinical evidence of "infection" was noticed a partial suturing technique with drain was advocated; and recall evaluation every 6 months was considered essential. Posner,¹⁸¹ in an attempt to enhance the acceptance and practice of periapical surgery, even went to the extent of minimizing the perceived difficulty and need for special expertise required to efficiently and effectively perform these procedures.

In 1924, an article by Blayney and Wach¹⁸² was published, which was "purely of academic interest," but it opened the doors for future investigation and challenge as to the exact nature of periradicular tissue repair following root-end curettage and resection. They showed that

Figure 15 Successful healing with cemental apposition along the resected root surface. From Coolidge ED. Root resection as a cure for chronic periapical infection: a histologic report of a case showing complete repair. *J Am Dent Assoc* 1930;17:239-249.

Figure 16 Weaver's "open window" surgical entry for periradicular curettage. From Weaver SM. Window method of periradicular curettage. *J Endodontia* 1947; 2:4-5.

the periodontal ligament would heal and new cementum was deposited on the resected dentin. Boulger¹⁸³ later, in 1928, showed that healing can occur over fractured root ends and exposed dentin. These case reports paralleled the findings of Bauer,^{119,120} Euler,¹²¹ and Kronfeld¹²² in Europe and led to closer scrutiny of healing responses as the next decade commenced.

Multiple investigations by Coolidge,¹⁸⁴ Blum,^{185,186} Hill,¹⁸⁷ and Aisenberg¹⁸⁸ in North America and Garcia in South America¹⁸⁹ showed that healing will occur at the root apex with the layering of new cementum and the reestablishment of periodontal ligament fibers (see Figure 15). However, case numbers were few in these investigations and, while the impact of these on the concept of focal infection was initially minimal, it served as a continuing spark for those surgeons and academicians committed to total endodontic care and tooth maintenance.

Surgical practices in North America in the 1930s did not undergo major changes, and approaches to root apices, as outlined and depicted by Berger, were to be used routinely over the next 40–50 years.¹⁹⁰ Silver nitrate was commonly used and would be well into the 1940s, as was the iodoform gauze drain.^{191,192} Gutta-percha was being placed with a sealer of zinc oxide-eugenol, and a hot burnisher was still the preferred treatment to smooth over the resected apex and perfect the seal.¹⁹³ However, a significant change in the root canal obturation technique in the 1930s was to have a lasting impact on not only non-surgical treatment but also surgical treatment and retreatment. While previous work had been done on the use of silver cones for root canal fillings in Germany, E. A. Jasper^{194,195} introduced the use of standardized silver cones for canal obturation in 1931. This single event not only would polarize the dental profession, but also would lead to multiple controversies and misconceptions in treatment. Its impact on periapical surgery is still with us today and, with the advent of multiple retreatment procedures, there has been a renewed interest in developing a compatible root-end filling material that can be placed against those silver cones that cannot be non-surgically removed.

Surgical endodontics began to receive greater attention in the 1930s in the South American countries.^{189,196–199} Coupled with input from Spain²⁰⁰ and influenced heavily by the work of the Germans, the root-end resection technique had gained acceptance in multiple professional Latin American countries. However, some peculiar differences did exist in surgical management. For example, pastes made of zinc oxide were being placed in the bony cavity and left there while granulation and osseous fill occurred.²⁰⁰

In 1935, Ries Centeno and Gietz^{197,198} published multiple articles on a comparative study of the methods of “apicectomy” as performed by leading professionals from South America and Spain. Questions to these leading authorities focused on types of anesthesia, flap design, methods of osseous entry, methods of root-end resection, pre-resection or post-resection canal obturation, materials used for obturation, experience with silver cone fillings, methods of obturation with canals presenting with posts, and the nature of surgical flap and cavity management after root-end resection. As would be expected, controversies existed in all areas of case management based upon the responses of the questioned individuals. Flap designs ranged from the semilunar to angled flaps in the attached tissue or at the free gingival margin, to an “S”-shaped flap design. Most clinicians had no experience with the filling of root canals “*con los conos de plata*” (with silver cones). Gutta-percha was the accepted canal filling material with some form of softening agent or paste, and amalgam was the apical filling of choice in properly prepared root-end cavity. “For the properly prepared retentive root-end cavity we use amalgam only...in cases of canals that are obstructed amalgam is placed at the end of the root... for root amputation amalgam is used.”

One of the contributors, Dr. Fernando Garcia from Buenos Aires, indicated an equal choice between amalgam and zinc oxide-eugenol.¹⁸⁹ This was one of the first indications of the use of zinc oxide-eugenol, by itself, as a root-end filling material. Interestingly, many of these same differences of opinion and controversies in practice exist today because the true biologic foundations of surgical endodontics are only now being explored with a serious purpose and intent.

Although small groups of surgical advocates and courageous individuals who believed in the tenets of quality endodontic therapy continued to pursue endodontic surgery, they did so under the shroud and pressure of the focal infection theory. Extractions were the treatment of choice for pulpless teeth. An editorial appeared in 1928²⁰¹ that was a stance adopted by a group of leading dental practitioners who believed that needless extractions were contraindicated and properly diagnosed, and executed root canal treatment would be as successful “as any other surgical procedures of similar exacting nature.” The serious nature of this editorial highlights the impact that William Hunter’s presentation in 1910 had upon the medical and dental profession.⁴⁴

During the next 20 years, the dental literature produced a scant number of articles on endodontic surgery as compared to the previous two decades. Attention was focused on specific innovative or efficient techniques in case management because they

facilitated the conservation of pulpless teeth during the exigencies of a period of world-wide aggression.

Between 1941 and 1950, Cyrus Jones from New York published multiple papers on the use of apical surgery in an expedient manner, primarily related to its use in the military setting.^{202–204} “The present national emergency and the lack of spare time for the conscript patient and dentist lead us to present the following paper. Twenty-three years ago the writer was stationed in England at Codford Wilts on Salisbury Plains. Each day an aero squadron passed through that camp on its way to the front. It was the last stepping off place, and as such a critical inspection of all units was the order of the day. Examinations were made of the equipment of each individual, who also received a thorough medicodental examination. With the help of two sergeants, both dentists, an early morning examination was made of every mouth. Hopelessly diseased teeth and roots were marked for extraction. Sedative fillings with cement were later placed in teeth which had good potentialities. Amalgam fillings, where cavities were not too extensive, were also placed. Then came the problem of what to do with infected anterior teeth. Most of the men did not mind losing posterior teeth, but the thought of losing a front tooth was abhorrent for these young soldiers.”

It was this set of circumstances that led Jones to recommend the one-visit root canal treatment followed by surgical curettage. He used chloroform at the apex to soften and dissolve the excess gutta-percha, “making a perfect joint and complete canal filling.” Jones also advocated the use of antibiotics in the surgical site as would many other authors in the era. His rationale for this approach was “this technique is bold, unorthodox, and alien to all accepted procedures, but it works,” especially in light of the frustration that plagued many unskilled dentists in their attempts to perform adequate non-surgical treatment. “In closing we will say that if a putrescent root canal may be filled perfectly at one sitting and the pathological effects of that tooth removed at the same time by means of a little oral surgery, why waste our time and energy and the patient’s time by trying to treat an enormously infected area through at tiny apical foramen. It’s like trying to put out a forest fire with a water pistol.”

Later papers by Shapiro and Masters²⁰⁵ in 1943 would also address the need for expediency in the management of infected anterior teeth in the military setting.

The post-resection filling technique, as described by Mead¹⁷⁴ in 1934 and Federspiel²⁰⁶ in 1936, was an alternative and popular way of managing roots at this time and was supported by Phillips and Maxmen,²⁰⁷

Droba,²⁰⁸ Wakefield,²⁰⁹ Shapiro and Masters,²⁰⁵ and Smith and Stevens.²¹⁰ Grossman²¹¹ also provided details on this technique but he generally favored the technique of Jones. Droba performed surgical curettage followed by a through and through root canal obturation technique. He used eucalyptol, as did Shapiro and Masters, with the gutta-percha for better adaptation in the canal, followed by removal of the excess at the apex with a warm instrument. Eckes and Adams also supported this technique of filling through the root but, instead of eucalyptol, used zinc oxyphosphate cement as the sealer with gutta-percha.²¹² Smith and Stevens used a zinc oxide-eugenol-iodoform injection filling technique.

During this period, more attention was focused on surgical curettage and total eradication of the soft tissues surrounding the root. Weaver developed his "open window apical curettage" method using a vertical incision down the long axis of the root^{213,214} (see Figure 16). Root canals were obturated first so that more "collateral canals will . . . be filled." He emphasized thorough curettage, especially palatal to the root. The actual procedure of root-end resection in conjunction with curettage was frowned upon except when resorption was present. There were major concerns that root reduction would weaken the tooth and reduce the amount of viable periodontal ligament attachment.^{213,215} Also, root-end resection may stimulate a resorptive process or create a source of continued periradicular irritation by opening the "infected dentinal tubules."²¹⁶ "There is no supporting logic for resection or amputation of the root unless it shows signs of absorption. Amputation of the root is objectionable since it merely reduces the leverage and strength of the tooth and opens up fresh dentinal tubules."

However, Sommer was not as concerned with the exposed dentin, even if infected, but rather with the leakage from the root canal.²¹⁴ ". . . so long as the porous apical third is removed, the risk of future infection after a root resection lies much more in leakage from the root canal than in retained infected dentin."

When root-end resection was performed because of resorbed root ends²¹⁷ or blocked canals, they were often coated with silver nitrate to address the patent dentinal tubules.²¹⁸ Wedendal²¹⁹ recommended a vitallium-type cap that was fabricated to be cemented over the entire resected root surface. Other authors were beginning to alter previous opinions regarding the amount of root structure that should be removed. Instead of removing the root to the base of the osseous lesion, only a small portion of the root tip was removed. This was a revolutionary concept in periapical curettage and a smoothing over or rounding-off of the apex as a popular procedure. Eventually, curettage was to be considered as a

terminal procedure, one that failed many times because the source of irritation in the poorly managed root canal system was not addressed.

An additional concern with the resection of the root end was the inability of the periapical tissues to form cementum over the exposed dentin. Even though this possibility had been shown in the 1920s, it still had a group of "doubting Thomases." However, histologic studies in the 1940s continued to show the presence of well-layered cementum on resected dentin with the formation of healthy connective tissue attachment.^{217,220} Herbert's²²¹ observations on the reformation of cementum on resected dentin with chronic inflammation over the root canal filling material were especially pertinent to the concerns of many practitioners, who were so concerned about infected tubules that they may have missed the true essence of what is necessary to achieve success with root-end resection. "Such inflammatory reaction as remains in connection with these teeth is strictly limited to the tissues immediately adjacent to the apical end of the root canal filling and is not found in association with the cut surface of the dentine, which shows evidence of repair over most of its surface. This suggests that so long as the porous apical third is removed the risk of future infection after root resection lies much more in leakage from the root canal than in retained infected dentine."

The use of root-end preparations and root-end fills with amalgam was supported by Gaerny,¹³⁸ Garvin,¹⁷² and Luks²²² as the most successful way to manage the end of the root canal system. "As stated in 1916, we are still of the opinion that root resection has a place in the general practice of dentistry and that in performing this operation it is preferable to place an amalgam filling in the apex of the tooth."¹⁷⁷

In 1958, Messing²²³ reintroduced the use of amalgam for the filling of the root canal prior to root-end resection, a technique reported by Lucas in 1916.¹⁵¹ Messing was concerned with changes that occurred at the root apex when gutta-percha was resected and felt that a hot instrument was insufficient to rectify the aberrations of the gutta-percha dentin interface. "However, when the apex is resected one may be faced with a serious problem; the rotating blades of the bur tend to pull the gutta-percha away from the walls of the canal thus creating a defect. This has been found to occur when a mesio-distal cut is made, or when the apex is planed away in a coronal direction with a rosehead bur. It is not always possible to correct this defect by touching the end of the point with a hot instrument and compressing it into the canal." He also developed a specific amalgam carrier for the placement of the material deep into the apical third of the root. Ironically, this instrument has

stood the test of time, known as the “Messing Gun” and is routinely used today for the placement of root-end amalgam fillings.

Sommer²¹⁸ and Eklof²²⁴ advocated the use of a reverse silver cone placement if access to the canal could not be obtained through the crown and the canal had not been previously filled or was poorly filled.

In 1951, Everett²²⁵ published a case report on the management of a non-vital maxillary lateral incisor. Root canal treatment and root-end resection were performed. Postoperative evaluation at 9 months revealed an asymptomatic tooth, with a relatively normal periodontal ligament space and nearly intact lamina dura. However, several millimeters apically there appeared a “well defined radiolucent area, giving the impression of a residual cyst.” Three years later, the findings were similar and an exploratory surgical procedure was performed. As is commonly recognized today, Everett was describing the presence and persistence of scar tissue following periradicular surgery due to the position of the root apex of the lateral incisor relative to the palatal cortical plate of bone. This entity is of no clinical importance unless it is inflamed.²²⁶ Previous identification of this type of lesion had been extremely limited²²⁷ and it would be over 20 years before further in-depth investigations of this finding would appear in the literature.²²⁶

In 1959, Maxmen²²⁸ published a lengthy paper entitled “The expanding scope of endodontics.” This paper went far beyond previous publications in highlighting the full scope of periapical surgery, in addition to emphasizing the uniqueness of this aspect of dentistry. With great foresight and experience, Maxmen dispelled the concept that for so many years had been sacrosanct in the United States, but not necessarily in Europe: that apical surgery was limited to anterior teeth or maybe an occasional single-rooted premolar. However, he did caution those choosing to do posterior surgery. “These procedures should not be undertaken unless the operator is well trained in surgery, asepsis, and careful handling of tissue, and has a good working knowledge of the local structures.” Not only is this paper to be considered as a classic article that would have a lasting impact on periapical surgery, but it also had an immediate impact on the solidification of the concepts of endodontic therapy, both non-surgical and surgical, that would in a few years serve as the basis for the approval of endodontics as a distinct specialty of dentistry.

With reference to surgical root or tooth resections, in 1884, Farrar²²⁹ reports 9 years of successful “radical removal by amputation of any portions of teeth that can be of no further use” (Figures 17 and 18).

Figure 17 Farrar’s initial description of managing an alveolar abscess by drilling through the cortical bone. If this were not possible, oftentimes a root would be resected as seen in Fig. 18. From Farrar JN. Radical treatment of alveolar abscess. *Dent Cosmos* 1880;22:376-383.

Figure 18 Farrar’s diagram of root-end resection of a palatal root. From Farrar JN. Radical and heroic treatment of alveolar abscess by amputation of roots of teeth. *Dent Cosmos* 1884;26:79-81.

Figure 19 **A**, Diagram of palatal root exhibits extensive "pyorrhea alveolaris" or periodontal disease. **B**, Tooth following root resection and osseous repair. From Black GV. Amputation of the roots of teeth. In Litch WF. The American System of Dentistry. Philadelphia: Lea Brothers; 1886.

Black²³⁰ in 1886 (Figures 19 and 20), Rhein²³¹ in 1890, White²³² in 1893, Younger²³³ in 1894, and Walker in 1895²³⁴ were also among the first to use this heroic procedure to eliminate roots chronically involved with "pyorrhea alveolaris" or "chronic abscess." Since then, the endodontic, periodontic, and surgical literature is replete with publications that support the use of resective procedures for furcation pathosis, horizontal and vertical fractures, excessive bone loss, non-restorable tooth structure, unfavorable root proximity, impaired endodontic management of the root canal, dehiscence, fenestration and root sensitivity, impaired prognosis of adjacent teeth, and resorptive and perforative defects. Historically,

Figure 20 Diagram of root resection on a mandibular molar advocated by Black. From Black GV. Amputation of the roots of teeth. In Litch WF. The American System of Dentistry. Philadelphia: Lea Brothers; 1886.

resections have received a wide range of creative and variable terminology, such as radisectomy, rhizectomy, odontic trisection, tooth separation, amputodontology, radectomy, root resection, odontosection, bisection, dissection, bicupidization, odontogenous resection, and tooth sectioning, with the commonly used terms of root amputation and tooth hemisection.²³⁵

One of the more interesting historical aspects of resections is the use of this procedure in teeth with vital pulps. This procedure was often used when the determination of the exact nature of the osseous destruction around a root could not be determined.²³⁵ Sternlicht²³⁶ is credited with initiating this approach to treatment, and other authors have reported on the use of this technique with long-term clinically successful follow-ups on both maxillary and mandibular teeth.²³⁷⁻²⁴⁴ However, following vital root resections, internal resorption, pulpal inflammation, and pulp necrosis have been reported.²⁴⁵⁻²⁴⁹ The long-term histological studies of Haskell,²³⁷ Haskell and Stanley,^{238,239,241,242} and Smuckler and Tagger²⁴⁰ have however supported this technique in selected cases.

ROOT REPAIR PROCEDURES RELATED TO PATHOLOGIC OR ODONTIATROGENIC PATHOSIS/DAMAGE

Radicular perforations have always been regarded as serious complications in the dental practice and from

a historical perspective most likely resulted in tooth extractions in the majority of cases. These types of defects, whether of pathologic or mechanical origin, often required a creative approach to management.

In 1893, the problems of managing root perforations were being addressed.^{250,251} Evans²⁵² discussed management of radicular perforations “below the line of the edge of the alveolar process” admitting that successful treatment is rare. In 1903, Peeso²⁵³ recommended various treatment modalities for apical, middle, and coronal perforations.

1. Apical—fill as is and, if symptomatic, handle as an alveolar abscess, that is, root-end resection.
2. Middle—force a softened gutta-percha plug into the root and remove it to ascertain the extent and nature of the perforation; then fasten the plug to a condenser and pack it tightly into the perforation or use copper amalgam after the plug of gutta-percha show the amount of amalgam necessary, with “... care being used not to force it (amalgam) beyond the outer wall of the root.”
3. Coronal—pack perforation in a similar manner to that for the middle, being careful not to force excess material into the tissues. In the furcation, a soft platinum or tin sheet was used to cover the perforation.

In 1912, Spaulding²⁵⁰ claimed to have at least 36 years of experience in the treatment of perforations with lead. In this treatise, he identifies a perforation in the middle to apical third of the root as “... almost fatal; and the lead treatment I have described is the only one which gives almost sure hope of saving the tooth.”

Since the late 1800s, many authors have recommended the sealing of root perforations with a multiplicity of materials, such as carbolic acid and tin foil, paraffin, gutta-percha, gold foil, zinc phosphate cement, formulations of calcium hydroxide, amalgam, iodiform, asbestos, Cavit, dentin chips, zinc oxide-eugenol, indium foil, Super-EBA cements, and Gelfoam, all with varying degrees of success.²³⁵

Prior to 1965, materials and techniques advocated in the non-surgical management of root perforations^{254,255} were based upon the extensive animal and clinical studies of Euler²⁵⁶ in 1925, Kubler²⁵⁷ in 1934, Ruchenstein²⁵⁸ in 1941, and Kaufmann²⁵⁹ in 1944. Numerous studies from 1965 to 1972 by Taatz and Stiefel,²⁶⁰ Lantz and Persson,^{261–263} Seltzer and co-workers,²⁶⁴ and Stromberg et al.²⁶⁵ also evaluated the periodontal response from the furcation to the apex in both animal models and human subjects. These historical studies have provided the guidelines for the contemporary clinical management of root and tooth perforations.

INTENTIONAL REPLANTATION/ REPLANTATION OF AVULSED TEETH AND MANAGEMENT OF OTHER TRAUMATIC TOOTH INJURIES (LUXATIONS)

Replantation was a common operation ten centuries ago and was used primarily for odontalgia. Weinberger credits Abulcasis⁷⁹ with the first account of replantation in the eleventh century. Intentional replantation was recommended by Pare (cited by Lufkin)²⁶⁶ in 1561 when a healthy tooth was extracted instead of a diseased one. In 1712, Pierre Fauchard²⁶⁷ replanted a tooth 15 minutes after extraction, and subsequent observations of the patient revealed a stable tooth and oral environment.

In Prussia in 1756, Phillip Pfaff²⁶⁸ described the use of tooth replantation and recommended root-end resection for long teeth, followed by root-end filling with wax or lead prior to replacement. In England, Thomas Berdmore⁸¹ recommended replantations in 1768 with both immature teeth and teeth with fully formed roots. As with Pfaff, Berdmore performed root-end resection on teeth with fully formed roots followed by lead or gold as a root-end filling.

John Hunter²⁶⁹ recommended the replantation procedure in 1778 when the crown was partially destroyed by caries (Figure 21). Once removed, the tooth was boiled to eradicate the disease process prior to replacement. Morrison²⁷⁰ began the routine use of replantation in 1862 and reported his personal experiences with 300 cases over a 16-year period. Extractions were done carefully and the “amputation of the root or roots (was) generally not performed.” The canals and pulp chamber were routinely filled prior to replantation. In 1876, Rabatz,²⁷¹ a court dentist in Vienna, presented 10 basic principles to be followed in transplanting and replanting teeth. All practitioners were cautioned to choose cases carefully and “never give our patient a decidedly favorable prognosis.”

Taft²⁷² recommended the use of intentional replantation in 1877 when teeth exhibited a root abscess. All debris was scraped from the root and decay was excavated from the crown: “... this will occupy from thirty to sixty minutes.” Following a new restoration, the tooth “should now be carefully replanted in its socket; the jaws should be closed firmly, which will carry the tooth to its precise position. Ordinarily, no stays or ligatures will be required to hold it in position.”

In 1881, Thompson²⁷³ presented a lengthy treatise on replantation before the International Medical Congress. He focused on the pericemental tissues “as upon the condition of this tissue replantation is wholly dependent for its success.” Further animal studies by

Fredel²⁷⁴ in 1887 and Scheff²⁷⁵ in 1890 began to address the role of the periodontal ligament in the success of replantation and the sequelae of the observed resorptive process following this procedure.

In the early 1900s, the use of replantation was minimal, having been partially replaced by the development of root-end resection techniques. However, for those who did practice the procedure of replantation, a controversy in technique and prognosis was evident at the Panama Pacific Dental Congress in 1915.²⁷⁶ Opposing points of view on treatment addressed immediate versus delayed replantation, root canal obturation prior to or after replantation, removal or retention of the periodontal ligament, and the goal of ultimate healing—osseous union or ligament repair.

Regarding traumatic injuries and subsequent tooth management, there was little codification of diagnostic

states and treatment regimes based on sound science until the later half of the twentieth century. This however does not negate the fact that history records many interesting aspects of the management of tooth trauma. For example, Abulcasis was known to use gold or silver wires to splint teeth loosened by trauma.²⁷⁷ Berdmore⁸⁶ identified silk ligatures for tooth stabilization in addition to describing management of various types of luxation injuries based on patient age. "When a tooth is loosened by violence, but not moved out of its socket, ligature alone, and stringent washes to brace the gums, are sufficient for the cure When a tooth loses its natural position, without departing from the socket . . . the nerve of the tooth is. In this case, generally broken off, and the tooth-ache which attends it, is owing to the pressure point of the root on the lacerated nerve at bottom; it should be pressed on, therefore, as little as possible; and if the uneasiness continues after it becomes pretty firm in the socket, a little of the top should be filed off, that the opposite tooth may not bear on it at all . . . the same may be said of teeth which are pushed inward, or outward or to a side, by violence . . . by luxation of a tooth, I mean when it is raised or partially or totally from the bottom of the socket . . . in young people a tooth which has been luxated, if instantly replaced, and forced quite to the bottom need only be secured by a ligature for some weeks . . . when the accident happens to a grown person, when the tooth is totally beat out, or when a surgeon is not at hand to reduce it in the very instant the swelling of the vessels, and extravasated blood prevent its sinking so deep as before; and as a prominence above the rest of the teeth would expose it to future injury and pain, it is found necessary to cut off a little piece of the point of the root, to smooth it well, to fill the hole in which the nerve formerly lodged with lead or gold; then to reduce it carefully and fasten it to the neighboring teeth . . . for people in advanced years, a hole should be drilled through the tooth sideways, close by the edge of the gums, before it is replaced; through which the gold wire or silken ligature should be passed, to secure the tooth more perfectly."

In the late 1930s, Zander and Law⁶⁷ were using the pulpotomy technique with calcium hydroxide on teeth that had suffered pulp exposures due to trauma. In 1945, Ellis²⁷⁸ provided us with his classification and treatment of injuries to the teeth, and subsequently, Grossman¹⁵ detailed these in his classical textbook citing many successful cases of managing apical root fracture management in the early 1930s. Even then, however, management of horizontal or diagonal root fractures in the middle or coronal third of the root

was considered unfavorable. Management of luxation injuries dictated that the pulp always be removed prior to replantation, and the root tip may be removed prior to placement into the socket. If desired, a knob-like titanium or vitallium extension could be added to the root end to compensate for the portion removed.¹⁵

Interrelationships between Pulpal and Periodontal Diseases

Interrelationships between pulpal and periodontal diseases have been both confirmed and denied for over 100 years. During this time, little has been written concerning the diagnosis and management of these interrelated entities, other than indicating that teeth having these problems were often extracted based on a poor prognosis for retention. This was especially true if a periodontal pocket united with an apical lesion of pulpal origin. As a consequence, these interrelationships have posed significant diagnostic and treatment dilemmas for the clinician over the decades.

Historically, Dr. Lester Cahn²⁷⁹ is often quoted as identifying a relationship between the presence of periodontal disease and its impact on pulpal demise, even though the literature is fraught with studies that claim that periodontal disease has no impact (Table 5). "... I have never found a pulp removed from a pyorrhetic tooth to be normal ... where a pathologic pulp is present, a pyorrhetic condition cannot be cured by treatment applied exclusively to the external surface of the root, with no treatment of the pulp itself."

From the opposite viewpoint, Seltzer et al.²⁸⁰ provided significant support for the impact of pulp disease on the periodontium. "... interradicular periodontal lesions can be initiated and perpetuated by inflamed or necrotic

pulps. Extension of the inflammatory lesions from the dental pulp apparently occurs through accessory or lateral canals situated in the furcation regions of premolars and molars ..."

As with many issues in dentistry, many remedies, techniques, processes, outcomes and classifications have been proposed to define the relationship between the pulp and the periodontium and to offer suggestions for treatment^{281–283} (see Table 5).

Endodontic Endosseous Implants (Diodontic or through the Tooth Implants)

Little has been written about this treatment modality, and the contemporary use of endodontic endosseous implants is quite limited in light of advances in implant technology and techniques. Endodontic implant stabilizer can provide in some cases a sound physiologic procedure for stabilizing mobile teeth by increasing root length, altering root crown ratios, immobilizing fractured roots and periodontally compromised teeth, or supplying combinations of these benefits.^{284–288} How will these be handled? The endodontic endosseous implant has an advantage in that it can be totally intraosseous without communication into the oral cavity.^{284,287}

The use of metallic implant gain credibility in 1937 when Venable, et al.²⁸⁹ determined the necessary characteristics of metallic substances to be used as intraosseous devices. They reported on the metal Vitallium that had been found to be completely inert in bodily fluids and consequently non-irritating to tissues. Recent studies, however, have questioned this outcome and newer alloys are being developed.²⁸⁸

Orlay²⁹⁰ was one of the first almost 50 years ago to report on the use of this treatment modality to stabilize

periodontally compromised teeth. Technique articles on the placement of these types of implants are few but thorough in their description and details.^{284,286} Prognosis has been reported to be over 90%; however, few if any extensive and meaningful studies are available in the last 30 years.^{287,291}

Bleaching of Discolored Dentin and Enamel

The bleaching of non-vital teeth has had few “historical” publications, and the technique and materials were heavily, empirically driven. Most details on this process come to us from Grossman in his text entitled *Root Canal Therapy*.¹⁵ In it, Dr. Grossman highlights the major causes for tooth discoloration:

- Decomposition of the pulp tissue
- Excessive hemorrhage following pulp removal
- Medicaments
- Filling materials
- General systemic conditions

Substances to reverse the stained tooth structure consisted of powerful oxidizing agents such as pyrozone (25% solution of hydrogen peroxide in ether), superoxol (30% solution of hydrogen peroxide), and sodium dioxide (yellowish amorphous powder). In an attempt to restore the translucency to the tooth, Renström (cited by Grossman)¹⁵ recommended an 80% solution of chloral hydrate that had an index of refraction same as that enamel according to Cape and Kitchin.²⁹² The bleaching of teeth that are stained systemically or due to patient factors and that have vital pulps is more of a contemporary, aesthetic-driven modality and will therefore not be addressed here.

Pearson²⁹³ brought a more contemporary perspective to bleaching almost 50 years ago, while Spasser,²⁹⁴ in 1961, provided a simple bleaching technique for pulpless, darkened teeth that use sodium perborate, and Nutting and Poe,²⁹⁵ in 1967, provided the dental profession with a more detailed treatise on the subject.

Revision of Previously Treated Root Canal Systems, Non-Surgical and Surgical

While surgical revision of less than ideal root canal treatment has a long and supportive history, routine application of non-surgical revision techniques had

little emphasis historically. Much of the focus was on the removal of broken instruments in the root canal. Even in these cases, root-end resection was heavily favored based on the skill and experience of the clinician.

Furher (cited by Grossman)¹⁵ in 1947 suggested a novel method of removing a broken instrument in the root canal. This consisted of inserting a broach alongside the broken fragment and attaching the broach to a spot-welding apparatus. The current was momentarily connected to spot-weld the broach to the fragment. When the broach was removed, the fragment attached to the broach was also removed. Unfortunately, there is no indication in his publication relation to the potential danger to the patient. Almost 30 years earlier, Waas²⁹⁶ recommended the use of a 25% solution of iodo-trichlorid for dissolving the broken segment. The solution was pumped into the canal, carefully, for 3 to 5 minutes followed by a thorough rinsing of the canal with sterile water. Apparently after one or two applications of this corrosive solution, the segment could be rinsed, generally in pieces, from the canal in most cases. Some situations required multiple visits. Prinz²⁹⁷ in 1922 recommended a similar solution called Lugol, which was made from 2 parts potassium iodide, 3 parts distilled water, and 2 parts iodine crystals. The solution was pumped into the canal to contact the fractured segment followed by the use of an explorer to pick around the segment. After several minutes, the solution was washed from the canal, the canal was dried, and the solution re-applied. After each application, the canal was rinsed with sterile water. If the segment could not be displaced, the Lugol solution was sealed in the canal for 2 to 3 days. However, because cotton fibers were dissolved by strong iodine solutions, asbestos fiber had to be placed in the canal and followed by a strong sealing cement.

G. R. Warner recommended that dialyzed iron be sealed in the root canal with a broken instrument fragment. The solution was changed every other day until the segment or its remnants could be rinsed from the canal.²⁹⁸ In later years, a solution of strong acid (sulphuric 40% or nitric 50%) was recommended⁵⁴; however, every few minutes after application, a solution of sodium bicarbonate was used to neutralize the acid. In doing so, the broken segment was often seen to rise from the canal within the resultant effervescence.

For the ready removal of gutta-percha, xylol or chloroform has been recommended^{15,54}; however, the use was recommended in stages over a number of appointments to prevent the potential irritation of the tissues beyond the end of the canal.

Coronal Restorative Procedures Involving the Root Canal Space and Coronal Access Openings

The restoration of endodontically treated teeth did not receive any significant attention regarding alterations in the nature of the tooth structure or unique methods to replace the missing coronal tooth structure due to caries or endodontic access openings until the late 1950s and early 1960s. Up until that point and even to the present day, it was and is thought by many that all root-treated teeth were weakened, or better yet “brittle” due to moisture loss following the removal of the dental pulp,^{299–302} even though G. V. Black³⁰³ could not identify in 1895 any appreciable moisture loss in teeth during his investigation of the physical properties of dentin. “I have made a diligent search to find whether or not teeth from which the pulp had been removed, and the canals and pulp chamber filled without admitting the fluids of the mouth, were subject to a similar deterioration of strength. It is now well known that teeth treated in this way retain their color almost perfectly; and from my observation of the relation of color to strength of the teeth I am prepared to entertain the suppositions that they retain their strength also. Only one tooth came into my hands with a root-filling. It was a central incisor, and had not sufficient tissue for me to obtain a block; but it showed no undue percentage of water, and the color was good. Up to the present time I have been unable to obtain the history of the filling of this root.”

However, the empirical concept of “brittleness” persisted and was further proffered by studies of Helfer et al.³⁰⁴ in 1972. Twenty years later, in 1992, Gutmann³⁰⁵ identified that potential changes in the strength of root-treated teeth reside in a multitude of factors that include a minimal but non-appreciable loss of moisture, alterations in the architectural changes of the coronal portion of the tooth subsequent to caries or endodontic access openings, the nature of collagen cross-linking in root-filled teeth versus normal vital teeth, the biomechanical behavior of the tooth structure of a root-treated tooth when placed under stress, and the nature of dentin toughness in pulpless teeth.

Present restorative challenges with root-treated teeth deal primarily with whether posts are necessary, the use of bonding agents and high compressive restorative materials. Here again, contemporary research efforts have shed light on historical dilemmas and have provided directions for present and future clinical considerations.^{306–309} Further dilemmas within this scope of endodontics have resided in

the possibility of coronal leakage through poor or faulty coronal restorations. While this latter dilemma began to surface in the 1980s, Dahlgren³¹⁰ in 1916 identified the problem of coronal leakage following the failure to restore root treated teeth properly.

Historical Faux Pas, Challenges, and Milestones

Throughout the history of endodontics, there have been many case reports or reviews or anecdotal observations that have impacted on our specialty and have led to significant changes in diagnostic and therapeutic patterns. Sadly, none of these were evidence based; however, clinicians and educators alike grasped onto the messages they provided and redirected courses of endodontic procedures, often in an erroneous manner and driven by sensationalism. The following represent only a few of these historical perspectives with comments regarding their possible role in our evolution over the years.

Tooth Resorption

Tooth/root resorption has been, for years, a difficult problem to prevent and manage. Historically, the destructive process was seen commonly with the use of intentional replantation in the eighteenth and nineteenth centuries.^{86,267–269} The treatment of choice during this time frame was to either boil the tooth to eradicate any disease process in the tooth (caries)²⁶⁹ or to scrape all the debris from the root (this will occupy from 30 to 60 min). Needless to say, these types of procedures encouraged the resorptive process. In the late 1800s, W. F. Thompson²⁷³ presented a lengthy treatise on replantation before the International Medical Congress. He focused on the pericemental tissues “as upon the condition of this tissue replantation is wholly dependent for its success.” Further studies by Fredel²⁷⁴ in 1887 and Scheff²⁷⁵ in 1890 began to address the role of the periodontal ligament in the success of replantation and the sequelae of the observed resorptive process following replantation. Certainly what is known today regarding the role of the periodontal ligament, inflammation, bacteria, and biofilms impacts greatly on the prevention and management of this process.^{173,311} Sadly, however, there are many non-endodontic specialists and general dentists worldwide who believe that resorption is the malady and not a result of other

insults. This has led to mismanagement of this destructive process, including multiple surgical procedures with ultimate failure and the wholesale extraction of teeth in many locations in favor of prosthetic replacement.

Surgical Root-End Filling Materials/ Procedures

For decades, amalgam was used as the main surgical root-end filling material. Farrar²²⁹ is often credited with one of the first reports of placing a root-end amalgam filling subsequent to root-end resection. Rhein³¹² used amalgams in 1887 to seal the pulp canal after complete root resection. Faulhaber and Neumann⁹⁶ in 1912 and von Hippel¹⁰⁸ in 1914 used amalgam to fill root canals from the resected root end when a post-core crown had been placed without proper non-surgical root canal treatment. Garvin¹⁷² reported witnessing a root-end resection in 1915, which was followed by a root-end amalgam filling. Early reports in the twentieth century^{151,155,161} indicated that amalgam was considered as a routine root-end filling material if the root canal filling material did not seal the canal at the newly formed apex. During that time and well into that century, amalgams contained high levels of copper or silver and definitely significant levels of zinc. The latter material was used primarily for its deoxidizing properties and for having an impact on the plasticity, retained mercury, dimensional change, compressive strength, and creep of the amalgam. However, in 1959, a single case report by Omnell,³¹³ which appeared in the dental literature, caused a significant change in the use of amalgam with zinc. In this case report, a zinc carbonate precipitate was identified as causing chronic inflammation at the resected root apex. This singular finding caused the endodontic profession to switch to the use of zinc-free amalgam for root-end filling, and a plethora of studies ensued that addressed the efficacy of zinc-free amalgams. Contemporary attempts to identify the presence and nature of this serendipitous finding have been unsuccessful.³¹⁴

A technique that had been promulgated for a number of years for the sealing of the resected root end was the use of a heated instrument to burnish the resected gutta-percha root canal filling as an alternative to placing a root-end fill. This technique was often used when the root canal had been filled immediately prior to root-end resection or if the endodontist had treated the tooth previously. Burnishing was claimed to seal the margins of the gutta-percha and resected dentin and was often used when

access to the resected root end was restricted or the endodontic surgeon did not have the necessary tools to achieve the task. However, in a publication by Tanzilli et al.,³¹⁵ extensive voids were noted on the resected root face between the gutta-percha and the dentin in a small group of specimens. This finding, presented in a case review format, caused the endodontist to abandon the use of heat burnishing the resected root end and encouraged the use of cold-burnishing, a technique that fared no better than did heat burnishing.

A similar impact on the endodontic profession occurred with the use of Super-EBA as a root-end filling material. In a single case report by Oynick and Oynick,³¹⁶ the presence of collagenous fibers was seen to be embedded in a Super-EBA root-end filling on an extracted tooth specimen. Endodontists were quick to adopt Super-EBA as the material of choice, with claims that the material would allow for a regenerative response (formation cementum, bone and periodontal ligament with insertion of Shapely's fibers)¹⁷³ on the resected root end, in particular on the root-end fill material. The same response was thought to occur with the use of immediate restorative material; however, in subsequent histological studies, regeneration could not be found. In all of the above cases, endodontists changed their clinical techniques and use of materials based heavily on empiricism and the desire to hope that the shortcomings of history could be transformed into future positive outcomes.

Within the realm of endodontics, and in particular surgical applications, many situations have arisen in which the course of history is repeated without regard for past achievements. For example, in 1962, Matura published a technique article that described the use of a slot preparation in the root end when access was limited. This technique was rapidly labeled as the "Matura" preparation.¹¹⁰ However, evidence for this technique and approach to managing the root end was already evident in 1914^{108,114} and with modifications purported in the mid-1930s.^{111,112} Another example would be the nature of the angle of root-end resection and patent dentinal tubules as pathways for microorganisms. This issue was addressed contemporaneously by Vertucci and Beatty³¹⁷ and Tidmarsh and Arrowsmith³¹⁸ and reinforced by the proponents of flat resections and the use of ultrasonic root-end preparation. Concern for the angled, resected root ends, and exposed infected tubules was expressed by Ross¹¹⁸ in 1935, and methods to manage were purported by both Ross, in 1939, and Castenfeldt.¹¹⁶

With regard to root-end cavity preparation, for almost 50 years the endodontic profession was limited

to using miniature handpieces and burs or straight handpieces, depending on the surgical access. With the advent of ultrasonic root-end preparation, the profession was very quick to adopt this technology with little or no evidence-based information as to its efficacy or safety. Since its advent, over 20 published research endeavors have attempted to determine, with mixed results, the ability and predictability of this technique to result in no root fractures during cavity preparation.

Non-Surgical Management of Symptomatic Teeth with Necrotic Pulp

Possibly for clinical expediency or lack of understanding of microbial and immunological implications, clinicians have opted to manage patients who present in pain due to teeth with necrotic pulps, with or without periapical lesions, by gaining coronal access and leaving the tooth open for drainage. While many of these patients become symptom free, many do not and the ultimate ability to finally close these teeth to the oral cavity becomes a significant and controversial challenge. In 1936, Walker³¹⁹ indicated that leaving teeth open for drainage was a highly unscientific practice that had begun to permeate the profession. The challenge that this clinical situation posed led to a number of publications trying to answer the question, “to close or not to close.”³²⁰⁻³²⁴ Generally, this question was resolved with both retrospective studies and a better understanding of the biologic aspects of root canal procedures and their outcomes.^{325,326} In the author’s experience, this question has probably been the most frequently asked question in continuing education courses for 25 to 30 years and occasionally continues to surface.

In 1883, Dr. Safford G. Perry³²⁷ wrapped gutta-percha around a gold wire and made gutta-percha points that were rolled in shellac and compacted into the root canal. In 1978, Dr. W. Ben Johnson³²⁸ introduced to the dental community gutta-percha that was plasticized and wrapped around a K-file, which ultimately resulted in product called ThermaFil. Scientific advances allowed the use of high-tech plastic for future core materials. However, while highly successful, the introduction of this material and technique may have been premature relative to the need for properly shaped root canals for it to achieve its full impact in root canal obturation. While in some respects history has repeated itself with the development of this type of product, the adage of putting the

cart before the horse may also have been an operative phenomenon.

Historical Stalwarts

The specialty of endodontics has had a long history of incorporating innovative materials, instruments, and techniques in order to remove offending etiologic factors and create the best possible environment for healing apically, following either non-surgical and/or surgical endodontic intervention. Historically, these entities served endodontics and its realm of applications quite well within a particular historical context. More often, however, their use or application was empirically based and would not necessarily pass the test of evidence-based contemporary directives. Furthermore, science has intervened and has dealt a blow to the continued use of many of these entities. The list below is only partial in nature as globally many other miracle cures, pastes, and mystery potions have existed but have never gained widespread use or endorsement.

1. Medicaments

- a. Formocresol, camphorated or aqueous para-monochlorophenol, beechwood creosote, metacrylacetate, carbolic acid
- b. PBSN (Penicillin, bacitracin, streptomycin & nystatin); PBSC (Penicillin, bacitracin, streptomycin & sodium caprylate)
- c. Microcide A
- d. SPAD
- e. Oil of cassia
- f. Iodoform
- g. Sulfathiazole
- h. Sulfanilamide
- i. Benzlog
- j. Arsenic trioxide
- k. Silver nitrate
- l. Mercuric chloride
- m. Azochloramid
- n. Serocalcium
- o. Dentinigine
- p. Calcium thymol
- q. Pulpatekt
- r. Citronellol
- s. Endoxyl

2. Irrigants

- a. Chloramine-T
- b. Hydrogen peroxide
- c. Anesthetic solutions
- d. Water

3. Surgical materials/instruments/techniques
 - a. Horsehair sutures, silk sutures
 - b. Root-end amalgams (zinc containing and zinc free)
 - c. Miniature handpieces for root-end preparations
 - d. Cold and warm burnishing of gutta-percha
 - e. Coating of resected root ends with silver nitrate
 - f. Curettage only procedures
 - g. Chisels for root-end resection
 - h. Canal preparation techniques/instruments/materials
 - i. Carbon steel instruments
 - j. Smooth broaches
 - k. Metallic-handled test files
 - l. Step-back instrumentation
 - m. Electrosterilization of the canal
 - n. Root canal culturing
4. Obturation materials/Techniques
 - a. Formaldehyde or paraformaldehyde-containing pastes (SPAD, N2, RC2B)
 - b. Mummification procedures
 - c. Silver cones
 - d. Oxychloride of zinc
 - e. Kerr #3 spreader
 - f. Chloroform-rosin (Johnson-Callahan) technique
 - g. Hydron
5. Anesthetics
 - a. Cocaine crystals
 - b. Novocaine

Even with the justified abandonment of many historical techniques and materials in favor of more scientifically sound or clinically documented successful entities, there persists in some global markets the continued use of historical and empirical clinical “favorites,” such as the following:

- Steroid creams and pastes as medicament
- Knockendeckel (bony lid) surgical methods
- Electrophoresis
- Surgical removal of sinus tracts
- Intracanal antibiotic pastes (using newer formulations)
- Cemented root canal files as filling materials
- Paste root canal fills (zinc phosphate and paraformaldehyde-containing fillings)
- Placement of posts in every root-treated tooth

- Surgical trephination with overextended root canal fillings
- Non-surgical root canal treatment without aseptic (dental dam) isolation

History Admonishes the Future

History is so vast and its fleeting information so elusive that it is impossible to record all occurrences or developments in but a few pages. Regardless of this shortcoming, by addressing the history of this specialty in the manner presented, this chapter does not lay claim to any future developments and directions, for that is within the remaining chapters of this text. These chapters record the intense clarification and codification that endodontics has received in the past few decades based on extensive scientific research and clinical practice, some of which is evidence based. However, as it is known that history has a tendency to repeat itself, astute endodontists and future endodontists must gird themselves to prevent falling into the empirical abyss of personal favorites, untested remedies, and unscientific claims to success. It is within this framework that we must view history and learn from at least some of its lessons, lest we fall victim to its entrapments.

CHAPTER 3

ETHICS, MORALS, THE LAW, AND ENDODONTICS

BRUCE H. SEIDBERG

Introduction

In decades past, society held dentists in high esteem; however, the former maternalistic/paternalistic mindset has been replaced with suspicion, and inquiries of what is being told to the patient is often fueled by Internet surfing and false information. Today's patients are becoming more sophisticated about their dental needs; they are also becoming more sophisticated about their legal rights. Dentists are held to the same standard as physicians and other health providers with the tort of malpractice.¹ One does not have to be wrong to be sued. While providing a scientific and technological service, your patient may decide that your dental work is not meeting certain expectations. What may begin as a difference in opinion could turn into a costly and time-consuming lawsuit.²

Malpractice is the negligence arising out of the doctor–patient relationship (DPR), whereas negligence is the unreasonable act or omission by a provider that results in patient harm. To sustain a cause of action, the plaintiff patient must prove the four elements of malpractice: duty, breach of duty, proximate cause (departure from the standard of care), and damages. Patients are likely to bring legal action for a number of reasons, included, but not limited to those listed in Table 1.

Frequency of Claims

Endodontics had been identified as number one in dentistry in terms of the frequency of malpractice claims filed in California in 1985³; however, in 1987, Harman⁴ reported that nationally, endodontic claims were the second most frequent producer of

Table 1 Common Elements of Malpractice and Negligence

1. Failure to meet the standard of care
2. Practice beyond the scope of license
3. Perform procedures not competent to do
4. Delegate to a nonqualified person
5. Use materials not meeting standards
6. Insurance fraud
7. Failure to diagnose
8. Failure to refer

claims and dollar losses, with oral surgery being number one. There was an increase in the number of malpractice claims involving endodontics, primarily against general dentists, noted in 1998.⁵ The American Association of Endodontists (AAE)⁵ also recognized an increase in the number of malpractice claims involving endodontics. Since general practitioners are performing 75% or more of the endodontic procedures in America, it is implied that they would be involved in the majority of the malpractice cases. Insurance companies are no longer providing the percentage differences between generalists and specialists in their recent releases. Even if the perception is true, that the majority of the malpractice cases arise from general practice offices, one cannot preclude that endodontic specialists are without exposure.

The current frequency of endodontic claims has been relatively status quo when compared to national statistics. Between 2001 and 2005, endodontics was still number one in malpractice claims in California. There was a slight change in the year 2006, however, when

Table 2 Treatments Involved in Paid Claims; ADA Council on MI&RP Study 2005

Crown and bridge	21.8%
Endodontics	20.0%
Simple extractions	13.6%
Dentures	6.7%
Surgical extractions	5.7%
Oral exams	5.1%
Implants	2.9%
Orthodontics	2.0%
Periodontal surgery	1.4%
Treatment of Temporal mandibular joint	0.2%
Other	20.6%
Total	100%

endodontics slipped to second place after restorative dentistry.⁶ The American Dental Association Council on Members Insurance and Retirement Plans (MI&RP)⁷ undertook a study in 2005 involving 15 insurance companies that provide dental malpractice insurance to approximately 106,000 dentists. The focus of the study was to determine the frequency of claims for various phases of dentistry. Due to the involved time frame in the legal system method of scheduling and hearing cases, the 2005 study detailed statistics from 1999 only up to 2003. This national study indicated that endodontics was number two in claims for malpractice or negligence. The ADA study also indicated that the majority of the replying insurers did not differentiate between generalists and specialists, except for oral surgeons, which implies that there would be no difference in the final statistics, or minimal at best. The ADA study also categorized frequency by identifying paid claims provided by generalists (Table 2); they did not separate specialists. MILMIC, an insurance company from New York State, categorized the frequency differently, reporting similar results for similar categories in 2006⁸ (Table 3). The MILMIC report also identified the percentage of indemnity for various claims, implying good news for endodontics, dropping to fourth place in the payment or settlement arena (see Table 3). The common areas of claims against endodontists are listed in Table 4.

Aside from the evidence-based scientific and technical methodologies, now known and available for patient care

Table 3 Frequency of Dental Claims: MILMIC Insurance 2007

	Frequency of Claims	Percent of Indemnity Payments
Crown and bridge/fillings	26.2	21.6
Endodontics	15.5	10
Oral surgery	7.9	13.5
Prosthodontics	4.2	1.0
Orthodontics	3.8	6.3
Periodontics	3.5	10.4
Implants	3.3	8.8
General negligence	20.6	6.3
Paresthesia	<1	7.6
All other	15.0	14.5
Total	100	100

Table 4 Alleged Errors in Claims against Endodontists

1. Treatment failure
2. Failure to meet the standard of care
3. "Broken instruments"
4. Treatment of the wrong tooth
5. Paresthesia
6. Inadequate precautions to prevent injury
7. Inappropriate procedures
8. Failure to warn (informed consent)

and endodontic therapy, and described elsewhere in this textbook, endodontists have to understand, and be concerned with, good risk management procedures, and have to improve communication skills with their referring dentists and patients. The major concerns affecting legal claims, as described by Seidberg, involve the DPR, informed consent, and good record keeping.⁹ In addition, endodontists must be aware of what "standard of care" is, and what it means.

Ethics and Morals

Ethics, morals, and the law all intersect, influence, and impact each other. Ethical behavior encompasses rules and standards that govern members of a profession.

Table 5 Ethics

E = Expertise
T = Truthful
H = Honesty
I = Integrity
C = Compassion
S = Sagacity

Endodontists are guided by the Codes of Ethics of the American Dental Association, the AAE and those of the states in which they are licensed. Ethics is a systematic study of moral behavior of which actions must be supported by reason (Table 5).

The ethical basis for standard of care is to recommend the best therapy while minimizing potential harm, and to avoid placing a patient at an unreasonable risk of harm. Ethical concepts include patient autonomy (the right to understand and consent), nonmaleficence (from the Hippocratic Oath: “Do no harm”), beneficence (doing what is best for the patient), justice (fairness in allocation of services), and veracity (requires honesty in all dealings). It is an unethical conduct to refuse services to patients because of patient’s race, creed, color, sex or national origin, or to deny care to patients based on a real or perceived disability. To do so violates the American Disability Act.

Moral behavior is concerned with principles of right and wrong in relation to human action and character. It conforms to virtuous standards arising from conscience or sense of obligation and follows rules or habits of conduct from one’s ingrained sense of what is right.

Standard of Care

As Milgrom and Ingle¹⁰ have noted, dentists can no longer consider themselves immune to malpractice litigation by hiding behind a doctrine of “local community standards.” Local community standards no longer have standing within the court systems.^{11–13} Standard of care is in a constant state of change, vacillating between expert witnesses’ testimony, new technology, and improved procedures. Local community standards have been replaced by national standards. The ease of availability to obtain continuing education from universities, professional journals, and local dental society-

sponsored courses, and the mobility of dentists to travel to educational centers, implies an ease to develop a national standard. Today all dentists must meet the national standard of care.

The standard of care is defined as “that reasonable care and diligence ordinarily exercised by similar members of the profession in similar cases in like conditions given due regard for the state of the art.”⁹ Generalists are held to the standard of care of the specialist using the same degree of care and skill when acting in the same or similar circumstances.^{14,15} Legal claims of malpractice and negligence will have the charge of a dentist’s deviation from the standard of care as its primary focus. Along with authors who have alluded to the subject,^{4,16,17} the AAE has issued guidelines that practicing endodontists are expected to adhere to and suggests a *national standard of care*. The *Appropriateness of Care and Quality Assurance Guidelines* can be obtained from the AAE.⁵ It must be remembered that the guidelines are templates and not mandates. They do not *legally* set the standard of care. Contrary to belief, it is neither the specialists nor the national specialty organizations that set the standard. In the court system, the *plaintiff’s dental expert witness* will define the standards and identify the deviation(s). The *defendant’s dental expert witness* will counter with a different approach to the evidence, demonstrating that the standard of care has not been deviated from. The judge and/or the jury will then decide the case, and that will become the standard of care for that specific case. The prevailing party is usually one whose expert can be the most convincing.

Many dentists, including specialists, are willing to evaluate records and testify as an expert witness in court, supporting patients, who in their view have been treated below the standard of care. Most states require a certificate of merit authored by a dental expert witness before a lawsuit can go forward. *A word of caution:* there are many frivolous suits that can be discharged at the initial document review stage. If one is a willing expert, one must have a history for providing services for both sides of the aisle, for the plaintiff and/or for the defendant (not for the same case) at different times. One should not review cases all the time for only one side. One must be able to evaluate a case honestly and determine the merits to state whether or not the case is meritorious to go forward, or be able to declare that, in your opinion, no case exists.

Cohen and Schwartz³ have stated that a meritorious claim by a patient is “any departure from the minimum

quality of endodontic care.” “Any departure” is rather broad and includes, but is not limited to, failure to properly diagnose, failure to perform comprehensive diagnostic tests, failure to properly document and record all findings and treatment, treatment of the wrong tooth, use of paraformaldehyde/steroid pastes such as N2 and other nonaccepted materials, root perforations, failure to obtain appropriate informed consent, failure to inform the patient of instrument separations in the canal, and failure to use a rubber dam.¹⁸ The minimum quality is harder to define.

From the aforementioned list, “failure to use a rubber dam” is unconscionable and may result in the most disastrous consequences, namely swallowing or inhalation of an endodontic instrument (Figure 1) that may become lodged in a body cavity or an organ and may require a subsequent medical surgical procedure.

Instrument breakage or, as it is euphemistically referred to, “instrument separation” is a “disquieting event” and not necessarily a deviation from the standard of care or an actionable event. One must ask, “Did the file break because of overzealous use... or was it defectively manufactured?”¹⁸ The unbroken

end of the file should be saved in a coin envelope and placed in the patient’s treatment record. If defective manufacturing can be proved, liability could shift to the manufacturer or be a shared responsibility. The root canal system is small and tortuous and the instruments very small and fragile. When in use, the instrument may bind and separate inadvertently. The act of separation can be argued as an unfortunate mishap and not negligence or malpractice. In any event, the patient should be informed promptly¹⁸ and the mishap and fact that the patient has been informed is documented.

An example of a standard of care controversy, that has been the focus of a number of claims, is the *final terminus* of a root canal filling material. Charges have been made over the issue of *overfilling* through a normal apical exit or *overextending* the root canal filling because the apical foramen has been grossly enlarged or resorbed. “Normal” overfilling is often found defensible, whereas gross overextension is often not. There is a difference between the overfilled/overextended and underfilled/overextended terminus of filling materials. One could be hard-pressed in court to defend gross overextending, sometimes to the point of filling the

Figure 1 Two examples of swallowed endodontic instruments because a rubber dam was not used. **A**, Radiograph taken 15 minutes after an endodontic broach (arrow) was swallowed. Reproduced with permission from Heling B., Heling J., *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 1977; 43:464. **B**, Abdominal radiograph showing a broach in the duodenum (arrow). Figure 2 Massive overextension of RC2B (N2) into the inferior alveolar canal. The patient suffered permanent paresthesia. The lawsuit was settled out of court against the dentist and in favor of a 26-year-old secretary in Pennsylvania. Courtesy of Edwin J. Zeneman, DDS, JD.

mandibular canal (Figure 2). Both have been shown to heal; therefore, the onus would be on the expert witness of the defendant to demonstrate that healing of “overfilled” or “overextended” fillings can happen, and that is not necessarily negligence. On the one hand, filling “short” of the radiographic apex is still debatable. But on the other hand, a “puff” of cement from the apical constriction has become acceptable. Again, both have been shown to heal.

Filling just short of the radiographic apex (0.5 to 1.0 mm), at the apical constriction, is supported by several institutions and reports. By the same token, an inadequate root canal filling is hardly defensible as rising to the standard of care, even though the filling might appear radiographically to extend to the apex (Figure 3). Grossly underfilled canals, 3.0 to 6.0 mm short or more, are also hard to defend, particularly if an associated periapical lesion is radiographically apparent.

One must realize, however, that some root canals are so thoroughly calcified (obliterated) that penetration to the apex is virtually impossible. Root canal fillings that appear to be “underfilled” or “inadequate” and some that appear to be “grossly underfilled” have also been demonstrated to heal. Once again, the onus would be on the expert witnesses to demonstrate an adverse effect. In any event, informing the patient of the terminus filling complication and documenting it will reduce liability risks.

Swedish scientists analyzed 70 cases of “obliterated” canals over a recall period of 2 to 12 years.¹⁹

Figure 3 Lateral section of endodontic failure. Gutta-percha point (arrow) in no way obliterates the foramen. Radiographically, from the labial, the canal appears filled to the apex. Unfilled canal space contains necrotic and/or bacterial debris, a toxic irritant.

The overall success rate for the partially filled canals was 89%. When, in the initial radiograph, an intact periradicular contour was present, the success rate was an amazing 97.9%. When preoperative periapical radiolucencies were present, the success rate dropped to a disappointing 62.5%.¹⁹ In the incompletely filled failure cases, it was theorized that canals were present but so narrow they could not be negotiated by the smallest instruments, but were still large enough for the passage of bacteria and their toxins.¹⁹

In the light of the low success rate (62.5%) of unfilled “obliterated” canals with apical radiolucencies, the dentist must seriously consider a surgical approach, and root end fillings would be within the standard of care if appropriately completed.

Paresthesia is another deviation claim from the standard of care in a patient's complaint following endodontic treatment or a surgical procedure. It has been identified with difficult extractions, improper injection techniques, or endodontic treatment mishaps. Numbness of the lip, chin, or cheek area affected is part of the claim that "the injection didn't wear off."²⁰ It may be caused by root canal sealers or cements that impinge on the inferior alveolar nerve when neurotoxic filling materials are used (e.g., N2, RC2B, Endomethazone, SPAD). It may also be caused by injections that separate the nerve bundle sheath, or extractions that adversely affect the mandibular nerve. Often, damage associated with alleged dental malpractice using paste fillings like N2 can result in complications seen with medical treatment, including death.^{1,21}

Ørstavik et al.²⁰ surveyed the literature for reported cases of paresthesia related to endodontic treatment. They found 24 published cases; 86% of the patients were female, and usually where a paste-type filling had been used. Although five cases "healed in four months to two years, 14 showed no indication of the paresthesia healing... from 3 months up to 18 years." The remaining cases were resolved by surgical removal of the offending material. Ørstavik reported the 25th case, paresthesia following overfilling with Endomethazone. If the paresthesia persists for 3 years or more, the possibility of regeneration of the nerve must be considered negligible.²⁰ Others have reported the same or similar causes of nerve damage and paresthesia.²²⁻²⁵

Paladino et al.²⁶ have warned of the indefensibility of using the Sargenti endodontic technique (N2 or RC2B), informed consent or no informed consent: "A general dentist who performs a Sargenti root canal (sic) is going to have as an expert witness testifying against him, virtually every endodontist in town."²⁶ Further, "any patient who comes to a lawyer with a Sargenti-treated tooth has a prima facie case of negligence" against the dentist. "There is no way... a dentist can justify performing that procedure."²⁶

Doctor–Patient Relationship

The DPR is the first of three primary concerns when thinking about risk management.⁹ The question is: when does the relationship become legally binding? The DPR is a fiduciary one in which mutual trust and confidence are essential.²⁷ Theoretically, when a patient walks into an office and provides information to a providing doctor, the relationship begins. When there is only limited observation and sugges-

tions made, however, no direct duty to the patient is attached.²⁸ Actually the relationship begins when the dentist examines the patient and gives advice about the care needed. In legal terms, this is referred to as *reliance*, and there is usually consideration in the form of a professional fee involved. There are circumstances, under the parameters of the American Disability Act, that supersede the preceding; a dentist cannot refuse dental care to any patient falling under the umbrella of that act of law. Good communication is critical for the DPR to reduce liability risk.⁹

Orr¹ reminds professionals that they be well advised to be very circumspect with regard to offering any criticism of a colleague, particularly without personally communicating with that colleague. A patient's subjective history and recollection of prior health professions interactions are notoriously inaccurate. There are many variables that interplay with bad experiences, including, but not limited to, a patient's difficulty to open wide enough for treatment, to comply with treatment, over anxiety reactions, medical compromises, and stress. The provider can also be having issues of being pressed for time, difficulty with the patient treatment, or just any other concern. Negative comments about previous providers or treatments should not be entered in patient documents.

Informed Consent

Informed consent is the second concern for risk management procedures.⁹ It is the conversation a dentist has with a patient, prior to treatment, in which options and possible risks of the proposed treatment are explained and discussed. It is required by law in most states in one form or another. There are three sentinel legal cases that shaped the current concept of informed consent. In the 1914 case of *Schloendorff v Society of New York Hospital*,²⁹ Judge Benjamin Cardozo concluded that: "every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault for which he is liable in damages." One of the first cases to label the lack of informed consent as professional negligence instead of assault and battery was *Nathanson v Kline*³⁰ in 1960. This case concluded that "the fundamental distinction between assault and battery on one hand, and negligence such as would constitute malpractice on the other, is that the former is intentional and the latter unintentional..." This was also the first case law to formalize the consent issue to dentists. The final

distinctive case relative to informed consent was *Canterbury v Spence*³¹ that refined the entire concept and established a new standard for information disclosure by concluding that “failure on the part of a health care provider to obtain a patient’s informed consent before treatment constitutes professional negligence (substandard care) and not the intentional tort of assault or battery.” Others have written extensively about informed consent.^{26,32–35} Both Bailey³² and Curley³³ have noted that informed consent was an outgrowth of assault and battery law, the unauthorized “offensive touching without consent.” The practitioner must bear in mind that informed consent is the “*rule of law rather than just a standard of practice.*”³³ Bailey³² has pointed out a variance among states in applying or interpreting the law. In the states of Alaska and Washington, for example, informed consent is not mandatory in severe emergencies. The Council on Insurance of the ADA noted that the issue of informed consent could be tried in court as a civil action where guilt is based on the “preponderance of evidence,” that is easier to prove than “beyond a reasonable doubt,” used in criminal cases.³⁴

Informed consent is defined as the ongoing dialogue between a patient and a health care provider in which both parties exchange information, ask questions, and come to an agreement on the course of specific dental/medical treatment. It is based on a special fiduciary relationship between the doctor and the patient; a relationship of trust, confidence, and responsibility is formulated.²⁷ The elements of informed consent are listed in Table 6. Weichman³⁶ described the importance of the doctrine of informed

Table 6 Elements of Informed Consent Required by Law

The dentist *must* explain:

- The indicated procedure in understandable terms
- Reasons for the procedure
- Benefits of the procedure
- Alternatives and consequences of alternatives including no treatment at all
- Risks associated with the procedure

consent, as well as other steps that must be taken by the dentist to maintain good patient relations. According to the doctrine of informed consent, a dentist must (1) describe the proposed treatment so that it is fully understood by the patient, (2) explain all risks attendant on such treatment, and (3) discuss alternative procedures or treatments that might apply to the patient’s particular problem. To this should be added (4) the risks associated with doing nothing. Selbst³⁷ recommended that special care be taken to advise the retreatment patient of increased incidence of complications associated with retreatment cases, particularly the retreatment of paste fills.

Objective standards for informed consent are whether a reasonable or prudent person, in the patient’s position, would have submitted to the dental procedure or the course of treatment if suitably informed of the risks. To sustain an informed consent lawsuit, a patient must prove that a reasonably prudent person (such as the patient) would not have undergone the treatment if

Sample Statement Of Consent For Endodontic Treatment	
1. I hereby authorize Dr. _____, and any other agents or employees of _____ and such assistants as may be selected by any of them to treat the condition(s) described below:	_____
2. The procedure(s) necessary to treat the condition(s) have been explained to me and I understand the nature of the procedure to be:	_____
3. I have been informed of possible alternative methods of treatment including no treatment at all.	
4. The doctor has explained to me that there are certain inherent and potential risks in any treatment plan or procedure.	
5. It has been explained to me and I understand that a perfect result is not guaranteed or warranted and cannot be guaranteed or warranted.	
6. I have been given the opportunity to question the doctor concerning the nature of the treatment, the inherent risks of the treatment, and the alternatives to this treatment.	
7. This consent form does not encompass the entire discussion I had with the doctor regarding the proposed treatment.	
Patient's signature	_____

fully informed of the risks, benefits, and alternatives and that the lack of informed consent served as the proximate cause for the injury. This means that the failure of the dentist to warn the patient is what proximately caused the injury and that is a deviation from the standard of care. "Inform before you perform"³⁶ is the appropriate approach.

The AAE has suggested an informed consent form that will cover most situations (Figure 4). However, the AAE has stated that "a written consent form cannot be used as a substitute for the doctor's discussion with each individual patient."³⁸ A lack of a documented informed consent may be interpreted by a jury as evidence that such a discussion was never

CONSENT FOR LOCAL ANESTHETIC INJECTIONS

Please circle the appropriate response where indicated.

I, (print name) _____, hereby authorize Dr. _____ to perform local anesthetic injections as necessary to perform the dental treatment for which I have been scheduled.

Very inflamed teeth may still have a sensation at the beginning of treatment due to the differences between the chemical makeup of the anesthetic agent and inflammation. If that occurs, additional anesthetic will be administered.

There are some risks in the administration of local anesthetics. Most risks are related to the position of the nerves under the tissue at the site of the injection which can not be determined prior to the administration of the anesthetic agent. Although the risks rarely occur, they might include, but are not limited to, loss of, or disturbed sensation of the tongue and lip on the side of the injection. If this occurs it is often temporary, and the normal sensation usually returns in several days. However, in very rare cases, the loss of sensation may extend for a longer period and may become permanent. In addition, injecting a foreign substance into the body such as an anesthetic may result in an allergic reaction, which is very rare, but may take place.

I further understand that individual reaction to treatment cannot be predicted, and that if I experience any unanticipated reactions following the injection(s), I agree to report them to the office as soon as possible.

The success of my dental treatment depends upon my cooperation in keeping scheduled appointments, following home care instruction, including oral hygiene and dietary instructions, taking prescribed medication and reporting to the office any change in my health status.

I acknowledge that no guarantees or assurances have been given by anyone as to the results that may be obtained. I have had an opportunity to discuss all of the above with the doctor, and have had all of my questions answered.

I **have** (*have not*) **had local anesthetic injections in the past.**
 I **do** (*do not*) **have a problem with local anesthetics with epinephrine.**

**CONSENT FOR ENDODONTIC CONSULTATION, X-RAYS, DIAGNOSIS AND/OR TREATMENT (NON-SURGICAL OR SURGICAL
ENDODONTICS)
PLEASE READ AND SIGN**

I hereby authorize **Dr.** _____ and/or to those in his employ: the charge for the care of the patient _____ and to administer any treatment, or to administer such anesthetics, and to perform such operations as may be deemed necessary or advisable in the diagnosis and the treatment of this patient.

I understand that the therapy, other than emergency care for the relief of pain, will not be started until the course of therapy has been explained to me, and once the nature and purpose of root canal treatment, and possible alternative methods of treatment have been explained to me, and the risks of not accepting the recommended therapy, I will verbally consent to accepting the therapy or request discharge from the doctor's care.

I do understand that during, or after, the treatment I may have periods of discomfort. I further understand that many factors contribute to the success or failure of root canal therapy which cannot be determined in advance. Therefore, in some cases treatment may have to be discontinued before it is completed, or may fail following treatment. Some of these factors include, but are not limited to, my resistance to infection, the location and shape of the root canal anatomy, my failure to keep scheduled appointments, the failure of my having the tooth restored following the treatment, periodontal (gum) involvement, or an undetected or after the fact caused split (crack) in the tooth.

I further understand that during and following treatment, I am to contact this Doctor's office if I have any additional questions, or I experience any unexpected reactions. I hereby give permission for the use of my x-rays and/or photographs taken during the course of treatment to be used in lectures, seminars and/or printed in journal format by the doctors.

I acknowledge that no guarantees or assurances have been given by anyone as to the results that may be obtained. I will not request or expect a refund of fees in the event that the treatment is not successful. It will be my responsibility to contact my family dentist within one week after treatment to have a cap/crown or other protective restoration placed on the tooth (teeth) and to phone this office for a recall appointment in one year for the evaluation of healing.

ADDITIONAL INFORMATION AS APPROPRIATE:

(This is the area where explanatory drawings may be made or additional comments relative to the specific case)

**CONSENT FOR ENDODONTIC CONSULTATION, X-RAYS, DIAGNOSIS AND/OR TREATMENT (NON-SURGICAL OR SURGICAL
ENDODONTICS)**
PLEASE READ AND SIGN

I hereby authorize Dr. _____ and/or to those in his employ: to examine, consult and treat the patient _____ and to administer any treatment, or to administer such anesthetics, and to perform such operations as may be deemed necessary or advisable in the diagnosis and the treatment of this patient.

I understand that the therapy, other than emergency care for the relief of pain, will not be started until the course of therapy has been explained to me, and once the nature and purpose of root canal treatment, and possible alternative methods of treatment have been explained to me, and the risks of not accepting the recommended therapy, I will verbally consent to accepting the therapy or request discharge from the doctor's care.

The doctor(s) has explained to me that there are certain inherent and potential risks in any treatment plan or procedure. I understand general risks of treatment include, but are not limited to, complications resulting from the use of dental instruments, drugs, sedation, medicines, analgesics (pain killers), anesthetics and injections. These complications include, but are not limited to: swelling, sensitivity, bleeding, pain, infection, numbness and tingling sensation in the lip, tongue, chin, gums, cheeks, and teeth, which is transient but on infrequent occasions may be permanent; reactions to injections, changes in occlusion (biting); jaw muscle cramps and spasms, temporomandibular (jaw) joint difficulty, loosening of teeth, crowns or bridges; referred pain to ear, neck and head; nausea, vomiting, allergic reactions, delayed healing, sinus perforations and treatment failure. **Specific to the non-surgical endodontic therapy**, risks include, but are not limited to, the possibility of instruments separated and left within the root canals; perforations (extra openings) of the crown or root of the tooth; damage to bridges, existing fillings, crowns or porcelain veneers; loss of tooth structure in gaining access to canals, and cracked teeth. Fractures of the tooth (teeth) or crown(s) may occur during or after treatment. **Specific to the surgical endodontic therapy**, risks include, but are not limited to, the possibility of swelling, discoloration of the face, sensitivity, bleeding, pain, infection, numbness and tingling sensation (paresthesia) in the lip, tongue, chin, gums, cheeks, and teeth, which is transient but on infrequent occasions may be permanent; I further understand that prescribed medications and drugs may cause drowsiness and lack of awareness and coordination, which may be influenced by the use of alcohol, tranquilizers, sedatives or other drugs. It is not advisable to operate any vehicle or hazardous device until recovered from their effects. The use of the penicillin drugs may have an adverse effect on the use of birth control pills.

I do understand that during, or after, the treatment I may have periods of discomfort. I further understand that many factors contribute to the success or failure of root canal therapy which cannot be determined in advance. Therefore, in some cases treatment may have to be discontinued before it is completed, or may fail following treatment. Some of these factors include, but are not limited to, my resistance to infection, the location and shape of the canal anatomy, my failure to keep scheduled appointments, the failure of my having the tooth restored following the treatment, periodontal (gum) involvement, or an undetected or after the fact caused split (crack) in the tooth.

I further understand that during and following treatment, I am to contact this Doctor's office if I have any additional questions, or I experience any unexpected reactions. I hereby give permission for the use of my x-rays and/or photographs taken during the course of treatment to be used in lectures, seminars and/or printed in journal format by the doctors.

I acknowledge that no guarantees or assurances have been given by anyone as to the results that may be obtained. I will not request or expect a refund of fees in the event that the treatment is not successful. It will be my responsibility to contact my family dentist within one week after treatment to have a cap/crown or other

protective restoration placed on the tooth (teeth) and to phone this office for a recall appointment in one year for the evaluation of healing.

I understand that I am financially responsible for all charges whether or not paid by insurance. I hereby authorize release of all information necessary to secure payment. In the event this account is turned over for collection, I agree to pay all attorney's fees and court costs. All fees are due and will be paid by the time of completion, unless I contract for a specific payment plan that is agreeable to the doctor(s). Payment may be made by either cash, check, credit cards

ADDITIONAL INFORMATION AS APPROPRIATE:
(this is the place for drawings and or other appropriate comments)

Figure 8 (Continued)

a nonlicensed dental individual, like an assistant or a receptionist.⁹

When discussing consent with a patient, or designing the actual consent form, one must avoid a list of risks so specific that it can be deemed to exclude risks not mentioned. When in doubt as to how specific one should be in discussions and in the written form, use the following phrase: "Risks for this procedure include, but are not limited to risk x, risk y and risk z."⁹

Record Keeping

Maintaining a proper record is the primary dental defense in claims and the third concern for risk management procedures.⁹ Good records are *accurate* (the

information is true and correctly recorded), *complete* (all required information is included), and *authentic* (the information in the record is reliable and has not been altered). Dental records can be the most effective resource for the defense in a liability issue if written carefully.¹ The format of all records should follow the universally accepted medical/dental form that includes the patient's chief complaint, the dentist's findings (including but not limited to diagnostic tests radiographs, clinical examinations), the assessment or preliminary diagnosis, and the treatment plan. The format is commonly referred to as the SOAP. method (Table 7). Typical contents of a proper record are listed in Table 8. Careful writing, in the SOAP format, would most likely include some evidence of the thought process, including differential diagnosis,

differing treatment options, and practitioner's and patient's preferences for treatment.¹ Weichman³⁶ and Hourigan³⁹ appropriately recommended that records should also consist, at a minimum, of good, well-processed, or digitalized radiographs; any variance at subsequent appointments; any objective findings made during treatment, such as the state of the pulp's vitality found on opening the chamber; any possible complications foreseen or encountered, such as curved roots, obliterated canals, postoperative problems, associated periodontal problems, anesthetics injected with a number of carpules; and full disclosure of any procedural accidents occurring during treatment, such as broken instruments, perforated or fractured roots. Additional items, listed in Table 9, should be entered in a patient's progress notes.

One must be careful not to enter derogatory or judgmental remarks about patients or former dentists in the records including infamous well-known coded descriptors. Juries quickly learn the meaning of the

acronyms and find them offensive and unprofessional. Do not write, for example, "Patient SOB" as code for "Patient short of breath."

All financial records must be kept separate from treatment records. It is not prudent to have a clear link of financial arrangements and fees tied to patient's treatments. There are times when only treatment records may be requested by third parties, and the financial information should not accompany them.

Good risk management procedures include obtaining thorough and reliable medical and dental histories (Table 10). Failure to do so constitutes a departure

from the standard of care. *Records should never be altered* because that would reduce authenticity and credibility. If corrections are necessary, they should be made with a single-line strikeout, the new entry made, dated, and initialed. All record entries must be initialed by the writer and all abbreviations must be understood by others. A list of office personnel abbreviations should be kept on file, including previous employees.

Referrals

Who among the many professionals caring for the patient shall assume responsibility? The referring dentist retains the responsibility for the directive care of the patient. “Who should be captain of the ship?” asked Beveridge (Beveridge EE, Personal communication to Ingle JJ, 1971). “Let it become a mutual objective that no patient shall move from one practitioner to another without someone in command. Every patient deserves to have a clearly understood, readily identified, ‘captain of his dental ship,’” he stated. Ideally, the dentist most responsible should be the general practitioner who has referred the patient to the endodontist, periodontist, or oral surgeon. His office should be the “clearinghouse” for central records and coordination of treatment. Howard³⁵ has also emphasized the importance of the general dentist being the “captain of the ship.” This does not remove the actual treatment responsibilities and outcome of the actual treating dentist and should not interfere with the referral process. The failure to refer can be the basis for a negligent claim. But, just when should an endodontic patient be referred? The case described below suggests several deviations from the standard of care that must be understood and vividly demonstrates the old adage, “when in doubt, refer it out” should be done with knowledge and caution. The guidelines (Table 11) as to why generalists should consider referrals are the same that endodontists should consider. The decision to make a referral is a personal one based on an individual’s own experience, an honest assessment of one’s abil-

Figure 9 Early radiograph of ameloblastoma initially diagnosed as an apical abscess.

ities in particular areas, and where the comfort level is, drawing the line as to where one’s expertise ends.

*Case history of interest*⁴⁴: The patient in question is a 38-year-old female trial lawyer. She first reported to a general dentist who took full-mouth radiographs and developed a treatment plan. She was unhappy with the dentist and his diagnosis, and, asking around, transferred her appointment and her radiographs to a recommended prosthodontist. The original radiographs clearly showed a circular radiolucent lesion, about the size of a dime, in the left mandibular premolar area (Figure 9). The general dentist made no remark about this apparent lesion, nor was it included in his diagnosis or treatment plan. The prosthodontist, using only the original radiographs that were now over a year old, developed a treatment plan that did not include the lesion, but recommended root canal retreatment for the molar adjoining the lesion so that he could make a crown for the tooth. Only one root of the molar was treated by the endodontist referred to by the prosthodontist. The endodontist also ignored the lesion. The prosthodontist completed the molar crown and then began full-mouth restorative procedures by placing a maxillary bridge opposing the mandibular molar. By now nearly 2 years had passed and still no one had commented on the unusual bone trabeculation of the lesion, though buccal swelling had started in the left mandible.

A good deal of time was lost because the bridge made by the prosthodontist kept falling out and had to be recemented. Finally the patient pointed out the swelling in the mandible, but because she had no pain in the area the prosthodontist ignored her concern. After some

Is the patient comfortable about my ability to perform the procedure?
Is this procedure in my repertoire?

time she insisted, so he referred her to the same endodontist who had treated her before. She did not remember being pulp tested, but his diagnosis was that she had an abscess from the first premolar and should have root canal treatment. He gave her an appointment, but when she arrived for treatment, his associate took over and did the treatment in one appointment. He also told her that he was treating an abscess, even though there was only bony swelling; no sinus tract, no discomfort or redness. He told her it would heal following the root canal treatment. He did not recommend a biopsy into the buccal lesion (Figure 10).

The lesion continued to noticeably swell to the buccal (but still no pain or sinus tract), and in disgust she went to another endodontist. He suggested root canal treatment

Figure 10 Later radiograph showing root canal filling placed in first premolar to treat what was thought to be an “apical abscess”.

for the second premolar, but by now she was disgusted and turned to the local university dental school for advice.

At the dental school clinic, the diagnosis was made that this was not a chronic apical abscess and sent her to oral and maxillofacial surgery where she had a biopsy taken and she was informed that she was suffering from an ameloblastoma that was not malignant but was destroying her jaw. By this time it had crossed the midline and was approaching the right first molar. They referred her to an oral and maxillofacial surgeon who specialized in such cases. He operated and excised her mandible from left second molar to right second premolar (Figure 11). He then implanted a section of one of her ribs and a metal device to maintain her jaw alignment (Figure 12).

Figure 11 Presurgery panograph showing the extent of the growth of the ameloblastoma. Black arrow (left) marks the initial lesion. Black arrow (right) marks the extent of growth. White arrow marks second premolar with root canal filling shown in Figure 10. The pen marks are evidently the surgeon’s mark for the left excision, and the parallel–diagonal marks are for the mandibular canal.

Figure 12 Postsurgical panograph shows the extent of excision of the mandible to remove the ameloblastoma—from left second molar to right second premolar. The metal framework holds the remaining mandible in position, while the implanted rib (vague image just above the metal) attaches and heals in place.

By now, over 6 years had elapsed, and she had been treated by a general dentist, a prosthodontist, three endodontists, an oral and maxillofacial surgeon in a dental school, and an oral and maxillofacial surgeon who had additional experience in such cases.

The patient lost over 2 years in her law practice, and even more when the word went out in the law community that she had “cancer” and would not live long enough to take on a new case.

She sued the original five dentists who all had the same insurance carrier. Expert witnesses testified about the lack of professional skill and their failure to meet the community standard of care. To protect their reputations they chose to settle out of court, and the insurance company paid over \$1,000,000 to the plaintiff as well as her lawyer’s fees. She eventually returned to her law practice.

The case history as reported above does not contain all of what is contained in the documents from all the providers to accurately comprehend and correlate the data and allegations. What can be pointed out is that the general dentist should have noted the radiographic lesion associated with the left mandibular premolars in his diagnostic workup and incorporated it in his treatment plan. He failed to make a proper diagnosis and recommendation. The patient left the general dentist prior to commencing treatment, and therefore he could have been dropped from the lawsuit. The prosthodontist should have taken new radiographs as he made a new treatment plan and he should have noted the lesion in question. He failed by requesting endodontic therapy on a tooth adjacent to the one with the alleged pathosis, and therefore he too failed to make a proper diagnosis. The first endodontist referred to should have seen the radiolucency in the premolar area on the radiograph when examining for the referred molar and should have pulp tested the premolars and discussed it with the patient and the prosthodontist. The endodontist had a duty to reevaluate his treatment on the molar since it had a complication and only one root was treated. If he had, he should have noted the changes in the premolar area. This was the third missed opportunity for a diagnosis. Had the prosthodontist initially listened to the concerns of the patient when she complained about the swelling in her mandible, he would have had another opportunity to redeem himself with a proper diagnosis or appropriate referral. The multiple failures of the bridge on the right side have no significance to the case at hand. The root canal filling by the first endodontist’s associate was acceptable, except that the diagnostic procedures, more likely than not,

failed to include all diagnostic tests to correlate clinical findings with radiographic findings—another failure to diagnose. The failure to not recommend a biopsy was not a deviation from the standard of care, unless there was more involvement than the case, as reported, states. The last endodontist failed to make a proper diagnosis and would have treated the second premolar unnecessarily had the patient agreed to his recommendation. Fortunately, the patient finally did receive a proper diagnostic evaluation in the dental school clinic that should have been made by all of the previous endodontists involved and by the prosthodontist. The patient suffered, due to the various deviations from the standard of care and from failure to be diagnosed and appropriately referred, as her case progressed with dental treatment through several providers.

Dietz⁴⁰ has listed four general categories in which referral should be considered.

- (1) The complex case involving multiple, dilacerated, obstructed, or curved canals; malpositioned and malformed teeth; and complex root morphology. To this one might add unusual radiographic lesions that do not appear to be “standard” periapical lesions.
- (2) Emergencies in which a patient needs immediate treatment for toothaches, broken crowns, clinical exposures, infection, or traumatically injured teeth.
- (3) Medically compromised patients with cardiovascular conditions, diabetes, and blood disorders.
- (4) Mentally compromised patients, those with a true mental disorder and those who have problems with dentistry.

Harman⁴¹ has added that if the general dentist believes that a good and proper diagnosis goes beyond his or her abilities, then the dentist should refer the patient. Nash⁴² has estimated that 85 to 90% of all endodontic referrals come from other dentists. The remainder are self-referrals, walk-ins, and patient or physician referrals.

Prearranged referral agreements are *not* appropriate. They violate the professional conduct rules of most State Education Departments as well as Codes of Ethics. It is not considered a prearranged referral to refer a patient to a plan participant in a managed care dental benefits plan or an employee dentist within a practice as long as she/he is a true specialist. It is *never* appropriate to give something of value in exchange for a referral.

The endodontist would much rather receive the patient at the beginning of treatment than become a “retreat-odontist.” Failure to refer to a specialist when the generalist knew or should have known that the treatment was beyond his or her knowledge, technical skill, or ability to treat with a reasonable likelihood of success; failure to inform the patient of the reason for the referral, options, and risks; and failure to avoid referral to a specialist whom the referring dentist knew or should have known that he/she provided substandard care; and failure to keep accurate and complete documentation of the patient are all liability issues.

Summary

The primary line of defense is to avoid causing the patient to seek legal counsel by communicating properly when the DPR is established. The second line of defense is to avoid having an uninformed patient by having an appropriate consent for treatment. The third line of defense is to avoid creating damaging evidence by having a good record-keeping system. The umbrella of all defenses is to practice within the accepted standard of care and within one’s capabilities.

CHAPTER 4

EFFECTS OF DENTAL IMPLANTS ON TREATMENT
PLANNING FOR PROSTHODONTICS,
PERIODONTICS, AND ENDODONTICS

MAHMOUD TORABINEJAD

After ascertaining the chief complaint, collecting pertinent information regarding the patient's medical and dental history, performing complete subjective as well as objective and radiographic tests, and analyzing the obtained data, the dentist should be able to come up with the right diagnosis. Once the nature of the problem is identified, proper treatment planning should be formulated for the patient. Treatment planning can sometimes become complicated and is affected by the views of the stakeholders (patients, insurance companies, dentists) who have different perspectives and expectations regarding the outcome of treatment. Patients are usually content as long as their treatment is functionally and esthetically pleasing. Insurance companies measure success by access to care, quality of care, and cost as well as survival rate of treatment. Dentists are usually concerned with the quality of delivery of provided care and fair compensation.¹

In addition to general expectation of the stakeholders, a number of other factors can influence the treatment planning. These include procedure involved, the restorative material used, the influence of one treatment on another, the availability of specialized expertise, the projected longevity of treatment, the functional and psychological satisfaction achievable, the ability of the patient to maintain the results of treatment, the affordability of the services, and the individual clinician's skill and support.²

Treatment planning should be patient-centered, not based solely on dental insurance benefits or guided by the desires and clinical experience of the practitioner. It should be evidence based and ideally should preserve the biologic environment while maintaining or restoring esthetics, comfort, and function. The real art of dentistry is to coordinate and interface these perspectives and expectations among stakeholders, provide the best quality of care to the patient, and satisfy the needs of the other involved parties in most clinical situations.

The art and science of dentistry have been unitized to prevent oral diseases such as caries and inflammation of the periodontium, and restore function and esthetics to teeth affected by these diseases, using periodontal treatment, root canal therapy, and restorative procedures. Advances in both the biologic and technologic aspects of dentistry have resulted in the retention and rehabilitation of millions and millions of natural teeth, to the satisfaction of patients throughout the world. Despite these advances, many teeth develop decay, severe periodontal involvement, become fractured, and succumb to extraction. Traditionally, these teeth were treated endodontically or periodontally, or if not restorable, they were extracted and replaced with either fixed or removable prosthesis.

Introduction of cylindrical-style endosseous implants^{3,4} to the dental profession, and their high survival rates, has significantly affected treatment planning in dentistry. The purpose of this chapter is to discuss the effects of dental

implants on treatment planning for prosthodontics, periodontics, and endodontics.

Effects of Dental Implants on Prosthodontics

The benefits of extraction and replacement of a missing tooth with a fixed partial denture (FPD) are prevention of shifting of the adjacent teeth, improved chewing ability, and esthetics (Figure 1). Studies have shown no adverse effect on the surrounding alveolar bone⁵ and attachment level between teeth supporting FPDs and a homologous tooth⁶ and no difference in plaque

index, gingival index, and probing depths between baselines.⁷ It has also been found that if hygiene is maintained to a high level, no inflammation of the mucosa should be seen under the pontic, regardless of the pontic material used.⁸

Tooth preparation, impression, temporization, and cementation while fabricating an FPD can, however, all result in pulpal injury.⁹ Endodontic treatment (Figure 2) is often needed in the years following crown cementation.¹⁰ When examining teeth with advanced periodontal disease over an average period of 8.7 years, abutment teeth for bridges needed endodontic treatment five times more often (15% vs 3%) than non-abutment teeth. In a clinical study, Goodacre et al.¹¹

Figure 1 Replacement of missing teeth with a fixed partial denture can prevent shifting of the adjacent teeth. **A**, Clinical photo. **B**, Radiograph.

Figure 3 After 5 years of service, development of decay under crown margin of second mandibular molar.

report on the incidence of decay (0–27%) (Figure 3), pulpal problems (3–38%), and periodontal problems (4%), as well as technical complications such as porcelain fracture (2%), in patients who have had fixed prosthodontics for a 5-year period. The findings in these studies should be considered during treatment planning in light of recent reports on the high success rate for single-tooth implants.

Whereas previously, all efforts would have been made to extract hopeless teeth and place fixed or removable prostheses, the palpable benefits of implants have caused a paradigm shift in prosthetic and surgical dentistry. Clinicians are regularly confronted with difficult choices: Should a hopeless tooth be extracted and replaced with an FPD or single implant?

Placing a dental implant, rather than an FPD, provides a functional stimulus to help preserve the remaining bone, and prevent resorption, while preserving the enamel and dentin of the adjacent abutment teeth. Furthermore, this approach is less invasive to the pulp of the adjacent teeth. The biologic advantages over traditional prosthodontic methods include preservation of the natural dentition and supporting periodontium, improved esthetics, improved hygiene accessibility, and reduced future maintenance.^{12,13} In a 3-year follow-up report of 78 single-tooth implants and 148 adjacent teeth, no adjacent teeth required extraction or endodontic treatment, and only 4 required restorations. Comparison of the periodontal status at crown placement and at follow-up revealed no differences for plaque and bleeding indices or for

pocket probing depths of the adjacent teeth. There was, however, a significant influence of the horizontal distance on interproximal bone loss in closer distances of the anterior region, but not in the posterior region.¹⁴ Peri-implant tissue differs from the gingiva surrounding natural teeth by having greater pocket depths and twice as much bleeding on probing.¹⁵ The connective tissue portion around implants contains significantly more collagen (85% vs 60%) than around natural teeth, and fewer fibroblasts (1–3% vs 5–15%).¹⁶ The majority of peri-implant tissue recession occurs during the first 3 months, with 80% showing buccal recession.¹⁶ In patients with appropriate oral hygiene, however, the intra-crevicular position of the restoration margin does not appear to adversely affect peri-implant health and stability.¹⁷

Recently, Curtis et al.² discussed the impact of new scientific advances on treatment planning in dentistry. According to these authors, treatment planning in prosthodontics has changed significantly because of the recent advances in the success rate of single-tooth implants. In 1994, Creugers and associates¹⁸ performed a meta-analysis on the dental literature since 1970, presenting clinical data regarding durability of conventional fixed bridges. These authors report an overall survival rate of $74.0 \pm 2.1\%$ after 15 years. Scurria et al.¹⁹ in another meta-analysis of the literature reported an 87% 10-year survival rate for FPDs and a 69% 15-year survival rate. A recent systematic review²⁰ compared the outcomes of tooth-supported restorations with those of implant-supported restorations. The authors concluded that at 60 months, single-tooth replacements, supported by implants, had a higher survival rate than those supported by FPDs; however, if resin-bonded FPDs were excluded, no difference was found. They reported that FPD success rates continued to drop steadily beyond 60 months. These results are consistent with the results of another systematic review by Torabinejad et al.²¹ that reported single-tooth implants, and endodontic treatments resulted in superior long-term survival, compared with FPDs.

Effects of Dental Implants on Periodontics

Previously, all efforts were made to save teeth with periodontal disease. Currently, the high success rates of implants have affected this concept, causing a paradigm shift in periodontics. Clinicians are asking:

Should a periodontally involved tooth be extracted and replaced with a dental implant?

The benefits of successful treatment of a tooth with periodontal disease include conservation of the crown and root structure, preservation of alveolar bone, and accompanying papillae, preservation of pressure perception, and lack of movement of the surrounding teeth. The harmful effects of extraction include bone resorption,²² shifting of adjacent teeth,^{23–25} and reduced esthetics and chewing ability.²⁶ Studies on long-term prognosis of teeth with periodontal disease show less than 10% tooth loss due to periodontal reasons.^{27–29} Single-rooted teeth have better prognosis compared with molar teeth.^{27–29} Presence of furcation involvement with or without surgical intervention is associated with poorer prognosis than those without furcation involvement.^{30,31} As in prosthodontics, the new innovations in implant dentistry have also decreased reliance on high-risk periodontal procedures for tissue preservation and regeneration for teeth with moderate to severe periodontal disease.² This paradigm shift in periodontics is evident in recent surveys conducted by the American Academy of Periodontology, which show 63% of periodontists are placing their primary emphasis on periodontics and 27% are placing their primary emphasis on implants.³²

Effects of Dental Implants on Endodontics

The high success rates of implants have also affected the thinking of clinicians for patients with pulpal and/or periapical diseases. Clinicians are asking: Should a pulpally/periapically-involved tooth be extracted and replaced with a dental implant? There are factors involved during decision-making in treatment planning, as to whether a tooth receives root canal treatment or is extracted and a dental implant placed. These factors can be divided into two broad categories: patient-related and treatment-related factors.³³

Patient-Related Factors

SYSTEMIC AND LOCAL HEALTH FACTORS

Based on available clinical data, it appears most of the preoperative factors such as age, gender, tooth location, lesion size, pulp status, and symptoms do not affect outcomes of root canal treatment. A history of diabetes, however, may have a negative impact on the healing of periapical lesions.³⁴ The presence of periapical lesions is the major preoperative factor having a negative influence on the outcome of root canal therapy.^{35–38}

Presence of some systemic disease can also affect the outcomes of implants.³⁹ Diabetic patients,⁴⁰ immune-suppressed individuals,³⁹ and patients who smoke^{41–44} have a higher risk of complications following placement of implants.

PULP AND PERIODONTAL CONDITIONS

Indications for root canal therapy include teeth with irreversible pulpitis, necrotic pulps, restorable crowns, salvageable periodontal conditions, salvageable resorptive defects, and favorable crown-to-root ratio. Contraindications for root canal therapy are teeth without pulpal pathosis (except those done for prosthodontics reasons), with un-restorable crowns, with unsalvageable periodontal conditions, with unsalvageable resorptive or fracture defects, and with poor crown-to-root ratio. Root canal treatment is contraindicated when there is limited remaining tooth structure and the definitive crown will not be able to engage at least 1.5 to 2.0 mm of tooth structure with a cervical ferrule.^{45,46} Bridge abutment teeth with root canal treatment fail more often than similar teeth with vital pulps.^{47–49} On the other hand, crown placement has a significant positive effect on the survival of endodontically treated teeth.⁵⁰

Indications for single-tooth implants are non-restorable tooth, unsalvageable resorptive defects, poor crown–root ratio, unstable abutment, and single-rooted teeth with infractions or vertical root fractures (Figure 4). Other indications for the use of implants

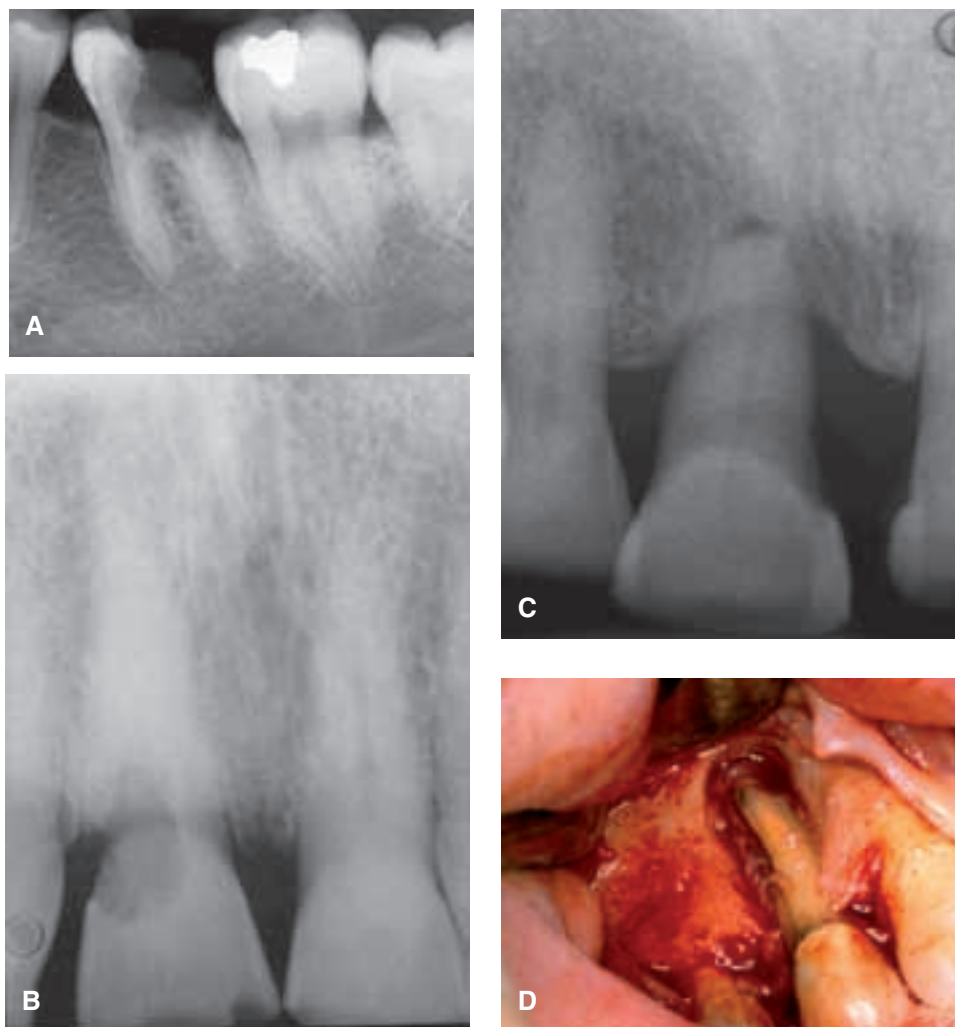

Figure 4 Root canal therapy is not indicated for teeth with **A**, un-restorable crowns; **B**, unsalvageable resorptive defects; **C**, poor crown–root ratio; or **D**, vertical root fractures.

include edentulous sites adjacent to teeth without restoration (Figure 5) or the need for restoration, abutment teeth with large pulp chambers, and abutment teeth with a history of avulsion or tooth luxation.⁵¹ Single-tooth implants are contraindicated in patients who desire to keep their natural teeth, medically compromised patients, smokers, patients who are too old or too young, and patients with difficult surgical procedures.

BIOLOGIC ENVIRONMENTAL CONSIDERATIONS

Some patients are prone to recurrent caries or periodontal disease (Figure 6). Retaining teeth in such patients can be challenging and frustrating for the practitioner as well as the patients. Placement of implants

Figure 5 Single-tooth implants are a treatment option in edentulous sites adjacent to nonrestored teeth.

Figure 6 Patients prone to **A**, recurrent caries or **B**, periodontal disease are poor candidates for fixed partial dentures.

may be more prudent in patients needing both root canal treatment and periodontal therapy. Patients with limited abilities or interest in performing routine oral hygiene procedures are also poor candidates for root canal treatment or periodontal therapy, and may be better candidates for placement of implants.

SOFT TISSUE ANATOMY

The interdental papilla sometimes does not fill the cervical embrasure space around crowns that attach to both root-canal-treated teeth and dental implants. It has been determined, however, that soft tissue will fill the cervical embrasure around a crowned implant when the incisio-cervical distance from the proximal contact to the interproximal bone crest is 5 mm or less.⁵²

Periodontal biotype (thick or thin) can affect the potential for soft tissue to fill the cervical embrasure space around implants (Figure 7). In a thin biotype, papillae adjacent to implants can seldom be recreated when the distance is more than 4 mm between the interproximal bone crest and the desired height of the interdental papillae.⁵³ Preservation of a tooth through root canal treatment may provide better soft tissue esthetics than extracting the tooth and placing a dental implant in a patient with thin biotype.

QUANTITY AND QUALITY OF BONE

Quantity and quality of bone have no significant effect on the outcome of root canal treatment. By contrast, the quantity of available bone affects the feasibility of placing implants without bone grafting. Bone quality also affects implant success with type IV bone (Figure 8), producing lower success compared with types I to III

bone.⁵⁴ Retaining teeth, through root canal treatment, having a poor long-term prognosis, and performing high-risk endodontic surgical procedures as well, can substantially affect the amount of bone and prognosis of future implants in those sites. Early removal of teeth with poor prognosis and placement of dental implants may produce an environment more suitable for ideal implant positioning and optimal esthetics.⁵⁵

TEETH WITH UNIQUE COLOR CHARACTERISTICS

Color matching in anterior teeth with unique dentin colorations can be a significant challenge for the practitioner. Retaining such teeth through root canal treatment (even with heroic efforts) without ceramic crowns may be esthetically advantageous to extracting them and placing implant crowns that do not match the surrounding environment (Figure 9).

Color-matching anterior teeth needing root canal treatment and a thick ceramic crown can sometimes be very difficult. Construction of a ceramic crown made for an implant usually produces a better color result because it can be fabricated with a greater thickness of porcelain that enhances the color-matching potential, particularly in esthetic regions of the mouth.

Treatment-Related Factors

ETHICAL CONSIDERATIONS

Dental practitioners have an obligation to provide the longest lasting, most cost-effective treatment that addresses the chief complaint of the patient and meets

Figure 7 **A**, Patients with thick biotype gingiva and teeth in esthetic zones are good candidate for dental implants. **B**, Patients with thin biotype gingiva and teeth in esthetic zones are good candidate for root canal treatment.

Figure 8 **A**, Mandibular molar region has good bone quality for implant placement. **B**, Maxillary molar region with poor quality bone is not ideal for dental implants.

or exceeds patient expectations whenever possible. Advice to the patient and the treatment provided should be patient-centered, not based solely on dental insurance benefits or guided by the desires and existing clinical experience of the practitioner. Practitioners should strive to present a balanced perspective

regarding alternative treatments. The capacity to achieve balance requires practitioners to be familiar with both treatments. It is difficult to objectively present alternative treatment options when an individual has only substantive clinical experience with one option.

Figure 9 Retaining teeth through root canal treatment and bleaching without ceramic crowns in esthetic zones may be esthetically advantageous over placing implant crowns that are difficult to match to adjacent teeth.

PATIENT COMFORT AND PERCEPTIONS

The studies that have focused on the pretreatment anxiety of patients seeking root canal treatment are inconclusive. Whereas some note no difference between root canal treatment and extraction,^{56,57} others⁵⁸ report higher anxiety levels in patients being considered for randomized controlled trial (RCT). A lack of data exists about examining pretreatment anxiety of patients seeking implant treatment. The most similar treatment that has been studied is extrac-

tion. However, patients presenting for extraction are often in pain, as are those presenting for root canal treatment. This may have the effect of raising the anxiety levels of both these patient populations.

The question of pain associated with treatment has been analyzed to some degree in implant literature, although not to the same extent as in the endodontic literature. Andersson et al.⁵⁹ found that 88.2% of subjects gave positive responses to the question of implant treatment being pain-free, with 70.6% giving a “Yes” response along with 17.6% stating, “Yes, with doubt.” Watkins et al.,⁶⁰ on the other hand, observed a mean pain score of 22.7 out of 100 in 333 subjects seeking RCT, with an additional score of 19.9 noted “unpleasantness.” Of significance, 20% of the endodontic cohort reported to the appointment in pain. One prospective study⁶¹ focused on implant complications and found that 92% of the subjects felt the number of complications was acceptable. No endodontic study was found to have evaluated this question.

PROCEDURAL COMPLICATIONS

Root canal treatment can sometimes be associated with procedural accidents (Figure 10A). These mishaps can occur during different phases of root canal treatment.⁶² Some of these accidents can have a negative impact on the outcomes of root canal treatment.^{63–65} Studies have shown that the apical extension of root canal filling materials as well as quality of obturation can affect the prognosis of root canal treatment.^{33,66}

As with root canal treatment, complications can occur with dental implants. Surgical implant complications

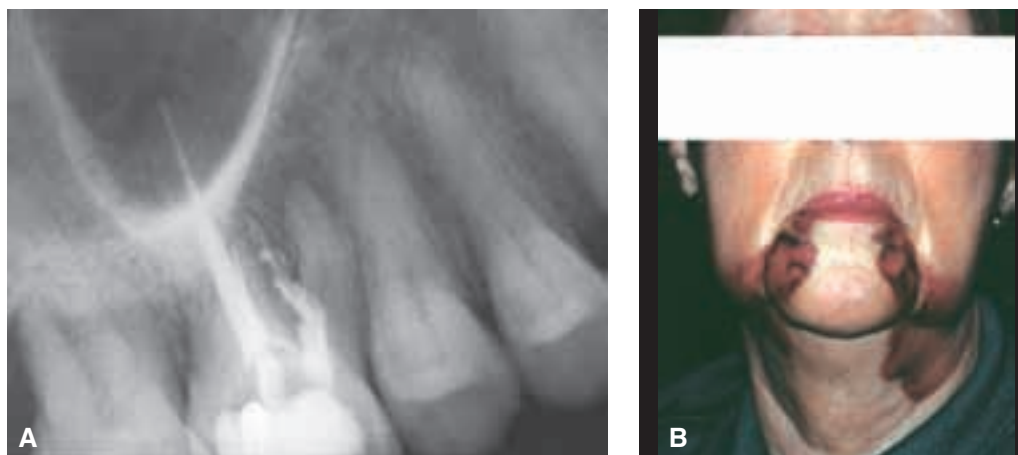

Figure 10 Root canal treatment or implant placement can sometimes be associated with procedural accidents. Examples are **A**, furcation perforation in a maxillary molar; **B**, a large hematoma following implant surgery.

include hematomas (Figure 10B), echymosis, and neurosensory disturbance.⁵⁴ Inflammation and/or proliferation of gingiva as well as soft tissue fenestration/dehiscence can occur following implant placement. Early implant loss can occur as a result of failure of the implant to integrate with the bone. Mechanical complications of implant placement include screw loosening, screw fracture, prosthesis fracture, and implant fracture.⁵⁴ Minor complications such as screw loosening are easily corrected, whereas major complications such as fenestration/dehiscence can result in clinical failure.

ADJUNCTIVE PROCEDURES REQUIRED

A number of adjunctive procedures can be performed in high-risk root canal treatment or placement of an implant and crown. Saving some teeth with significant decay or periodontal disease may require crown lengthening through surgery or orthodontic extrusion as well as periodontal disease therapy. In light of high success rates with dental implants, the value of such procedures needs to be reevaluated.

Lack of bone prior to placement of an implant may require bone grafting or distraction osteogenesis, sinus grafting, and ridge augmentation. These highly difficult technical procedures are expensive, unpleasant, and time consuming.

COST OF TREATMENT

According to the data collected by the American Dental Association (Jack Brown, personal communication) through its Services Rendered Survey that yield national and subnational estimates of fees for general practitioners (GPs) and specialists for each CDT4 code, the initial cost of an extraction, endosteal implant, abutment, and crown is approximately \$2,850 and does not vary substantially whether a GP, an oral surgeon, or a periodontist provides the surgical care. On the other hand, the costs of an anterior root canal treatment provided by a GP with a resin-composite restoration, and a molar root canal treatment provided by an endodontist followed by an amalgam build-up and a porcelain fused to high noble metal crown are approximately \$743 and \$1,765, respectively. This simple analysis does not include consultation fees and pre-operative radiographs that may vary from simple periapical views to cone-beam tomography and CT scan for implant placement. Additional separately charged procedures such as surgical guides (stents) or provisional restorations may also be necessary. Retention of a periodontally sound tooth through root canal treatment clearly has tremendous cost benefit and cost-

effectiveness in comparison with any alternative where the tooth is lost.

TREATMENT OUTCOMES

Clinical and radiographic examinations are the most common procedures used to determine outcomes of root canal therapy. Examination of the data regarding success and failure of root canal treatment shows significant variability in material composition, treatment procedures, and evaluation criteria. Some studies use recognized evaluation methods, such as the periapical index.⁶⁷ The periapical index relies on the comparison of the radiographs with a set of five radiographic images representing a radiographically healthy periapex (score 1) to a large periapical lesion (score 5). Another evaluation method that has been used in several studies is the system suggested by Halse and Molven,⁶⁸ who place radiographic findings in one of the following groups: (1) success, where there is no visible periapical lesion; (2) uncertain, where there is an uncertain finding such as an existing increased width of the periodontal ligament space; and (3) failure, where there is a pathologic finding such as a periapical radiolucency. The shortcomings of these methods of evaluation are that they determine "success" strictly on the basis of radiographic findings. As early as 1966, Bender and coworkers⁶⁹ noted that radiographic interpretation is often subject to personal bias and that a change in angulations can often give a completely different appearance to the lesion, making it appear either smaller or larger. It has also been shown that different observers may not agree on what they see in a radiograph, and in fact the same observer may disagree with himself if asked to review the same radiograph some time later.⁷⁰

Based on the results of studies published since 1996, the American Dental Association Council on Scientific Affairs reports high implant survival rates for various clinical situations.³⁹ With regard to the single-tooth implant, the Council's evaluation of 10 studies involving over 1,400 implants shows survival rates (without giving length of time) ranging from 94.4% to 99%, with a mean survival rate of 96.7%. High mean survival rates were also reported for partially edentulous patients with implant FPDs. This report states that immediate loading of implants does not lower the survival rates, with three studies reporting survival rates ranging from 93.5% to 95.6%.³⁹ In a systematic review of clinical implant studies, Creugers and associates⁷¹ predicted a 4-year survival rate of 97% for single implants. In another paper, Lindh et al.⁷² performed a meta-analysis of

implant studies involving partially edentulous patients. They reported a success rate of 97.5% after 6 to 7 years for a single-implant crown.

In a recent systematic review, Torabinejad et al.²¹ compared the outcomes of endodontically treated teeth with those of single dental implant-supported crown, FPD, and no treatment following extraction. Success data in this review consistently ranked implant therapy as being superior to endodontic treatment, which in turn was ranked as being superior to fixed prosthodontic treatment (Table 1). At 97%, long-term survival was essentially the same for implant and endodontic treatments and was superior to extraction and replacement of the missing tooth with a FPD. Iqbal and Kim⁷³ have reported similar findings when they compared the survival of restored endodontically treated teeth with implant-supported restorations.

ALTERNATIVE TREATMENTS

The treatment options following unsuccessful initial root canal treatment are re-treatment and/or endodontic surgery. In two separate searches, investigators at Loma Linda University searched for clinical articles pertaining to success and failure of nonsurgical and surgical re-

treatment, and assigned levels of evidence to these studies. Their first search, related to nonsurgical re-treatment, resulted in the identification of 31 clinical studies and 6 review articles.⁷⁴ The success rate of non-surgical re-treatment ranged between 40% and 100%. Based on the literature, it appears that the success rate is very high in teeth without periapical lesions and when the cause of failure is identified and corrected properly.⁷⁴ Their second search, pertaining to success and failure of periapical surgery, located many clinical studies, most of which were case series.⁷⁵ The success rate of surgical endodontics varied from 31% to over 90%. The significant differences in the techniques, materials, and methods of evaluation make it very difficult to compare these studies. Most recent studies using new materials and techniques report high success rates for endodontic surgery.⁷⁶⁻⁷⁹

Considering factors involved in treatment planning for patients who have been afflicted by oral diseases or traumatic injuries, decision to keep a tooth through root canal treatment or periodontal therapy, or extraction and placement of a fixed or partial denture, or an implant supported restoration, should be based on scientific evidence. Ideally one should strive to preserve the biologic environment, while maintaining or restoring long-term esthetics, comfort, and function for the patient.

Table 1 Pooled and Weighted Survival and Success Rates of Dental Implants, Root Canal Treatment, and Three Unit Bridges 2-4, 4-6, and Over 6 Years

	Success	Survival
2-4 years		
Dental implant (pooled)	98 (95-99)	95 (93-97)
Dental implant (weighted)	99 (96-100)	96 (94-97)
Root canal treatment (pooled)	90 (88-92)	94
Root canal treatment (weighted)	89 (88-91)	-
Three unit bridge (pooled)	79 (69-87)	94
Three unit bridge (weighted)	78 (76-81)	-
4-6 years		
Dental implant (pooled)	97 (96-98)	97 (95-98)
Dental implant (weighted)	98 (97-99)	97 (95-98)
Root canal treatment (pooled)	93 (87-97)	94 (92-96)
Root canal treatment (weighted)	94 (92-96)	94 (91-96)
Three unit bridge (pooled)	82 (71-91)	93
Three unit bridge (weighted)	76 (74-79)	-
6+ years		
Dental implant (pooled)	95 (93-96)	97 (95-99)
Dental implant (weighted)	95 (93-97)	97 (96-98)
Root canal treatment (pooled)	84 (82-87)	92 (84-97)
Root canal treatment (weighted)	84 (81-87)	97 (97-97)
Three unit bridge (pooled)	81 (74-86)	82
Three unit bridge (weighted)	80 (79-82)	-

PATHOBIOLOGY

CHAPTER 5

STRUCTURE AND FUNCTION OF THE DENTIN–PULP COMPLEX

SYNGCUK KIM, KARIN J. HEYERAAS, SIVAKAMI R. HAUG

This chapter is dedicated to the late Dr. Yoshiaki Kishi, Department of Oral Anatomy, Kanagawa Dental College, Yokosuka, Japan, who contributed significantly toward the understanding of the microvasculature in the oral tissues.

The dental pulp is a connective tissue like other connective tissues in the body. It consists of nerves, blood vessels, ground substances, interstitial fluid, odontoblasts, fibroblasts, and other cellular components. On a radiograph, the dentist sees the pulp as a dark line running coronal to apical in the center of the root. A researcher sees the pulp as a fibrous connective tissue strip with blood (Figure 1). As the late I.B. Bender said, “The pulp is a small tissue with a big issue.” The uniqueness of the pulp can be appreciated only when perturbed, since the pulp resides in a rigid capsule consisting of enamel and dentin layers.

Figure 1 The young dog pulp shows highly vascularized connective tissue encased in rigid tissues that provide a unique hemodynamic environment. Pulp extirpation slide.

Unlike in other tissues this encasement creates a low-compliance environment in which a small increase in tissue volume, due to inflammation, has serious consequences. The other uniqueness of the pulp is that it consists primarily of sensory fibers. Despite its confinement by enamel and dentin, the dentin–pulp complex functions as an exquisitely responsive sensory system, using unusual mechanisms to defend it from insults. Its sensory fibers together with its microcirculatory vasculature make the pulp a unique organ to study the neurovascular interactions during various states of inflammation.

When the pulp is involved, endodontists face diagnostic dilemmas such as when presented with a tooth with thermal sensitivity, sensitivity to osmotic pressure and/or hydrostatic pressure, as well as other symptoms. The treatment option recommended to the patient must be based on sound biological/physiological knowledge. As such, one must understand the very tissue frequently eliminated by endodontic therapy.

The purpose of this chapter is to bring together the available information on the development, structure, and function of the dentin–pulp complex, with the aim that this knowledge provides a firm biological basis for clinical decision making.

EMBRYOLOGY

Human tooth development begins as early as the fifth week of gestation for primary dentition. Mineralization of primary dentition begins during the 14th week of gestation at the same time when the permanent teeth start to develop. The first primary teeth erupt around the age of 6 months and the first permanent teeth around 5 to 6 years. The third molars are the last teeth to be

formed with the completion of crown development between 12 and 16 years. Thus, tooth development starts from the embryonic stage and continues into early adulthood. Recent findings have revealed multiple growth and transcription factors from several signaling families acting as critical regulators at the initiation, and subsequently throughout all stages, of tooth development. Gene-targeting experiments have demonstrated the biological function of transcription factors in regulating tooth morphogenesis. Today over 200 genes have been demonstrated to be active in the developing tooth, and a detailed list can be found in a database at <http://bite-it.helsinki.fi/>. This chapter will cover an overview of tooth development while referring details to excellent reviews in this field.^{1–4}

Teeth derive from two principal cell types: the ectoderm and the cranial neural crest-derived ectomesenchyme. The ectodermal component gives rise to the ameloblasts that form the enamel of the tooth crown while the ectomesenchyme gives rise to the dentin, pulp, and periodontal tissue. The neural crest cells migrate from the crest of neural ectoderm. Only neural crest-derived mesenchyme has the ability to respond to the initial signals from the dental epithelium and contribute to tooth formation.^{5,6} Initiation of tooth development begins with the formation of dental lamina, a thickening of the oral epithelium. Localized proliferation within the dental lamina leads to the formation of a series of epithelial outgrowths/buds at sites where the tooth should be, thus marking the time and position of tooth development. The underlying mesenchyme underneath, called the dental papilla, forms the future dentin and pulp. The dental follicle or sac surrounds the dental papilla and the enamel organ and gives rise to the supporting tissue.

There are three stages in the early tooth development: the bud, the cap, and the bell stage. During the bud stage, the mesenchyme underneath condenses and begins to appear like a cap on the dental papilla, thus leading to the stage known as the cap stage. The dental epithelium becomes to be known as the enamel organ from the cap stage. The enamel organ, the dental papilla, and the dental follicle constitute the dental organ or the tooth germ. Transition from the bud to the cap stage is a critical step in tooth morphogenesis involving multiple signaling molecules within the enamel organ epithelium. These have been implicated to regulate the expression of various transcription factors in the surrounding mesenchyme.^{4,7,8}

During the cap stage, a critical signaling center, the enamel knot, is formed within the enamel organ epithelium. The enamel knot is a dense population of epithelial cells without any proliferative activity and marked by the expression of multiple signaling molecules that are critical for the proper development of the tooth organ. The enamel knot serves as a transient signaling

center and is removed by programmed cell death. In molar teeth, this primary enamel knot is replaced by secondary enamel knots that are responsible for inducing cusp development. The enamel knot is critical for the patterning process such as cusp shape and size during tooth morphogenesis.⁴ Determination of tooth identity depends on the expression of certain homeobox genes in the mesenchyme.^{9,10} Continuous growth of the tooth germ leads to the bell stage during which the crown assumes its final shape (morphodifferentiation) and the cells that will be making the hard tissue (ameloblasts and odontoblasts) acquire their distinctive phenotype (histodifferentiation) (Figure 2). Cranial neural crest-derived

Figure 2 Early dental pulp, or dental papilla, exhibiting a cellular mass at the center of the tooth bud in the early bell stage. Nerve fiber bundles are evident in cross section as dark bodies apical to dental papilla yet are absent in the papilla itself. Human fetus, 19 weeks. Palmgren nerve stain. Reproduced with permission from Arvil T, Hågströms I. Innervation of the teeth. *Transactions Royal School of Dentistry, Stockholm*, 3:1958.

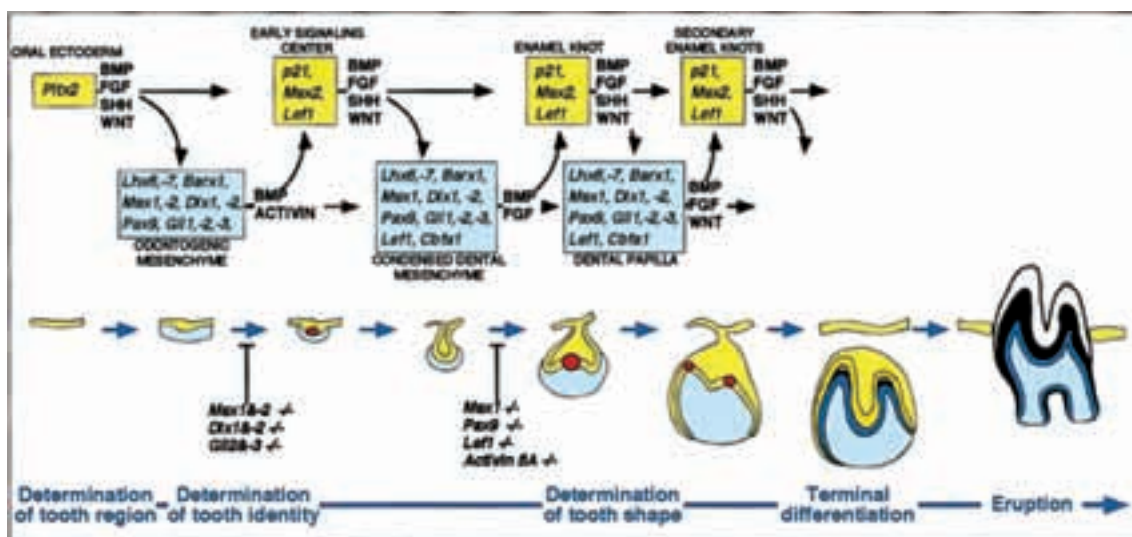

Figure 3 Schematic representation of the signals and transcription factors mediating the reciprocal signaling between epithelium and mesenchyme during advancing tooth development. The molecular cascades are shown above and the corresponding morphological stages below. The transcription factors and signals considered to be important for particular development stages are indicated in the squares and above the arrows, respectively. Note how the same signaling pathways are used reiteratively during advancing tooth development, and how tooth development arrests in the knockout mouse experiments to the early signaling center or the enamel knot stage. Yellow, tooth epithelium; red, enamel knots; blue, tooth mesenchyme. Reproduced with permission from Jernvall J and Thesleff I.⁷

odontogenic mesenchyme and its adjacent inner enamel organ epithelium differentiate into preodontoblast and preameloblast, respectively. Dentin and enamel will begin to form at the junction between odontoblasts and ameloblasts to complete the tooth-forming process (Figure 3).

Blood supply to the developing tooth is via the dental follicle during the cap stage. The enamel organ is avascular although there are numerous blood vessels in the adjacent follicle. These blood vessels ramify around the tooth germ, their number in the dental papilla increase reaching a maximum when matrix deposition begins. The vessels in the papilla are arranged in groups that coincide with the future root-forming site.

The first trigeminal nerve fibers are present in the vicinity of the tooth at the bud stage and around the tooth organ in the dental follicle during the cap and bell stages.¹¹⁻¹⁵

In the bell stage, sensory nerve fibers containing the neuropeptides calcitonin gene-related peptide (CGRP) and substance P (SP) are present in the dental follicle but not in the dental papilla and the enamel organ.¹⁶ In the advanced bell stage, after initiation of dentin and enamel formation, CGRP- and SP-containing nerve fibers enter the dental papilla. Sympathetic nerve-derived neuropeptide Y (NPY) appears later at the beginning of the root formation.¹⁶ With the start of root development,

a subodontoblastic nerve plexus gradually forms with concomitant appearance of CGRP- and SP-containing nerve fibers within the dentinal tubules (Figure 4). Also

Figure 4 Expression of calcitonin gene-related peptide (CGRP) (bottom) and substance P (SP) (top) in the pulp by an immunocytochemical method. CGRP and SP receptors (arrows) are colocalized and surround blood vessels.

with the start of root formation, CGRP-, SP-, and NPY-immunoreactive nerves begin to appear in the developing periodontal ligament (PDL), although a mature distribution pattern does not occur until root formation is nearly completed.¹⁶

The expression of nerve growth factors such as nerve growth factor, brain-derived neurotrophic factors, gonadotropin neurotrophic factor, NTN, neurotrophin 3, and neurotrophin 4 (NT-4) has been shown at specific locations during various developing stages of the tooth.^{17–19}

Structures and Functions

DENTAL–PULP COMPLEX

As long as dentin is covered peripherally by enamel on coronal surfaces and cementum on radicular surfaces, the dental pulp will generally remain healthy for life, unless the apical blood supply is disrupted by excessive orthodontic forces or severe impact trauma. Most pathological pulp conditions begin with the removal of one or both of these protective barriers via caries, fractures, or abrasion. The result is the communication of the pulp soft tissue with the oral cavity via dentinal tubules. A classic work done by Pashley et al.,²⁰ using radioactive ¹³¹I in dog teeth, clearly demonstrated that once dentin tubules are opened, molecules can permeate to the pulp easily (Figure 5). This dentin perme-

Figure 5 Pashley's experimental setup for the study of dentin permeability. ¹³¹I, as the marker, was diffused through the buccal chamber attached to the naked dentin of the tooth. Blood was drawn from the venous system and checked for ¹³¹I radioactivity. The appearance of ¹³¹I in the blood demonstrates the degree of permeability of the dentin. ability has a huge impact on the pathogenesis of the pulp in many clinical situations. This will be discussed later.

It is apparent that substances easily permeate dentin, permitting thermal, osmotic, and chemical insults to act on the pulpal constituents. The initial stages involve stimulation or irritation of odontoblasts and may proceed to inflammation and often to tissue destruction. First, one must examine the dentin structure.

DENTIN STRUCTURE

Dentin is a calcified connective tissue consisting of approximately 70% inorganic material and 10% water. Organic matrix accounts for 20% of dentin, of which about 91% is collagen. Most of the collagen is type I, but there is a minor component of type V. Noncollagenous matrix components include phosphoproteins, proteoglycans, *g*-carboxyglutamate-*n*-containing proteins, acidic glycoproteins, growth factors, and lipids.

Dentin is penetrated by millions of tubules; their density varies from 40,000 to 70,000 tubules per square millimeter^{21,22} (Figure 6A). Tubules are from 1 μ m in diameter at the dentinoenamel junction to 3 μ m at their pulpal surface. These variations in the size of the tubules, in the dentin surface area, and in the surface area covered by the tubules are important in the pathogenesis of pulpal inflammation. For instance, permeation of toxic substances to the pulp created by caries or restorative procedures from the dentinoenamel junction is less likely compared to permeation from the middle of the dentin due to the degree of surface area covered by the tubules. From a purely anatomical standpoint, possible pulpal damage increases exponentially the deeper toxins reach into the dentin.

Dental tubules contain a fluid that has a composition similar to extracellular fluid.²³ If the fluid becomes contaminated with carious bacterial endotoxins and exotoxins, it becomes a reservoir of injurious agents that can permeate through dentin into the pulp to initiate inflammation.²⁴ It is useful to understand the important variables that control dentin permeability.

DENTIN PERMEABILITY

Dentinal tubules in the coronal dentin converge from the dentinoenamel junction to the pulp chamber.²⁵ This tends to concentrate permeating substances into a smaller area at their terminus in the pulp. The surface area occupied by tubules at different levels indicates the effect of tubule density and diameter. One can

Figure 6 A, This picture shows the heterogenous nature of the dentin tubular diameters along the dentin length and dentin surface. The tubular diameter increases (up to 4 μm) and the dentin surface area occupied by the tubules increases logarithmically approaching the pulp. Courtesy of Dr. H. Trowbridge. **B**, Scanning electron micrograph (SEM) of a cross section of tubules. Courtesy of Dr. D. Pashley.

calculate from Garberoglio and Brännström's²² observations that the area of dentin occupied by tubules is only 1% at the dentinoenamel junction and increases to 45% at the pulp chamber (Figure 6B).

The clinical implications of this are enormous. As dentin becomes exposed to increasing depths by

restorative procedures, attrition, or disease, the remaining dentin becomes increasingly permeable.^{26,27} Thus, dentin removal renders the pulp more susceptible to chemical or bacterial irritation. This functional consequence of tubule area is also responsible for the decrease in dentin microhardness closer to the pulp^{28,29}; as tubule density increases, the amount of calcified matrix between the tubules decreases. This relative softness of the dentin lining the pulp chamber facilitates canal enlargement during endodontic treatment.³⁰

Overall dentin permeability is directly proportional to the total surface area of exposed dentin. Obviously, a leaking restoration over a full crown preparation provides more surface for diffusion of bacterial products than would a small occlusal restoration.³¹ Restorations requiring extensive and deep removal of dentin (i.e., preparation for a full crown) would open more and larger tubules and increase the rate of injurious substances diffusing from the surface to the pulp—thus the importance of “remaining dentin thickness.”^{32,33} The permeability of the root is 10 to 20 times less than that of a similar thickness of coronal dentin.³⁴ This may account for the lack of pulpal reactions to periodontal therapy that removes cementum and exposes root dentin to the oral cavity.

Recent evidence indicates that dentin permeability is not constant after cavity preparation. In dogs, dentin permeability fell over 75% in the first 6 hours following cavity preparation.³⁵ Although there were no histological correlates of the decreased permeability, dogs depleted of their plasma fibrinogen did not decrease their dentin permeability following cavity preparation.³⁶ The authors speculated that the irritation to pulpal blood vessels caused by cavity preparation increased the leakage of plasma proteins from pulpal vessels into the dentinal tubules, where they absorb to the dentin, decreasing permeability. Future study of this phenomenon is required to determine if it occurs in humans.

The character of the dentin surface can also modify dentin permeability. Two extremes are possible: tubules that are completely open, as seen in freshly fractured³⁷ or acid-etched dentin,³⁸ and tubules that are closed either anatomically³⁹ or with microcrystalline debris.⁴⁰ This debris creates the “smear layer” that forms on dentin surfaces whenever they are cut with either hand or rotary instruments.⁴¹ The smear layer slows bacterial penetration,^{42,43} but permits a wide range of molecules to readily permeate dentin. Small molecules permeate much faster than large molecules. Smear layers are often slowly dissolved over months to years as oral fluids percolate around microleakage channels between restorative

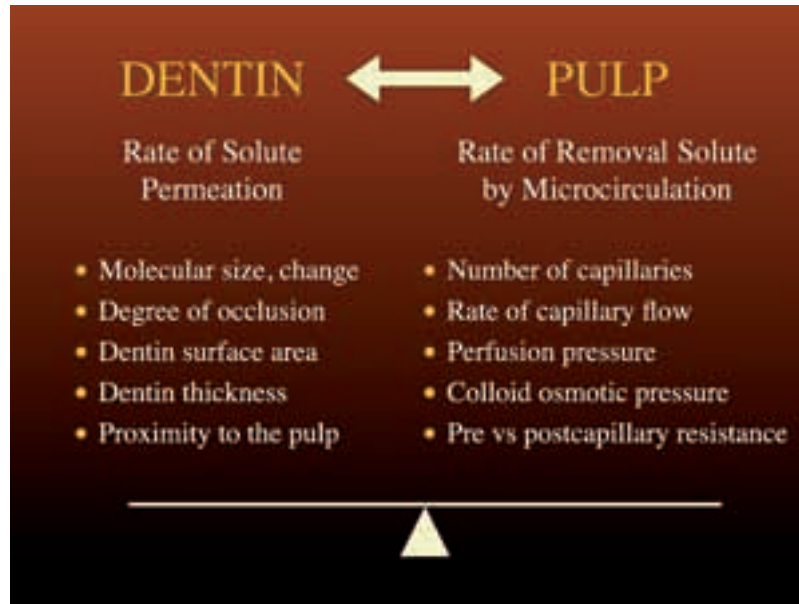

Figure 7 Diagram showing the delicate balance between the dentin and the pulp. On the left side of the balancing beam are factors governing the dentin and on the right side are factors that govern the pulp.

materials and the tooth.⁴⁴ The removal of the “smear layer” by acid etching or chelation increases dentin permeability⁴⁵ because the microcrystalline debris no longer restricts diffusion of irritants and also permits bacteria to penetrate into dentin⁴⁶ There is considerable debate as to whether smear layers created in the root canal during biomechanical preparation should be removed.⁴⁷ Its removal may increase the quality of the seal between endodontic filling materials and root dentin. It may also increase the bond strength of resin posts.⁴⁸

PULP REACTION TO PERMEATING SUBSTANCES

What happens when permeating substances reach the pulp chamber? Although bacteria may not actually pass through dentin, their by-products^{49,50} have been shown to cause severe pulp reaction.^{49,51} The broad spectrum of pulp reaction, from no inflammation to abscess formation, may be related to the concentration of these injurious substances in the pulp. Although exposed dentin may permit substances to permeate, their concentrations may not reach levels high enough to trigger the cascade of events associated with inflammation. This would indicate that the

interstitial fluid concentration of these substances can be maintained at low concentrations. As long as the rate of pulpal blood flow is normal, the microcirculation is very efficient at removing substances diffusing across dentin to the pulp chamber. This delicate balance between the dentin and the pulp is illustrated in Figure 7. There is enough blood flowing through the pulp each minute to completely replace between 40 and 100% of the blood volume of the pulp.⁵² Since blood is confined to the vasculature, which comprises only about 7% of the total pulpal volume,^{52,53} the blood volume of the pulp is replaced 5 to 14 times each minute.

If pulpal blood flow is reduced,^{54–67} there will be a resultant rise in the interstitial fluid concentration of substances that permeated across dentin. The increased concentration of injurious agents may degranulate mast cells,^{68–70} release histamine⁷⁰ or SP,^{71–75} produce bradykinin,⁷⁶ or activate plasma proteases.^{77,78} All of these effects would initiate inflammation. The endogenous mediators of inflammation produce arteriolar vasodilation, elevated capillary hydrostatic pressure, increased leakage of plasma proteins into the pulp interstitium,⁷⁹ and increased pulp tissue pressure.^{80–82} These events, by causing the

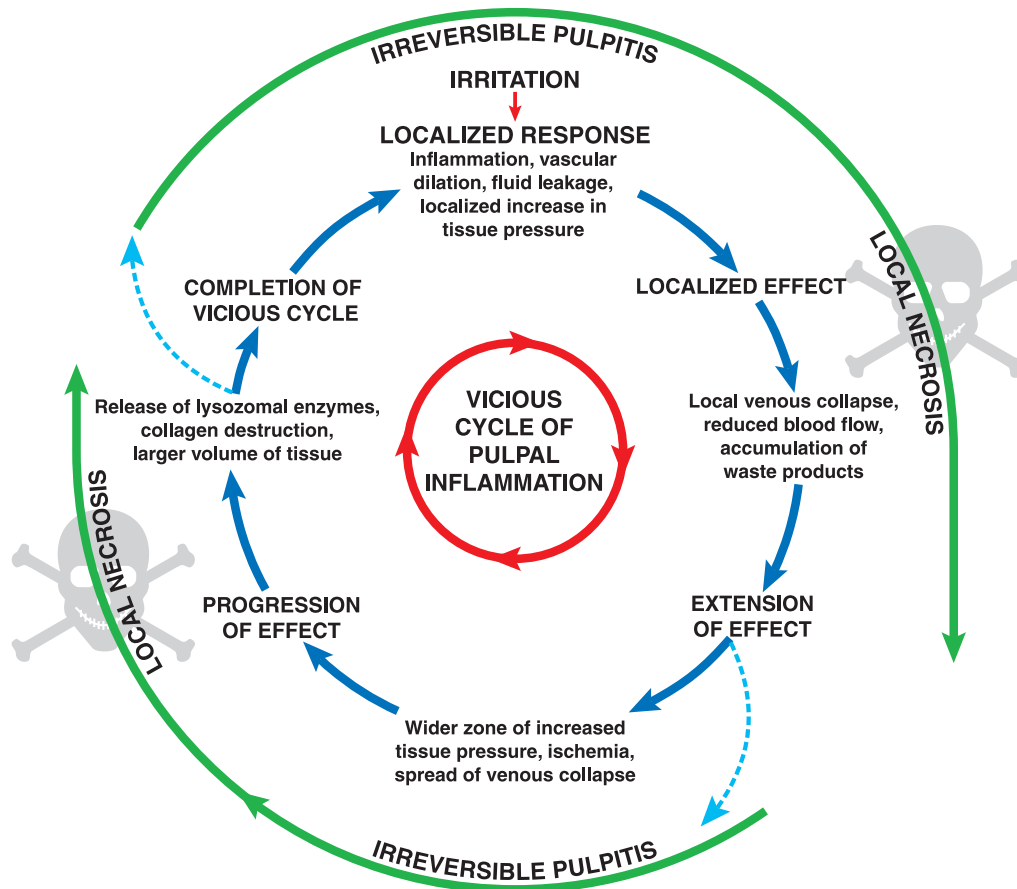

Figure 8 Vicious cycle of pulpal inflammation that begins with irritation (top), leads to a localized response, and may progress to a lesion of increasing severity and eventual irreversible pulpitis.

collapse of local venules, lead to a further reduction in pulpal blood flow.⁸³ With an even higher interstitial concentration of irritants, a vicious cycle⁸⁴ is created that may terminate in the pulp (Figure 8).

DENTIN SENSITIVITY

Clinicians recognize that dentin is exquisitely sensitive to certain stimuli.^{85,86} It is unlikely that this sensitivity results from direct stimulation of nerves in dentin (Figure 9). As previously stated, nerves cannot be shown in peripheral dentin.^{87,88} Another speculation is that the odontoblastic process may serve as excitable “nerve endings” that would, in turn, excite nerve fibers shown to exist in deeper dentin, closer to the pulp.^{87–89} The experiments of Anderson et al.⁹⁰ and Brännström⁹¹ suggest that neither odontoblastic processes nor excitable nerves within dentin are responsible for dentin’s sensitivity. This led Brännström et al. to propose the “hydrodynamic theory” of dentin

sensitivity, which sets forth that fluid movement through dentinal tubules, moving in either direction, stimulates sensory nerves in dentin or the pulp.^{91,92} Further support for the hydrodynamic theory came from electron microscopic examination of animal^{93–95} and human dentin^{93,96,97} demonstrating that odontoblastic processes seldom extend more than one-third the distance of the dentinal tubules. A work by LaFleche et al.⁹⁸ suggested that the process may retract from the periphery during extraction or processing. Obviously, more investigation will be required before any definitive statement can be made regarding the distribution of the process. The tubules are filled with dentinal fluid that is similar in composition to interstitial fluid.⁹⁹ The hydrodynamic theory satisfies numerous experimental observations. Although it cannot yet be regarded as fact, it has provided and will continue to provide a very useful perspective for the design of future experiments.^{100–102}

Figure 9 Schematic diagram of essentials of three theories of dentin sensitivity. **A**, Classical theory proposed that stimuli applied to dentin caused direct stimulation of nerves in dentin. **B**, Modified theory proposed that stimuli applied to the odontoblastic process would be transmitted along the odontoblast and passed to the sensory nerves via some sort of synapse. **C**, Hydrodynamic theory proposed that fluid movement within tubules transmits peripheral stimuli to highly sensitive pulpal nerves. **C** more accurately represents the actual length of the odontoblastic process relative to the tubules. Nerves are seldom found more than one-third the distance from the pulp to the surface. Modified with permission Torneck.

DENTAL PULP

The dental pulp consists of a loose connective tissue. A single layer of dentin-producing cells, the odontoblasts, lines the peripheral part of the pulp separating the loose connective tissue of the pulp from the predentin. The odontoblasts represent the link between dentin and the pulp. The dental pulp connective tissue is somewhat special in regard to its encasement within rigid dentin walls (see Figure 1). The pulp receives its blood supply from arterioles and lacks a collateral blood supply. The cellular constituents of a human pulp specimen examined under the microscope are presented in Figure 10, and these are explained in subsequent sections. Also shown in Figure 11 are different layers in the pulp and its constituents.

INTERSTITIAL FLUID

The rigid encasement allows the tissue-limited possibilities to expand and keeps the extracellular fluid volume, that is, blood and interstitial fluid, relatively constant. The extracellular fluid volume in the dental pulp is normally relatively high of about 63%.¹⁰³ Due to the low compliance a small increase in the pulpal volume caused by an increase in blood or interstitial

fluid will raise the hydrostatic pressure inside the tooth. This is shown to happen normally by any increase in blood flow and thus blood volume.¹⁰⁴ However, as long as there are no noxious stimuli that increase the vessel permeability, any change in tissue pressure caused by blood volume changes will be transitory, because interstitial fluid is absorbed back to the blood vessels, and no harm will happen to the pulp (Figure 12).

The hydrostatic pressure in this fluid is the interstitial fluid pressure, or the so-called tissue pressure. The interstitial fluid is similar to blood plasma, except for a lower concentration of plasma proteins (albumin and globulin). In health, plasma proteins do not permeate through the capillary wall and the concentration in the interstitial fluid is normally low. However, in a recent study in rat incisors, surprisingly high protein concentration in the pulp interstitial fluid during physiological conditions was reported.¹⁰³ The main function of the interstitial fluid is as a transport medium for nutrients and waste products between cells and capillary blood. Accordingly, the interstitial fluid acts as a middleman between cells and blood, or as an extension of the plasma. Every cell must have nutrition and the means to rid itself of waste products, and these metabolic requirements are taken

care of by the blood and the interstitial fluid (see Figure 12). Blood is brought to the tissues by the smallest blood vessels, the capillaries. Substances are transported between the blood and the interstitial fluid mainly by diffusion through the capillary wall

(see Figure 12). These capillaries are so widely distributed that no cells are more than 50 to 100 μm from the blood vessels. Due to the short distance, the exchange of substances between blood and interstitial fluid may take place rapidly by simple diffusion.

Figure 12 The interstitial fluid is the fluid that surrounds all cells in the body.

CELLULAR STRUCTURES

The odontoblasts are derived from ectomesenchymal cells and are responsible for the formation of dentin. These cells line the periphery of the pulp and consist of a cell body and a cytoplasmic/odontoblastic process. The shape of the odontoblast varies according to the functional state of the cell. The cells are tall and columnar in shape about 50 to 60 μm long in the coronal occlusal portion while they are cuboidal in the floor of the pulp chamber and the inner surface of the pulp. The odontoblast layer is separated from the mineralized dentin by a 10- to 40- μm -thick layer of unmineralized matrix, the predentin. Odontoblasts are involved in the production of predentin–dentin matrix, an extracellular framework that becomes mineralized. The matrix includes a complex mixture of proteoglycans, glycoproteins, sialoproteins, phosphoproteins, and a variety of other molecules.

FIBROBLAST

Fibroblasts originate from the mesenchymal tissue and are the predominant cells of the connective tissue. Fibroblasts are elongated with little cytoplasm and nucleus-containing condensed chromatin. They are responsible for the formation and maintenance of the fibrous components and ground substances of the

connective tissue. Fibroblasts can synthesize and secrete a wide variety of extracellular molecules that include fibrous elements of extracellular matrix (ECM) such as collagen, elastin, proteoglycans, glycoproteins, cytokines, growth factors, and proteinases. They are also involved in the remodeling of connective tissue through the degradation of collagen and other ECM molecules and their replacement by newly synthesized molecules. Fibroblasts release proteolytic enzymes such as the matrix metalloproteinase (MMP) family. MMPs are secreted as inactive precursors and cleave to become active. Extracellular degradation often occurs in inflammatory lesions. Inhibitors to MMPs, called tissue inhibitors of metalloproteinases, are also secreted by fibroblasts to regulate extracellular degradation. Intracellular degradation is for the normal physiological turnover and remodeling of collagenous connective tissue.

ODONTOBLASTS

Odontoblast, the principal cell of the dentin-forming layer, is the first cell type encountered as the pulp is approached from the dentin (Figure 13). These cells

Figure 13 Pseudostratified appearance of odontoblasts. Dark horizontal line (arrow) delineates the cell body from the odontoblastic processes and predentin and was once termed “pulpodentinal membrane.” Ultrastructural examination has shown this to be a terminal cell web that forms a support and attachment area between adjoining cells. arise from peripheral mesenchymal cells of the dental papilla during tooth development and differentiate by acquiring the characteristic morphology of glycoprotein synthesis and secretion¹⁰⁵ (Figure 14). Glycoprotein forms the predentin matrix that is rendered mineralizable by the odontoblast, a unique cell producing a unique tissue, dentin. Synthesizing and secretory activities render the odontoblast highly polarized, with synthesis occurring in the cell body and secretion from the odontoblastic process. The cell body contains organelles that represent different stages of secretion of collagen, glycoproteins, and calcium salts.¹⁰⁶ Matrix secretion precedes mineralization, with these two events separated in time and space by the predentin.

As happens in bones, the initial mineral seeding of predentin at the dentinoenamel junction is by the formation of “matrix vesicles.”^{107,108} Classic studies by Weinstock et al.,^{109–111} using an autoradiographic technique, have demonstrated the functional sequence of matrix production and secretion. This material has

Figure 14 Odontoblasts, as viewed under the electron microscope, show organelles essential for protein synthesis: a plump nucleus filled with euchromatin, cytoplasm rich in rough endoplasmic reticulum (R), and a well-developed Golgi apparatus (G). Courtesy of Dr. Dale Eisenmann.

recently been reviewed by Holland.¹¹² In histological sections viewed under a light microscope, odontoblasts appear to vary from tall, pseudostratified columnar cells in the coronal pulp to a single row of cuboidal cells in the radicular pulp to a flattened, almost squamous shape near the apex.^{113,114} These squamous-shaped cells often form an irregular, atubular dentin. The large nucleus is located in the base of the cell, giving it a pear-shaped appearance.¹¹⁵

From an exquisite scanning electron microscopic study, investigators have demonstrated that odontoblast cell bodies “appear tightly packed in the pulp horn and successively pear-shaped, spindle-shaped, club-shaped, or globular from the crown to the apex.”¹¹⁶ During dentin formation in the crown, the odontoblasts are pushed inward to form the periphery of a pulp chamber, a circumference that is increasingly smaller than the original circumference at the dentinoenamel junction. This explains why the cells are packed and palisaded into a pseudostratified appearance of coronal odontoblasts. Conversely, because the space is not so compressed in the radicular pulp, the odontoblasts maintain a columnar, cuboidal, or (in the apical region) squamous shape. Also, the resulting cell and tubule density is much higher in the pulp chamber than in the root pulp.¹¹⁷ This increased tubule density in the chamber may explain the greater sensitivity and permeability of the dentin of the crown. The cell body manufactures the matrix material; the material is transported to and secreted from the odontoblastic process.

Classically, the odontoblastic process has been described as extending from the cell body to the dentinoenamel junction, a distance of 2 to 3 mm. This concept was based on the observations of many light microscopists using a variety of special procedures and stains.⁴⁰ When dentin was examined by electron microscopy, the odontoblastic process was determined to be limited to the inner third of dentin, with the outer two-thirds of the tubule devoid of processes or of nerves but filled with extracellular fluid.^{118–121} More recent investigations indicate that odontoblastic processes may indeed extend to the dentinoenamel junction.^{122,123} However, tubular structures in dentinal tubules are not necessarily odontoblastic processes.^{124,125} Unequivocal identification can be done only by identifying a trilaminar plasma membrane around the putative process using transmission electron microscopy.^{126,127} The extent of the odontoblastic process remains controversial.¹²⁸ Therefore, modern interpretations of pulpal injury following conservative cavity preparation may not be attributable to amputation of odontoblastic processes but to desiccation, heat, and osmotic effects. Further, dentin sensitivity may not be related to direct stimulation of either odontoblastic processes or nerves

in the peripheral dentin since the tubules may be devoid of such structures in the periphery of dentin. After initial dentin formation, the odontoblast, via its process, can still modify the dentin structure by producing peritubular dentin. This is a hypermineralized cuff with little organic matrix within the tubule, decreasing the diameter of the tubule.^{129–131} When stimulated, the odontoblast can accelerate peritubular dentin formation to the point of complete occlusion of the tubule.^{132–134}

When tubule occlusions extend over a large area, it is referred to as sclerotic dentin, commonly found in teeth with cervical erosion.¹³⁵ Alternatively, irritated odontoblasts can secrete collagen, amorphous material, or large crystals into the tubule lumen; these occlusions decrease dentin permeability to irritating substances.^{132–134} Although these secretions have been described as a defensive reaction by the odontoblast to protect itself and the underlying pulp, this “protection” has never been proved.

IMMUNOCOMPETENT CELLS

A normal dental pulp has a large number and a variety of indigenous immunocompetent cells that play a crucial role to maintain homeostasis.^{136,137} Cells expressing Class II major histocompatibility complex (MHC) molecule are present throughout the dental pulp. Class II antigen-presenting dendritic cells are considered to participate in immunosurveillance. These cells have distinctive cytoplasmic extensions, have a high surface area for capturing antigens, while lacking intracellular lysosomes and phagocytic vacuoles, thus having phagocytic capacity of their own.¹³⁷ Dendritic cells are predominantly located in the paraodontoblastic area and along the pulp–dentin border. They are also present in the central portion of the pulp. Macrophages also express MHC molecules, and these cells are present in the central portion of the dental pulp. In the normal dental pulp, they may act as scavengers, eliminating dead odontoblasts and apoptotic bodies.^{138,139} Class II MHC-expressing cells increase in number shortly after tooth eruption and continue to increase even after the completion of tooth formation.¹⁴⁰

T lymphocytes are largely present in the normal dental pulp with both cytotoxic and helper subtypes present in the central pulp.^{137,141} B lymphocytes have not been clearly demonstrated in the normal dental pulp. Mast cells have not been shown to exist in the uninfamed dental pulp.^{136,142}

Immune cells in primary teeth are very similar to those in permanent teeth, except that the T-lymphocyte

population in deciduous teeth have slightly more CD4⁺ cells than CD8⁺ cells, whereas in permanent teeth CD8⁺ cells outnumber CD4⁺ cells.^{137,143,144}

EXTRACELLULAR MATRIX

ECM, or ground substance, is a structureless mass making up the bulk of the pulp tissue. It consists primarily of complexes of proteins, carbohydrates, and water. These complexes are composed of combinations of glycosaminoglycans, that is, hyaluronic acid, chondroitin sulfate, and other glycoproteins. Proteoglycans are a large group of extracellular and cell surface-associated molecules that consist of a protein core to which glycosaminoglycan chains are attached that binds them to water. Hyaluronic acid, a large glycosaminoglycan, forms a viscous hydrated gel. Proteins, glycoproteins, and proteoglycans of the ECM function in cell–matrix adhesion and signaling; regulate diffusion of nutrients, waste products, and soluble signaling molecules.

Cytokines, growth factors, and other inflammatory mediators are released by fibroblasts, endothelial cells, and immune cells in the dental pulp. Normal dental pulp contains cytokines such as interleukin-1 α (IL-1 α) and tumor necrosis factor- α (TNF- α),¹⁴⁵ however, during inflammation, orthodontic tooth movement, and other stimulation, IL-1 α , IL-1 β , IL-8, TNF- α , prostaglandin E2, platelet-derived growth factor, insulin-like growth factor-1, transforming growth factor- β (TGF- β 1), vascular endothelial growth factor, basic fibroblast growth factor (FGF-2), hepatocyte growth factor, and keratinocyte growth factor.^{146–152} These molecules mainly act locally and play important roles during development, inflammation, and wound healing.

FIBERS

Collagen is the major organic component in the dental pulp. The morphology of collagen fibers, a principal constituent in the pulp, has been described at the level of both light and electron microscopy.¹⁵³ Collagen is synthesized and secreted by both odontoblasts and fibroblasts. However, the type of collagen secreted by odontoblasts, to subsequently mineralize, differs from the collagen produced by pulpal fibroblasts that normally does not calcify. They also differ not in the basic structure but in the degree of cross-linking and in slight variation in hydroxylysine content. Tropocollagen is an immature collagen fiber that remains thin and stain black with silver nitrate, described in light microscopy as argyrophilic or reticular fibrils.

If tropocollagen molecules aggregate into larger fibers, they no longer stain with silver and are then termed “collagen fibers.” If several collagen fibers aggregate (cross-link) and grow denser, they are termed “collagen bundles.” Collagen generally becomes more coarse (i.e., develops more bundles) as the patient ages. Collagen fibers are inelastic but have great tensile strength, giving the tissue its consistency and strength. Collagen type I and III make up the bulk of the tissue collagen. Collagen type IV is found in basement membranes. In the pulp proper, type III collagen appears as fine-branched filaments, whose distribution is similar to reticular fibers.

Fibronectin is insoluble and the fibrils form part of the ECM. It acts as a mediator for cell–cell and cell–matrix adhesion. In the odontoblast layer, fibronectin is the fibrous structure between odontoblasts and probably corresponds to von Korff fibers, as they appear as corkscrew fibers passing from the pulp into predentin parallel to the long axis of the odontoblasts.¹⁵⁴ In the pulp proper, fibronectin forms a reticular network of fibrils, with an increased encasement around blood vessels. Integrins are transmembrane receptors that link intracellular actin network with ECM.

GROUND SUBSTANCE

This structureless mass, gel-like in consistency, makes up the bulk of the pulp organ. It occupies the space between formed elements. The ground substance resembles that of other areolar, fibrous connective tissues consisting primarily of complexes of proteins and carbohydrates and water. More specifically, these complexes are composed of combinations of glycosaminoglycans, that is, hyaluronic acid, chondroitin sulfate, and other glycoproteins. The ground substance surrounds and supports structures. It is the medium through which metabolites and waste products are transported to and from cells and vessels. Aging of the pulp alters the ground substance, although there is no substantive proof that these alterations significantly inhibit pulp functions.

PULPAL MICROVASCULATURES

The arterial supply of the pulp has its origin from the posterior superior alveolar arteries and the infraorbital and the inferior alveolar branch of the internal maxillary arteries. The main arterioles enter, and the main venules and lymphatics exit the dental pulp through the apical foramen or foraminae. Corrosion cast studies have shown that numerous arterioles and venules pass through the apex of the root.¹⁵⁵ Vessels

Figure 15 Vessel architecture in the pulp visualized by the India ink suction technique developed in 1950 by Dr. Kramer. This picture shows lateral canal vessels connecting the pulp and the periodontal ligament (PDL).

also enter and leave the pulp via accessory lateral canals that may be located anywhere on the root, but most commonly in the apical region.^{156,157} The tooth lacks a collateral, alternative blood supply that makes the apical region a critical point. There is evidence, however, that vessels have been identified connecting the pulp to the PDL (Figure 15). The degree to which these vessels play a role in pathogenesis remains to be investigated. Increased tooth movement in the apical area due to trauma, periodontitis, or orthodontic tooth movement may damage the pulpal blood supply.

Because the pulp itself is small, pulp blood vessels do not reach a large size. As such, the terms artery and vein cannot be used. Rather they are called arterioles (diameter in the range of 100 μm) and corresponding venules (diameter in the range of 200 to 300 μm).¹⁵⁸ Arterioles pass through the root pulp to supply the coronal pulp. As the arterioles travel straight to the coronal area, 90° branching patterns develop. These branching vessels have very thin smooth muscle coating at the juncture and lose the coating as they reach toward the dentin, forming a capillary network. Near the dentin, around the odontoblastic area, they form a dense terminal capillary network in the subodontoblastic region.¹⁵⁹

(Figure 16). Figure 17 illustrates the basic microvascular units in the pulp. Terminal capillary networks are the key vessels in the pulp and are involved in transporting nutrients and gas to the cells and

removing waste products and CO₂ from the cells to maintain pulp homeostasis. Any damage or inflammation to the pulp must alter the normal function of these vessels first. And thus these vessels have been carefully investigated ultrastructurally.

Pulpal Microvascular Units

Figure 16 Pulpal microvascular units. Scanning electron micrograph (SEM) and a diagram based on the SEM are presented on the right side. The basic unit shows arterioles running parallel with venules in the center of the pulp. The small arterioles branch off almost 90° from the main arterioles. These small arterioles get smaller in diameter as they come near the dentin. These small arterioles also lose their smooth muscle coating and become capillaries forming the capillary network (CN). When they reach the odontoblastic layer, they become the terminal capillary network (TCN). They drain into the venular network (VN). Courtesy of Drs. Takahashi and Kishi.

Coronal Pulp

Figure 17 Corrosion resin casts of the pulp vessels of a dog premolar. These scanning electron micrographs (SEMs) clearly show heterogeneity of the pulpal microvascular architecture. *The coronal pulp:* Higher magnification of the region identified by arrows reveals many hairpin capillary loops within the pulp horn. Higher magnification of the area (left) shows an individual loop with a diameter just over 10 μm. The blood flow per unit volume per minute is 125 mL/min/100 g tissue. *The apical pulp:* Higher magnification of the root canal lesion shows a very different architecture than the coronal pulp. Here the microvessels show a net type architecture surrounding the main arteriole and venules. The blood flow in this lesion is 22 mL/min/100 g, significantly less than that in the coronal pulp. Courtesy of Drs. K. Takahashi, Y. Kishi, and S. Kim.

ARTERIOVENOUS ANASTOMOSIS AND “U”-TURN LOOPS

Before the arterioles break up into capillary beds, arteriovenous anastomosis (AVA) often arise to connect the arteriole directly to a venule.¹⁶⁰ The AVAs are relatively small vessels, having a diameter approximately 10 μm.¹⁶¹ Their presence is more frequent in the radicular area of the pulp. The functional role of these vascular structures is not completely known. However, one can speculate that AVAs play a role in the regulation of blood flow. Theoretically they could provide a mechanism for shunting blood away from the area of injury or inflammation, where damage to the microcirculation may result in thrombosis and hemorrhage. An interesting observation to support this view is during an intravital microscopic study, using the live rat incisor teeth. When the pulp is approached during tooth preparation, one sees a sudden appearance of AVA shunts and “U”-turn loops filled with streaming blood. “U”-turn loops are frequently found in the pulp vascular network, and it is believed that their functions are similar to the AVA’s (Figure 18).

Capillary density is highest in the subodontoblastic region with loops passing between odontoblasts Y (Figure 19).^{158,160,162} In the subodontoblastic region, capillaries with fenestrations occur frequently in both primary and permanent teeth.¹⁶² However, the function of this fenestration is still disputed. Capillaries and the smallest postcapillary venules are the site of exchange between blood and the interstitial fluid. The terminal capillary network in the coronal area exhibits numerous short hairpin loops,¹⁵⁷ while the capillary network in the root area is similar to capillaries in the connective tissue elsewhere. Capillaries empty into small venules that connect with fewer and successively larger venules. At the apex, multiple venules exit the pulp. These venules connect with vessels that drain the PDL and adjacent alveolar bone. Vessels of the pulp have thinner muscular walls (tunica media) than vessels of comparable diameter in other parts of the body. This is probably an adaptation to the surrounding protective and unyielding walls. The vascular architecture can be divided into different vascular segments based on the morphology of periendothelial cells, such as smooth muscle cells and pericytes. These segments are muscular arterioles, terminal arterioles, precapillary arterioles, capillaries,

Figure 18 Corrosion resin casts of the arteriovenous anastomosis (AVA) **A** and a "U"-turn loop **B**. These unique features seem to play an important role in blood flow regulation especially during the initial stages of inflammation.

Figure 19 Capillary loops passing under or above the odontoblastic layer. Capillaries that are not in focus represent their position in relation to the cells, either under or above them. Prepared by modified H&E technique. Courtesy of Drs. Takahashi and Kishi.

postcapillary venules, and collecting or muscular venules. In most arterioles and in some venules, smooth muscle cells maintain a state of partial vasoconstriction at all times, and a variety of substances such as neurotransmitters, hormones, and local factors influence this muscle tone and therefore the blood flow.¹⁶³ Nerves have intimate association with the blood vessels, with arterioles being the most densely innervated. Characteristics of pulpal vasculature are illustrated in Figure 20.

The fraction of blood in the coronal pulp of cat canines is 14.4%. Compared to other connective tissues, the dental pulp has a high resting blood flow of 40 to 50 mL/min/100 g. This is nearly as high as blood flow in the brain (Figure 21); however, the metabolic

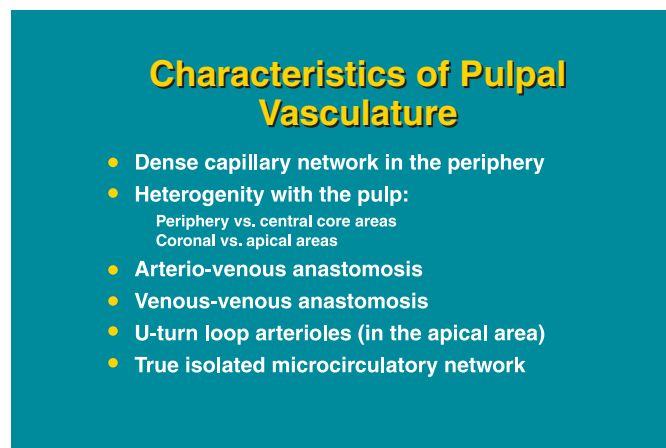

Figure 20 Summary of characterization of the pulpal vasculature.

or functional requirements of this high resting blood flow in the pulp remain partly unexplained. Sometimes it is called a luxury perfusion. Figure 21 shows the comparison of blood flows among various tissues and organs, adjusted according to weight. Pulpal blood flow is intermediate between muscle and heart blood flow per unit weight.

REGULATION OF PULPAL BLOOD FLOW

Pulpal blood flow is regulated by sympathetic α -adrenergic vasoconstriction,¹⁶⁴ β -adrenergic vasodilation,¹⁶⁵ sympathetic cholinergic vasoactive system, and an antidromic vasodilation, that is, axon reflex. It has been shown

Figure 21 Blood flow rate in milliliters per minute per 100 g tissue of several important tissues and organs in a dog determined with a radioisotope-labeled microsphere technique. The pulpal blood flow is similar to that of the brain but far less than in the major organs like the heart or the spleen.

that a parasympathetic vasodilator mechanism is not present in cat dental pulp.¹⁶⁶

The walls of arterioles and venules are coated with smooth muscles, innervated by unmyelinated sympathetic fibers. When stimulated, the muscle fibers contract, thus decreasing the diameter of the vessel. This phenomenon is called vasoconstriction. It has been shown experimentally that electrical stimulation of sympathetic fibers leading to the pulp results in a decrease in pulpal blood flow.^{164,165} The sympathetic nerve-induced vasoconstriction of pulpal vessels is accomplished by the activation of α -adrenergic receptors in the smooth muscle of the arteriolar vessels.

Activation of α -adrenergic receptors by the administration of an α -agonist norepinephrine results in a marked decrease in pulpal blood flow. This reduction in pulpal blood flow is blocked by pretreatment of the pulpal vessels with α -antagonist. These two sets of experimental results clearly demonstrate that pulpal vessels are heavily equipped with sympathetic adrenergic receptors and their activation causes vasoconstriction.

Blood circulation in an inflamed pulp involves very complex pathophysiological reactions that have not been fully elucidated, in spite of numerous studies.^{167,168} A unique feature of the pulp is that it is

rigidly encased within dentin. This places it in a low-compliance environment, much like the brain, bone marrow, and nail bed. Thus pulp tissue has limited ability to expand, so vasodilation and increased vascular permeability, evoked during an inflammatory reaction, result in an increase in pulpal hydrostatic pressure.^{169,170} Presumably any sudden rise in intrapulpal pressure would be distributed equally within the area of pressure increase, including the blood vessels. Theoretically if tissue pressure increases to the point that it equals the intravascular pressure, the thin-walled venules would be compressed, thereby increasing the vascular resistance and reducing the pulpal blood flow.¹⁶³ This could explain why injection of vasodilators such as bradykinin into an artery leading to the pulp results in a reduction rather than an increase in pulpal blood flow.^{163,165,170} Heyeraas,¹⁷⁰ however, observed that an increase in intrapulpal tissue pressure promoted absorption of tissue fluid back into the blood and lymphatic vessels, thereby reducing the pressure. Thus it would appear that blood flow can increase, in spite of an elevation in tissue pressure. Obviously a combined multidisciplinary approach is needed to better understand the intricate circulatory changes occurring during the development of pulpal inflammation.

Using the laser Doppler technique to study pulpal blood flow in dogs, Sasano et al.¹⁷¹ suggested that an increase or a decrease in pulpal blood flow is more dependent on systemic blood pressure than on local vasoconstriction or vasodilation.

THE STEALING THEORY

The dental pulp receives its blood supply through the so-called end arteries. These arterioles, entering the apical pulp, have a relatively low blood pressure, and the pressure drop from the arterioles entering the pulp to the venules leaving is only about one-fourth of the total arteriovenous pressure difference.¹⁶⁹ Accordingly a considerable part of the vascular resistance that regulates the pulpal blood circulation is located in the venules and also outside the pulp.¹⁷² This implies that changes in circulation in the neighboring adjacent tissues, such as the gingiva, alveolar bone, and PDL, will change the blood flow to the pulp because it will affect the feeding pulpal arterial blood pressure. Any vasodilation in tissues that receive their blood supply through side branches of the end arterioles feeding the pulp will, according to the Poiseuille law, steal blood pressure from the pulp¹⁶⁹ (Figure 22). It should therefore be borne in mind that clinical treatment causing vasodilatation in adjacent tissues may decrease the circulation to the dental pulp. Thus

the mere application of a matrix may affect the pulpal circulation and cause a fall in pulpal blood flow. The pulp may become ischemic.

LOW-COMPLIANCE SYSTEM THEORY

The dental pulp is encased in rigid structures, namely dentin, enamel, and cementum, creating a low-compliance system. In this system, any increase in blood flow or vasodilation has a limit depending on the degree of increase in tissue pressure. In normal condition, venular pressure is higher than the tissue pressure in the pulp. However, introduction of a known vasodilator, such as isoproterenol, causes an initial increase in pulpal blood flow which in turn causes a sudden increase in tissue pressure.¹⁷³ When the tissue pressure exceeds that of the venular pressure, a passive compression can cause a decrease in pulpal blood flow. Injection of various vasodilators caused a biphasic flow response, an increase followed by a decrease using the radioisotope microsphere injection technique.¹⁷⁴ In clinical situations, the effects of vasodilators produced by the initiation of inflammatory process on pulpal blood flow seem to be based on the low-compliance system theory. Thus, outpouring of inflammatory mediators that are mostly vasodilators has grave consequences for pulpal survival due to passive compression of the low

Figure 22 Stealing theory.

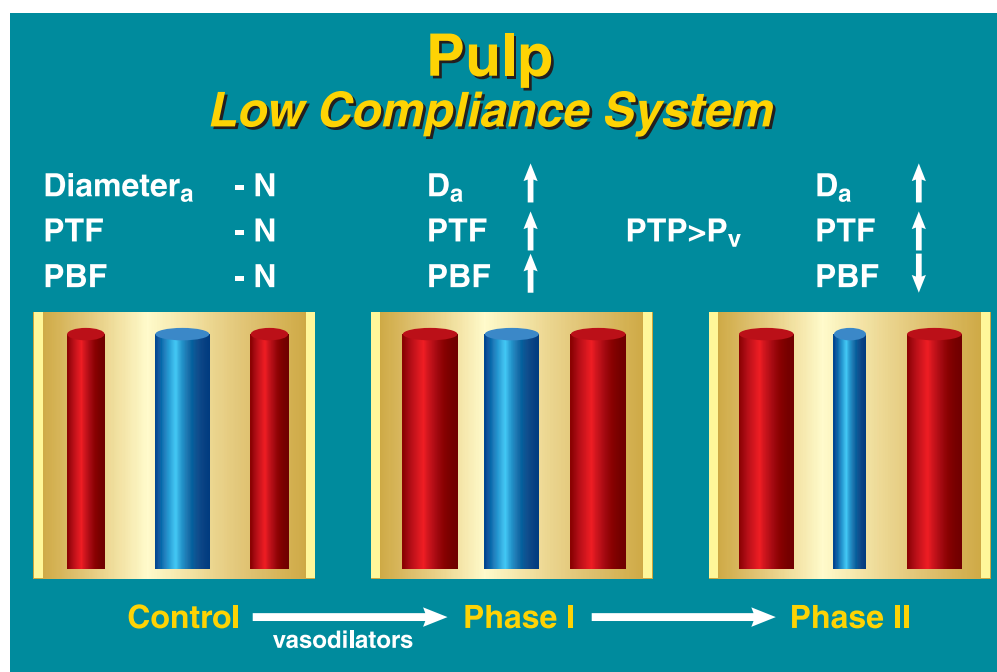

Figure 23 Schematic diagram illustrating the low-compliance system and its effects on pulpal hemodynamics.

pressure venules by a high tissue pressure. Figure 23 illustrates this theory.

TRANSCAPILLARY FLUID FLOW

At the same time the exchange of substances occurs across capillaries, another completely distinct process also takes place, that is, the bulk flow of fluid across the capillary wall. The function of this bulk flow of fluid is not the exchange of nutrients and waste products, but the distribution of the extracellular fluid. This distribution is governed by the hydrostatic pressure difference and the colloid osmotic pressure difference across the capillary wall. These pressures determine how much of the extracellular fluid will be located within the vessels as blood plasma and how much as interstitial fluid. The difference in protein concentration between plasma and interstitial fluid is important because it creates a higher colloid osmotic pressure in plasma than in the interstitial fluid, thus favoring bulk fluid movement back into the capillary. The hydrostatic pressure outside the vessels is normally considerably lower than the blood pressure inside the capillaries. Usually, this difference in hydrostatic pressure favors filtration, or bulk flow of fluid out of the vessels. However, in the dental pulp, where a small increase in volume increases the tissue pressure, absorption may take place during

vasodilation. In the low-compliant pulp, a nearly simultaneous increase in blood volume and tissue pressure, as a result of vasodilation and/or venous stasis,⁸¹ has been recorded, showing that vascular distension with an increase in blood volume compresses the pulpal tissue and raises the tissue pressure. Thus, a rapidly responding hydrostatic counterpressure develops that lowers the transmural hydrostatic pressure difference. Consequently, capillary filtration will be reduced and absorption may occur, and the tissue pressure is rapidly normalized, according to the Starling forces.¹⁷⁵ The interstitial fluid in the pulp reaches out in dentinal tubules and forms a continuum that extends out to the dentinoenamel and cementoenamel junctions. The mere cutting of dentin as it occurs during cavity and crown preparation may thus affect the dental pulp.¹⁷⁵ Furthermore, sensory nerve fibers are located in the subodontoblastic space of most tubules in the crown. Research during the last decades has shown that sensory nerves have a strong impact on the blood circulation in the dental pulp, due to liberation of vasodilating neuropeptides. In the cat pulp, most of the sensory nerve fibers contain these neuropeptides. The majority of sensory nerve fibers containing the vasodilating neuropeptides in the main pulp seem to be located in the walls of the blood vessels, a finding that implicates these neuropeptides in blood flow regulation.

LYMPH VESSELS

The only mechanism for the removal of proteins and macromolecules that may leak out from the blood vessels in any tissue is the lymphatics. The existence of lymph vessels in the dental pulp is well established.^{177,178} Recovery of inflammation depends on the removal of macromolecules and plasma proteins from the tissue, thus a reversible pulpitis is dependent on functional lymph vessels.¹⁷⁹

Most lymphatics have been found in the root pulp, whereas in the coronal area, lymph vessels are observed in the more central part, and a few in the peripheral odontoblastic layer. Some studies conclude that in the coronal part, real lymph vessels are lacking and that lymph is collected in interstitial clefts and drains toward lymphatic vessels in the apical region of the pulp.¹⁸⁰ The lymphatics in the peripheral pulp zone join to form larger collecting vessels.¹⁸¹ These vessels unite with progressively larger lymphatic vessels that pass through the apex together with the blood vessels. Numerous authors, using both histological and functional methods, have described extensive anastomoses between lymph vessels of the pulp, the PDL, and the alveolar bone.^{182–185} The structural identification of lymph vessels^{178,185} complements the functional studies demonstrating that substances placed in the pulp chamber can be found in regional lymph nodes. The open endothelial margins and incomplete basal lamina permit the entry of large molecules and even bacteria into the lymphatics. The fact that materials placed on pulps can migrate to lymph nodes¹⁸⁶ indicates the possibility of the spread of bacteria or bacterial products from the pulp.¹⁸⁷ The anastomoses of pulpal, periodontal, and alveolar lymphatics may be important routes for the spread of pulpal inflammation into adjacent tissues during the removal of irritants and fluid from the pulp.

The architecture of the initial lymphatics, the so-called lymph capillaries, in different tissues varies considerably. Although in general they are wider than the blood capillaries, their number is much smaller. The wall of the initial lymphatics consists of a single layer of thin endothelial cells, often with overlapping margins. Open gaps between the cells, up to 2 to 5 μm , are frequent in many tissues. The initial lymphatics dilate and the number of open junctions increases during edema formation. It seems thus widely accepted that interstitial fluid pressure is the main determinant of lymph flow, and that lymph flow increases consistently when the tissue pressure is increased.¹⁸⁸ In the low-compliant pulp, this would imply that the increased local tissue pressure, as measured during pulpitis, induces increased lymph flow that will normalize the pressure and also drain off bac-

teria and bacterial products, promoting healing of the pulp. An enhanced lymph flow during inflammation has also been suggested by Feiglin and Reade.¹⁸⁹ They deposited radioactive microspheres in rat pulps and found more microspheres in the submandibular lymph nodes in those rats whose pulps had been exposed for 5 days in comparison with those with acute pulp exposure.¹⁸⁹

The relationship of teeth to the cardiovascular and lymphatic systems is intimate and absolute. Clinicians should remember this when performing dental procedures since their placement of materials on dentin or the pulp may result in widespread distribution of that material or medicament.

Nerves in the Pulp

CLASSIFICATION OF NERVES

The dental pulp has an abundant supply of both sensory and autonomic nerves (Figure 24). This sophisticated arrangement of neural network plays an important role, although not fully understood, in managing the microenvironment of the dental pulp. The majority of these nerves are sensory. The trigeminal ganglion supplies sensory innervation to the pulp via the maxillary and mandibular nerves. Sympathetic nerves are less numerous with its source from the superior cervical ganglion. Parasympathetic fibers have been suggested to exist in the pulp, although the source of this innervation is still disputed.

Anatomical and electrophysiological studies have classified nerves according to their diameter and conduction velocity (Table 1). The pulp contains two types of sensory nerve fibers: A fibers that are myelinated and C fibers that are unmyelinated. Nerve fibers enter teeth via the apical foramen, and arborize coronally to form the plexus of Rashkow in the subodontoblastic region. Some axons leave the plexus of Raschow, lose the myelin sheath to become unmyelinated, and pass between odontoblasts to reach inner dentin.¹⁹¹ Nerve fibers have been found in more than 50% of tubules in inner cuspal dentin.^{190–194} Coronal dentin is more densely innervated than radicular dentin. Axons do not traverse beyond 200 μm into coronal and radicular dentin but usually end less than 200 μm from the pulp.¹⁹¹ A fibers include both A- β and A- δ with A- δ amounting to approximately 90% of the A fibers.¹⁹⁵

Classical electrophysiological studies have shown the afferent function of sensory nerves in pain sensations. Some overlapping of functions have been

Figure 24 Schematic diagram showing the course of sensory and sympathetic nerves to the dental pulp. Sensory nerves (yellow) derive from the trigeminal ganglion while sympathetic nerves (green) are from the superior cervical ganglion. Postganglionic sympathetic nerves travel with the internal carotid nerve, reach the trigeminal ganglion, and supply teeth and supporting structures via the maxillary and the inferior alveolar nerve (yellow).

Table 1 Classification of Nerves in the Pulp

Type of Fiber	Function	Diameter (μm)	Conduction Velocity (m/s)
A α	Motor, proprioception	12–22	70–120
A β	Pressure, touch	5–12	30–70
A γ	Motor	3–6	15–30
A δ	Pain, temperature, touch	2–5	12–30
B	Preganglionic autonomic	<3	3–15
C	Pain	0.4–1.2	0.5–2
Sympathetic	Postganglionic sympathetic	0.3–1.3	0.7–2.3

shown between pulpal A and C fibers.^{195–199} The A- δ fibers in the dental pulp have been involved in transmitting fast pain usually perceived as sharp, piercing pain, while C fibers transmit slow pain described as dull, aching pain.²⁰⁰ Sympathetic nerves in general have been shown to have a vasoconstrictor effect, while parasympathetic nerves have a vasodilator effect.

NEUROPEPTIDES

In addition to their vasoactive functions, stimulated sensory and autonomic nerves release biologically active peptides, known as neuropeptides, that influence neural activity and functioning.^{201–203} Neuropeptides are synthesized on ribosomes in the neuron cell body, processed through the endoplasmic reticulum and Golgi complex, transported in vesicles to the nerve terminals (Figure 25), and released from the peripheral terminals of mainly A- δ and C fibers.²⁰⁴

Neuropeptides can be classified according to the nerves from which it is derived. For example, sensory nerve-derived neuropeptides include CGRP, SP, and neurokinin A (NKA), while NPY is typically a sympathetic nerve-derived neuropeptide. Vasoactive intestinal peptide (VIP) has been shown to be in parasympathetic nerves. The introduction of immunohistochemical labeling of neuropeptides has contributed greatly to our understanding of the neural network of the dental pulp.

DISTRIBUTION

CGRP-containing or CGRP-immunoreactive (CGRP-IR) nerve fibers are the most abundant in the dental pulp (Figure 26). It is three to four times more

Figure 25 Calcitonin gene-related peptide-immunoreactive (CGRP-IR) neurons in the trigeminal ganglion. Low-magnification **A**, view of darkly stained neurons that contain CGRP. abundant than SP.²⁰⁵ CGRP-IR fibers enter the pulp via the apical foramen in bundles either surrounding the blood vessels or individually and ramify into a network of fine fibers in the coronal pulp.^{205–207} Coronally, individual fibers penetrate the odontoblast layer and predentin to terminate in the inner 100 μm of the dental tubules. Radicular pulp fibers run parallel to the long axis of the tooth with little arborization and little penetration of the odontoblast layer.

SP is commonly found in C fibers with similar distribution to CGRP.^{205,208,209} NKA fibers have similar distribution to SP-IR nerve fibers.²¹⁰ CGRP, SP, and NKA have been shown to coexist in the same nerve fibers in the dental pulp. NPY is usually found in sympathetic nerves and its distribution varies from the sensory neuropeptides. It enters the pulp mainly surrounding the blood vessels and terminates in the floor or the mid-coronal part of the pulp chamber. It is more numerous in the radicular than in the coronal pulp.^{205,211–214}

Coronally, nerve fibers branch extensively. **B**, CGRP-IR fibers penetrate the cuspal odontoblast layer and enter dentin. **C**, In the mid-coronal region, thick bundles of fibers are seen surrounding the blood vessels and in root pulp. **D**, Thick band of fibers surrounding the blood vessels are in the root pulp. Courtesy of SR Haug and KJ Heyeraas.

VIP-immunoreactive (VIP-IR) fibers in the dental pulp are associated with blood vessels²¹⁵ or occur as free and interlacing nerves in the central pulp and the subodontoblastic plexus.^{215,216} Nerves containing neuro-peptides are also found in close contact with

immunocompetent cells suggesting important neuro-immune interactions (Figure 27).

FUNCTION

Neuropeptides are released by various stimulations. What happens when a sensory neuropeptide is released? A classical demonstration of neuropeptide activity is the flare component of the “triple response” in the human skin: wheal (edema formation), local reddening

(increased blood flow), and flare.²¹⁷ The flare is a consequence of the sensory nerve-mediated axon reflex and involves antidromic stimulation of sensory nerves to release neuropeptides such as SP and CGRP. These neuropeptides can be coreleased when an antidromic impulse depolarizes the peripheral end of the nerve. CGRP is a strong vasodilator. SP is also a vasodilator and in addition it increases vascular permeability and stimulates inflammatory and immune cells (Figure 28). NPY has many physiological effects including vasoconstriction,

Figure 27 Calcitonin gene-related peptide-immunoreactive (CGRP-IR) nerve fibers in close proximity to immunocompetent cells in the dental pulp. Courtesy of SR Haug and KJ Heyeraas.

Figure 28 Schematic illustration summarizing some of the effects of neuropeptides (calcitonin gene-related protein, CGRP; substance P, SP) released from sensory nerves. Sensory nerves conduct afferent sensory information (e.g., pain sensations/dentin sensitivity) to the central nervous system and have an efferent function such as vasodilation and increased permeability of blood vessels. It affects various aspects of immune function such as activation and chemotaxis of immune cells, and release of cytokine and growth factors from various cellular structures in the dental pulp. Sensory nerves have also been shown to be involved in the formation of dentin.

immune regulation, and pain perception. In the dental pulp, CGRP and SP increases the blood flow while NPY decreases it.

Perhaps one of the most important function, although, little understood is how nerves affect the immune system, a term known as neuroimmunomodulation. SP and NKA are considered to have a proinflam-

matory role, while NPY and VIP are said to have an anti-inflammatory role on the immune system.^{218–221}

Classic work by Byers et al.^{222–225} has shown that CGRP and SP-IR nerve fibers undergo sprouting during inflammation in the dental pulp. These fibers also change in quantity and architecture when inflamed (Figure 29). Recent studies have shown that NPY-IR nerve

fibers also sprout in long-standing inflammatory lesions (Figure 30).²¹² Quantification studies have shown that SP, CGRP, NKA, NPY, and VIP are increased in pulps diagnosed clinically as irreversible pulpitis (Figure 31).^{218,226}

RECEPTORS

Neuropeptides cannot cross the cell membrane and therefore their action is dependent on the existence of

specific receptors (Table 2). Without the existence of a particular receptor, release of neurotransmitters or neuropeptides will have no effect. Therefore identifying the location and distribution of these receptors is important for understanding the functionality of a neuropeptide in a given location. NK1 receptors, specific for SP, are present in the blood vessels in the root pulp and smaller vessels along the odontoblast layer.^{227,228} Fibroblasts express NK1 receptors during mechanical orthodontic stress.²¹²

Figure 31 Quantification of neuropeptide content in healthy and inflamed human pulp tissue. Reproduced with permission from Caviedes-Bucheli J et al.²²⁶

Table 2 Neuropeptides and Their Origins Including Some of Their Actions and Specific Receptors

Neuropeptides	Released From	Actions	Receptors
Substance P	Sensory	Vasodilation, increases vascular permeability	NK1
Neurokinin A	Sensory	Increases vascular permeability	NK2
Calcitonin gene-related peptide	Sensory	Vasodilation	CGRP1 and CGRP2
Neuropeptide Y	Sympathetic	Vasoconstriction, pain modulation, immune function	NPY Y1-6
Vasoactive intestinal peptide	Parasympathetic?	Vasodilation, immune function	VIP 1 and 2

Antagonists to these receptors are now being widely studied as therapeutic agents against inflammatory diseases or diseases involving overexpression of neuropeptides.

NEUROPHYSIOLOGY

Experimental animal model studies are widely used to investigate the role played by nerves in the dental pulp. Removing sensory nerves either by nerve transection or chemical removal has shown that sensory nerves are important for secondary dentin formation.²²⁹ Releasing neuropeptides in the dental pulp by electrical stimulation results in transendothelial migration of inflammatory cells. This was absent when sensory nerves were previously removed from the dental pulp.²³⁰ Recently studies have demonstrated that sympathetic nerves are involved in the modulation of the immune system (Figure 32). Sympathetic nerves inhibit the production of proinflammatory cytokines, while stimulating the

production of anti-inflammatory cytokines.²²⁰ Teeth lacking sympathetic nerves also tend to undergo necrosis more frequently.²¹¹

Sympathetic nerves have been shown to be important in the recruitment of granulocytes during electrical stimulation of teeth and experimental tooth movement.^{231,232} Sympathetic imbalance results in the recruitment of plasma cells in an intact tooth suggesting an immune dysfunction.²³³ Sympathetic nerves have also been shown to have an inhibitory effect on osteoclast resorption activity and on the cytokine IL-1 α .^{145,212,232} NPY that is coreleased in the sympathetic nerve terminal has recently been reported to modulate immune function in a wide range of inflammatory conditions. Therefore, the effects one sees in the dental pulp and surrounding structures could be due to the neuropeptide released from the sympathetic nerve terminal since an upregulation of NPY has been seen in the dental pulp.

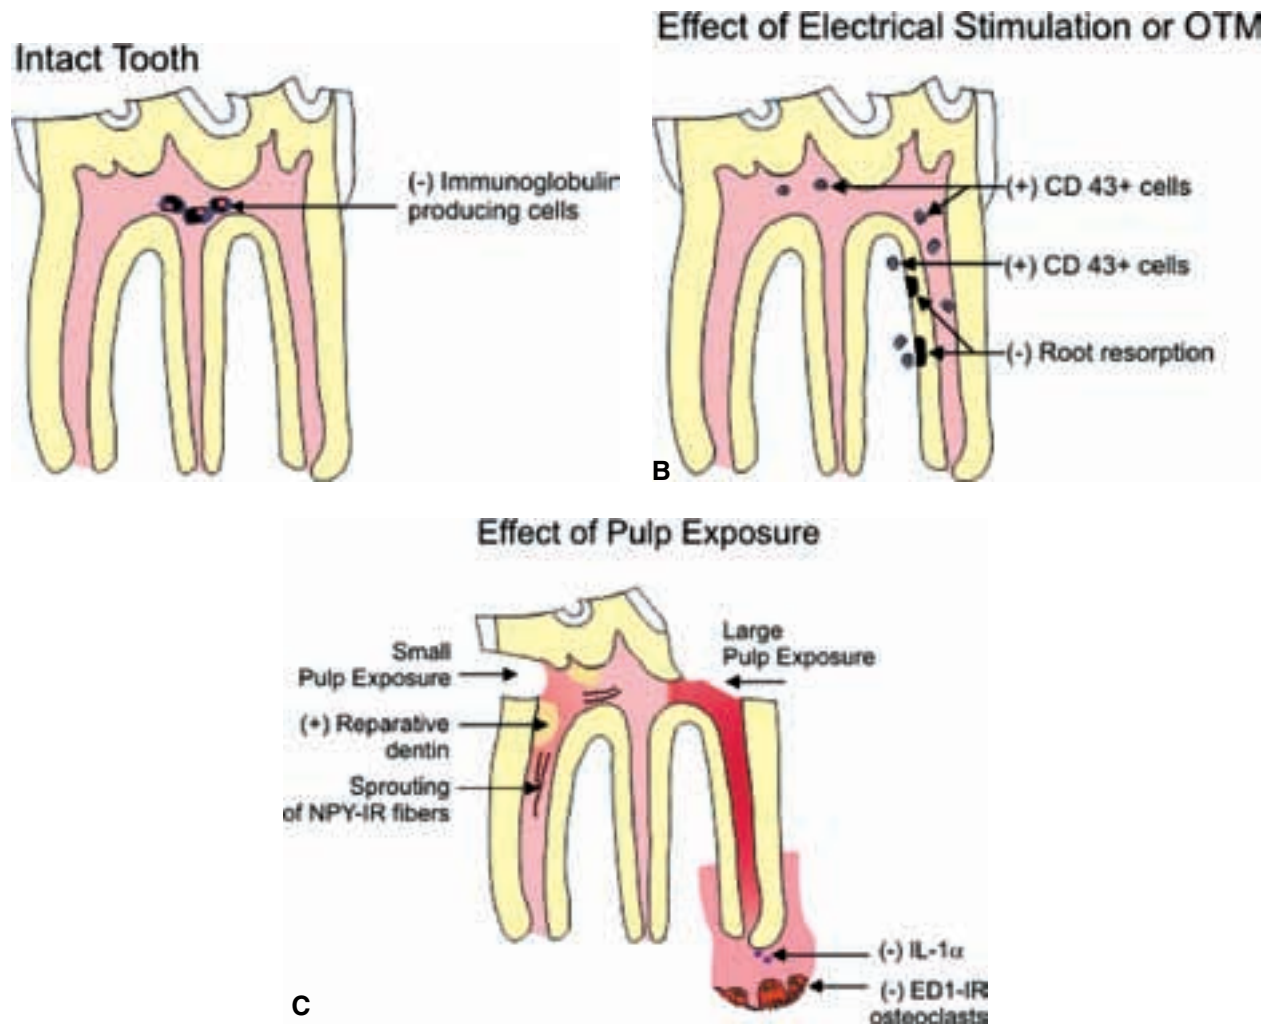

Figure 32 Schematic illustrations of rat molar teeth in three different conditions summarizing the potential effects of sympathetic nerves on teeth. Stimulating effects of sympathetic nerves are indicated by (+) and inhibitory effects by (-). **A**, Normal uninfamed pulp with sympathetic imbalance caused by unilateral sympathectomy recruits immunoglobulin-producing cells. **B**, Electrical stimulation of sympathetic nerves causes recruitment of CD43⁺ granulocytes in the normal dental pulp. During experimental orthodontic tooth movement (OTM), sympathetic nerves have an inhibitory effect on hard tissue resorption and a stimulating effect on CD43⁺ cell recruitment in the dental pulp and the periodontal ligament (PDL). **C**, The inflamed pulp shows increased reparative dentin formation and sprouting of sympathetic nerve fibers, while the periapical lesion shows decreased IL-1 α production and number of osteoclasts when compared to a denervated sympathectomized tooth.²²⁰

CHAPTER 6

MORPHOLOGY OF TEETH AND THEIR ROOT CANAL SYSTEMS

BLAINE M. CLEGHORN, CHARLES J. GOODACRE, WILLIAM H. CHRISTIE

Successful root canal therapy requires a thorough knowledge of tooth anatomy and root canal morphology,^{1,2} which may be quite variable within the norm. Root canal system anomalies rarely occur outside the norm. Even the incidence of the various anomalous root anatomy forms within the adult human dentition can be quite variable.

For each tooth in the permanent dentition, there is a wide range of variation reported in the literature with respect to the frequency of occurrence of the number and the shape of canals in each root, the number of roots,²⁻¹⁶ and the incidence of molar root fusion.¹⁷⁻²³

A number of factors contribute to the variation found in these studies (Table 1). The root canal morphology of teeth is often extremely complex and highly variable^{2,3,5,12,14-16} as illustrated in the 3D models of the maxillary first molar in Figures 1-3.⁵ Variations also result due to ethnic background and age and gender of the population studied. The following is a description of the normal and the many variations in human tooth anatomy and root morphology as gleaned from the available literature.

The data generated from a specialty endodontic practice may not represent the frequency of incidence in a general population, as more complex cases are

more likely to be referred,²⁴ thus skewing the sample reported in some clinical studies. Differences in reported results may also be due to the study design (clinical radiographs versus laboratory, gross morphology, or microscopic).²⁵ There is also a wide variety of methods used in these studies. These laboratory methods include various types of clearing studies using

decalcification⁹ injection with India ink,^{6,10,17,25–29} Chinese ink,²³ hematoxylin dye,¹³ plastic¹⁸ or metal castings,^{7,30} in vitro endodontic access with radiography and instruments^{31,32} or instruments only,^{29,33} in vitro radiopaque gel infusion and radiography,²² in vitro root canal treatment (RCT),³⁴ in vitro radiography,^{35–37} in vitro macroscopic examination,¹⁹ scanning electron microscope examination of the pulp floor,³⁸ and grinding or sectioning.^{4,8,39,40}

Clinical methods include evaluation of endodontic access openings during endodontic treatment using magnification or a surgical operating microscope (SOM),^{11,41–43} or during endodontic treatment where magnification was not specified,^{26,39,44–53} or retrospective evaluation of patient records of endodontically treated teeth only^{11,45,54–57} or radiography of all teeth,²¹ and *in vivo* radiographic examination.^{20,58,59}

All of these factors contribute to variations in the reported results. There can also be variations in the number of canals reported, due to the authors' definition of what constitutes a canal. A separate canal is defined in some studies as a separate orifice found on the floor of the pulp chamber,³⁴ two instruments placed simultaneously into two mesiobuccal canals of a maxillary first molar to a minimum depth of 16 mm from the cusp of an intact tooth,³⁹ one that can be instrumented to a depth of 3–4 mm¹¹ or an analysis of treatable canals in retrospective clinical studies.⁴² Other studies fail to provide a clear definition of what defines a canal in their reported data.

In 1969, Weine et al.⁴⁰ provided the first clinical classification of more than one canal system in a single root and used the mesiobuccal root of the maxillary first molar as the type specimen. Pineda and Kuttler³⁶ and Vertucci¹³ further developed a system for canal anatomy classification for any tooth having a broad buccolingual diameter and more applicable for use in laboratory studies (Figure 4). All canal types reported in this chapter are based on the Vertucci classification. Additional canal types not included in Vertucci's original classification system

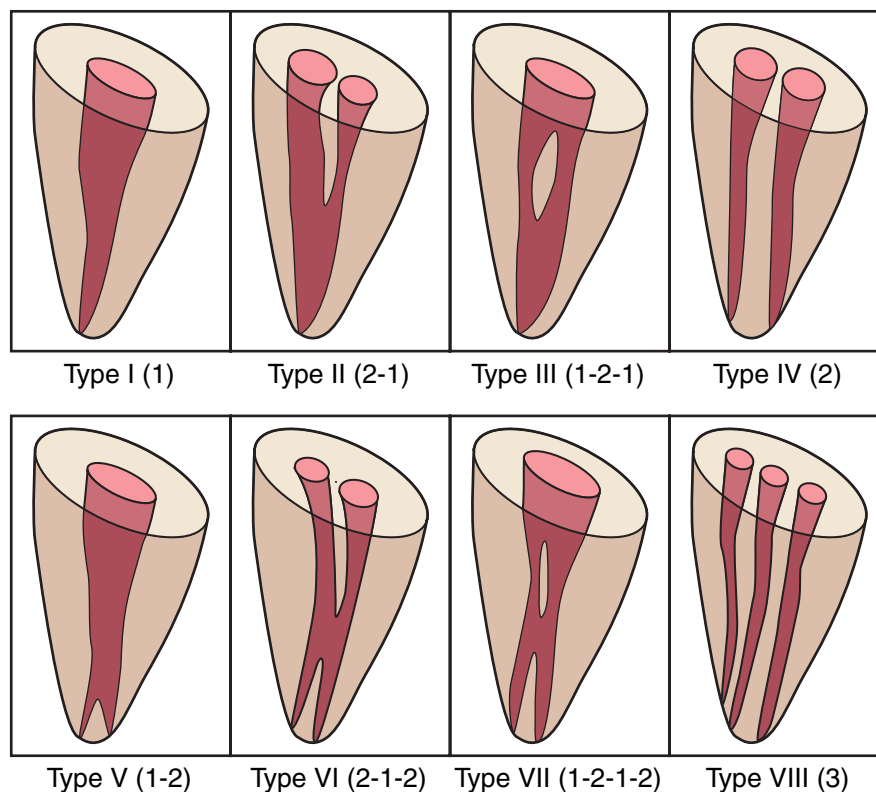

Figure 4 Vertucci's Classification of Root Canal Systems (Types I–Type VIII).

have been reported by Sert and Bayirli¹⁰ (Figure 5) and Gulabivala et al.⁶⁰ Sert and Bayirli reported an additional 14 new canal types that have not yet been classified.¹⁰

Vertucci found the proximity of the canal orifices to each other as indicative of whether they joined or remained as separate canals.¹³ If the separation of the orifices was greater than 3 mm, the canals tended to remain separate through their entire length. In contrast, canals usually joined together if the orifices were less than 3 mm apart. Canals were found to join more coronally as the distance between the orifices decreased.

Successful endodontic therapy is dependent on the cleaning, shaping, and obturation of the entire root canal system.^{1,2} The presence of accessory canals and the ability to cleanse and seal these canals can also have an impact on prognosis.⁶¹ Accessory canals include both lateral and furcation canals. These canals are smaller than the main canal but branch from the main canal through to the periodontium.^{2,62} Pineda and Kuttler found that 30.6% of teeth had such

ramifications. The majority of the ramifications or accessory canals were found in the apical third of the root.^{36,61,63} Zolty and others have indicated that endodontic failure can be due to infected accessory canals.⁶¹ Clinical studies have demonstrated that careful cleansing and sealing of the main canal and accessory canals, associated with lesions of endodontic origin, can result in healing of these defects.^{61,64}

This chapter is intended to provide a review of the literature on the root and root canal morphology of each of the teeth in the permanent dentition from central incisor to second molar in both maxillary and mandibular arches. The permanent third molars have not been included in this review due to their high degree of variability of crown and root morphology. External root anatomy, canal numbers and types, and root canal system anatomy are described through a literature review of anatomical studies and case reports. The percentages reported in the tables may exceed 100% due to rounding of numbers to tenths or to incorrect tabulations from papers cited.

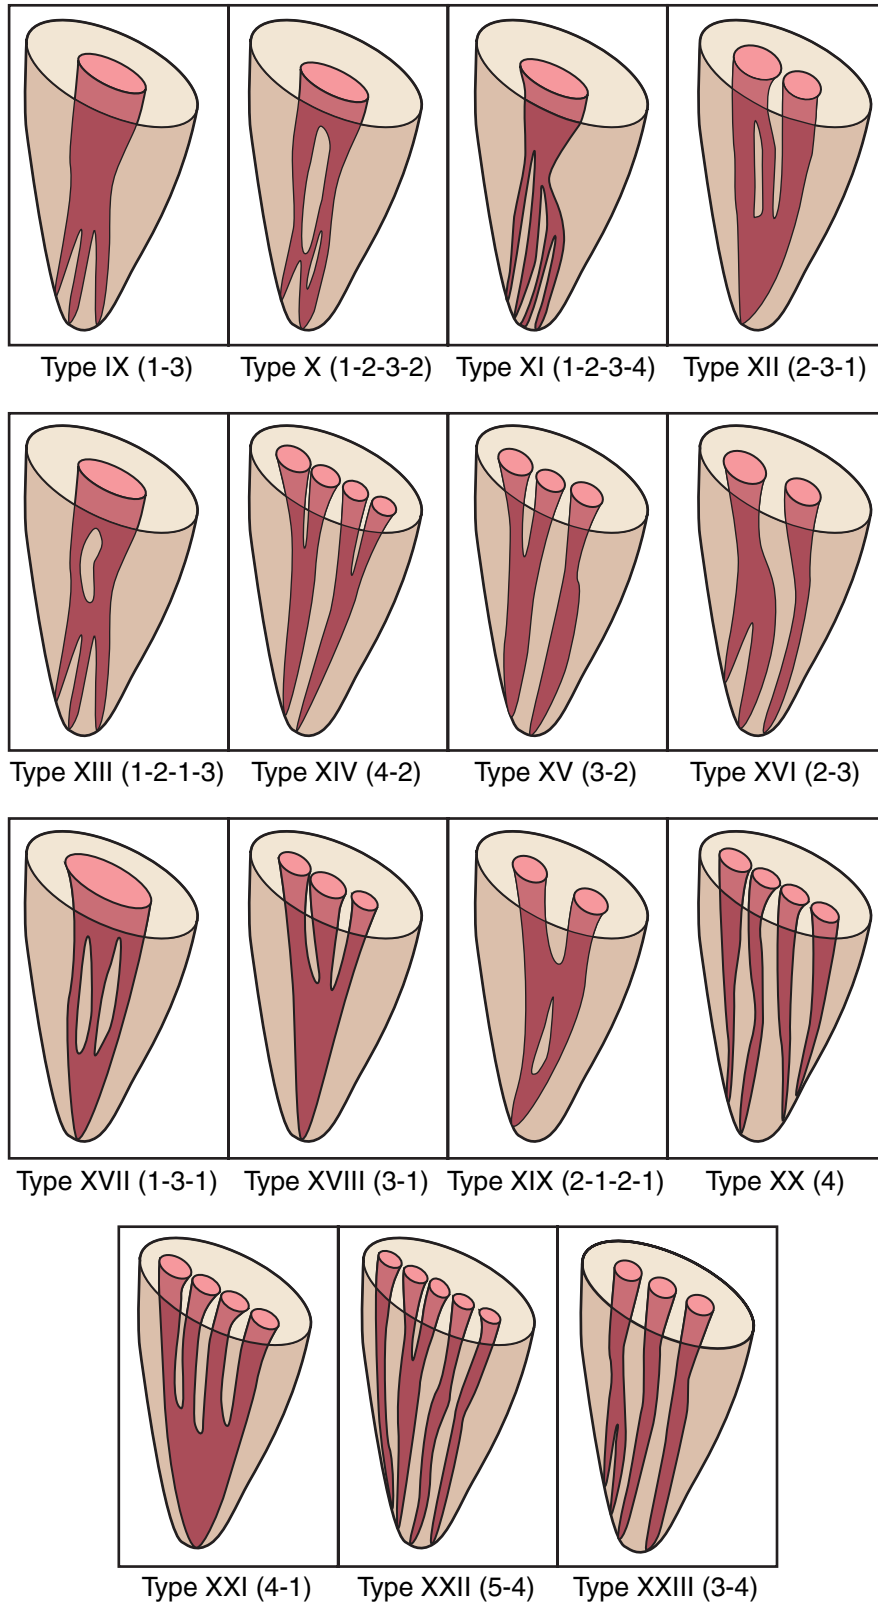

Figure 5 Sert and Bayirli's Additional Canal Types to Vertucci's Classification of Root Canal Systems (Types IX–Type XXIII).

Maxillary Central Incisor

EXTERNAL ROOT MORPHOLOGY

The cross-sectional root anatomy of the maxillary central incisor is triangular or ovoid in shape and tapers toward the lingual^{3,5,12,14,16,65} as illustrated in Figures 6–8. Root concavities are normally not present in maxillary central incisors.⁶⁶ The root trunk is generally straight and tapers to a blunt apex. The overall average length of the maxillary central incisor is 23.5 mm with an average crown length of 10.5 mm and an average root length of 13 mm.³

Figure 6 Labial view of maxillary right central incisor. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary Central Incisor- Rotations & Slices.

ROOT NUMBER AND FORM

The majority of anatomical studies found that the maxillary central incisor is a single-rooted tooth^{4,6,10,13,36} (Table 2). A few case studies of anomalous root anatomy have reported more than one root or root canal system.^{67–71}

CANAL SYSTEM

The maxillary central incisor is usually a single-root canal system^{4,6,10,13,36} (Table 3). Mid-root and apical

Figure 9 Maxillary right central incisor with normal anatomy; two mesial lateral canals are present. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary Central Incisor- X-ray Database.

lateral canals and apical delta canals are common, however (Figures 9 and 10). These lateral canals with small arterioles and venules serve as collateral circulation. When the pulp becomes diseased, Schilder referred to them as “portals of exit” into the surrounding periodontal ligament space.⁶⁴

Relatively few studies have investigated the apical root anatomy of teeth. Altman et al.⁷² investigated 20 extracted maxillary central incisors. On histological examination, accessory or lateral canals were found

Figure 10 Maxillary right central incisor with normal anatomy; three mesial lateral canals are present. Courtesy of Dr. W.H. Christie.

in three quarters of the specimens, exhibiting 1–4 accessory canals. One specimen was found to have 20 separate foramina but this anomalous canal anatomy occurred on a central incisor in a 9-year old individual. They concluded that radiographic examination was not accurate in diagnosing accessory canals and that resorptions, appositions, pulp stones, and accessory canals were commonly found in the apical 2.5 mm of the maxillary central incisors. Precise cleaning and shaping were therefore critically important.

The classic stereomicroscopic study of root apices by Green found that the average diameter of the major foramen in the 50 teeth studied was 0.4 mm while the accessory foramina were 0.2 mm in diameter. The average distance of the major apical foramen from the anatomical root apex was found to be 0.3 mm. Approximately 12% of the maxillary central incisors exhibited accessory foramina.⁷³

Mizutani et al. investigated the anatomical location of the apical foramen in 30 maxillary central incisors.⁷⁴ The root apex and the apical foramen were displaced distolabially in the majority of the specimens. The coincidence of the apical foramen and the root apex was found in only one out of six specimens.

Kasahara et al.⁷⁵ assessed the apical anatomy of 510 extracted maxillary central incisors. Apical ramifications were found in 12.3% (62/510) or one-eighth of the teeth in the study. Lateral canals were present in 49.1% (247/510) or approximately half of the specimens. Only 38.6% (194/510) of the teeth had a simple main canal without lateral canals or apical ramifications. Ninety percent of the foramina in this study were located within 1.0 mm of the anatomical apex.

VARIATIONS AND ANOMALIES

Ethnic variations have been reported for some traits. Shovel-shaped incisor crowns are a common feature in Asian* populations but are relatively rare in Caucasian population.^{12,76–81}

A study by Pecora and Cruz Filho⁸² assessed the incidence of radicular grooves in the maxillary incisors of 642 patients (Table 4). Loss of periodontal attachment associated with these grooves can result in a deep, narrow, vertical periodontal pocket. The prognosis, even with combined periodontal–endodontic treatment in such cases, can be poor.⁸³ The incidence of radicular grooves was found to be 0.9% in the maxillary central incisors and 3.0% in the maxillary lateral incisors. Reports of other types of anomalies associated with the maxillary central incisor are relatively uncommon.

Table 4 Maxillary Central Incisor

1	642	0.9% (6)

*Adjective of or relating to the division of Humankind including the indigenous people of East Asia, South East Asia and the Arctic regions of North America, characteristically having dark eyes, straight hair, pale ivory to dark skin, and little facial or body hair.

Table 5 Maxillary Central Incisor

Number of Studies Cited	Number of Teeth	Fusion	Gemination
1	534	2.6% (14)	0.94% (5)

The prevalence of fusion and gemination was assessed by Hamasha and Al-Khateeb in a Jordanian population.⁸⁴ The prevalence of fusion was found to be 2.6%, while gemination was found in 0.94% of the samples for a total incidence of 3.6% of the so-called “double teeth” (Table 5). The maxillary central incisor had the highest incidence of fusion and gemination of all permanent teeth.

Al Nazhan⁸⁵ reported a case of a central incisor with enamel hypoplasia and two canals in a single root. Examples of fusion with a supernumerary tooth,^{84,86–88} fusion with a maxillary lateral incisor,⁸⁹ gemination,^{84,86,90,91} talon cusps,^{90–94} two canals,^{95,96} dens invaginatus⁹⁷ (Figures 11 and 12), and maxillary central incisors with

Figure 11 Dens invaginatus Type 3; three-canal maxillary right central incisor. Courtesy of Dr. W.H. Christie.

Figure 12 Dens invaginatus Type 3; three-canal maxillary right central incisor. Courtesy of Dr. W.H. Christie. (Same case as Figure 11 after completion of non-surgical root canal therapy).

two roots^{67–71,98} are occasionally documented in case reports. A single case of gemination and fusion with a supernumerary tooth resulting in a tooth with three canals was reported by Hosomi et al.⁹⁹

An unusual combination of anomalies was reported by Lorena et al.¹⁰⁰ Anomalies in the maxillary arch included shovel-shaped incisors, dens invaginatus, peg-shaped supernumerary teeth, and Carabelli cusps on the maxillary first molars in the absence of any developmental anomaly. McNamara also reported a combination of anomalies that included maxillary central and lateral incisors that had talon cusps, short roots and dens invaginatus, premolars with short roots and Carabelli cusps on the maxillary first and second molars.¹⁰¹ A rare case of a labial talon cusp on a maxillary central incisor was reported by de Sousa et al.⁹³

Maxillary Lateral Incisor

EXTERNAL ROOT MORPHOLOGY

The cross-sectional root anatomy of the maxillary lateral incisor is described as being circular, oval, or ovoid in shape and tapers toward the lingual as illustrated in Figures 13–15.^{3,5,12,14,16,65,74} Root concavities are normally not present on the root of the maxillary lateral incisors.⁶⁶ The root trunk is generally smaller than a central incisor and has a finer root tip,

Figure 13 Labial view of maxillary right lateral incisor. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary Lateral Incisor-Rotations & Slices.

often terminating in a curve to the distal or the lingual, or both (Figures 13–16). The overall average length of the maxillary lateral incisor is 22 mm with an average crown length of 9 mm and an average root length of 13 mm.³

ROOT NUMBER AND FORM

Anatomical studies indicate that the maxillary lateral incisors are single-rooted, virtually 100% of the time,^{4,6,10,13,36} as listed in Table 6. However, numerous case reports demonstrate significant variability in anatomy. Most reported cases of two-rooted maxillary lateral incisors are a result of fusion or gemination and are usually associated with a macrodont crown. There are a few reported cases of two roots associated with normal crown dimensions.^{102–104} Anomalous two-rooted maxillary lateral incisors are usually associated with a developmental radicular lingual groove.

Table 6 Maxillary Lateral Incisors

Number of Roots	Number of Studies Cited	Number of Teeth	One Root
	6	757	100% (757)

CANAL SYSTEM

The maxillary lateral incisor usually presents with a single canal^{4,6,10,13,36} as demonstrated by the anatomical studies listed in Table 7. Mizutani et al. investigated the anatomical location of the apical foramen in 30 maxillary lateral incisors.⁷⁴ The root apex and the apical foramen were displaced distolingually in a majority of the specimens. Displacements in all directions were also found in the study. The coincidence of the apical foramen and the root apex was found in only two (6.7%) of the specimens. Therefore, the exploration of the apical foramen and the constriction, with a

fine precurved #10 size file tip and the electronic apex locator, is essential to locate the foramen.

The stereomicroscopic study of root apices by Green found that the average diameter of the major foramen in the 50 maxillary lateral incisors studied was 0.4 mm, while the accessory foramina were 0.2 mm in diameter. The average distance of the major apical foramen from the anatomical root apex was found to be 0.3 mm. Approximately 10% of the maxillary lateral incisors exhibited accessory foramina.⁷³

VARIATIONS AND ANOMALIES

Maxillary lateral incisors often present anomalous anatomy resulting in diagnostic and treatment chal-

Number of Studies Cited	Number of Patients	Radicular Grooves
1	642	3.0% (19)

lenges. Complications resulting from radicular grooves have been well documented by Simon et al.⁸³ The incidence of radicular grooves is 3.0% in maxillary lateral incisors (Figure 17) in a study by Pecora and Cruz Filho,⁸² as listed in Table 8, and there are several case reports in the literature

confirming the high probability of this finding.^{105–111} Peikoff and Trott reported an endodontic failure in a maxillary lateral incisor with an accessory root and a radicular groove.¹¹²

An SEM investigation of 14 extracted maxillary lateral incisors with radicular grooves concluded that direct communication between the groove and the pulp was evident in these specimens and that accessory canals were the primary mechanism of communication between the periodontium and the pulp.¹¹³ As with maxillary central incisors, the degree of shovel-shaped feature of the crown is varied and is often based on the ethnic background. Again, this feature is common in Asian populations and rare in Caucasian populations.^{12,76,77,79–81} Reports of this and other coronal anomalies associated with the maxillary lateral incisor are common. Dens invaginatus or *dens in dente*^{93,107,114–136} can be present in various forms.

Oehlers¹³⁷ classified dens invaginatus into three types based on the severity of the defect. Type 1 dens

invaginatus is an invagination confined to the crown. Type 2 extends past the cementoenamel junction but does not involve periapical tissues. The most severe form and the most complex to treat is the Type 3 defect. The invagination extends past the cementoenamel junction and may result in a second apical foramen. A combination of nonsurgical and surgical therapy is often used to successfully treat Type 2 and Type 3 cases.^{107,114,116–118,122–125,128,129,131,136,138} Nonsurgical management of the dens invaginatus, including the more severe Type 3 defects, has also been reported.^{107,115,119–121,126,130,132–135} Occasionally, vitality of the pulp in the main canal has been shown to be maintained while treating (surgically, nonsurgically, or both) the accessory canal system, when there has been no communication between the two.^{119,123,124,127,132}

There are reports of maxillary lateral incisors with fusion with a supernumerary tooth,^{139–143} fusion with a maxillary central incisor,⁸⁹ gemination (Figure 18),^{138,144–146} two roots (Figure 19),^{102–104,107}

Figure 18 Gemination of a maxillary right lateral incisor. Courtesy of Dr. W.H. Christie.

Figure 19 Accessory root with sealer filling in the canal space on the distal of a maxillary left lateral incisor. Courtesy of Dr. M.D. Peikoff.

dens evaginatus,^{147,148} two canals in a single root,⁹⁶ and anomalies where gemination, fusion, or dens invaginatus could not be determined.^{149,150} Mupparapu¹⁵¹ reported a rare finding of both dens invaginatus and dens evaginatus associated with one maxillary lateral incisor.

Maxillary Canine

EXTERNAL ROOT MORPHOLOGY

The root of the maxillary canine is oval in shape and tapers toward the lingual as illustrated in Figures 20–22.^{2,3,5,12,14,16,65} The root is wider labiolin-

Figure 20 Labial view of maxillary left canine. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary Canines- Rotations & Slices.

gually and is the longest root in the dentition, averaging approximately 17 mm in length.³ Prominent developmental depressions can be present on both its mesial and distal surfaces, especially in the middle third of the root, as shown in Figures 21 and 22.^{3,5} The root tip may be blunt or it may end in a fine, often curved tip (see Figures 20–22). The overall average length of the maxillary canine is 27 mm with an average crown length of 10 mm and an average root length of 17 mm.³

ROOT NUMBER AND FORM

Most studies have found that the maxillary canine has a single root 100% of the time,^{4,6,10,13,36,152} as shown by the anatomical studies in Table 9. There are,

Figure 22 Root cross-sections of the maxillary left canine. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary Canine- Rotations & Slices.

however, rare case reports of two-rooted maxillary canines.^{153,154}

CANAL SYSTEM

The maxillary canine usually has a single canal (Figures 23 and 24). A small percentage of maxillary canines have two canals (3.5%), as listed in Table 10.^{4,6,10,13,36,152} Of those having two canals, the majority (75%) join in the apical third and exit through a single foramen. Accessory (lateral) canals are not uncommon and become evident radiographically after the completion of RCT (Figures 23–25). The majority of lateral canals occur in the apical third of the tooth (see Figures 23 and 24),

Figure 23 Maxillary left canine with normal anatomy and a mesial and apical lateral canal in the apical third. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas* Version 3.0. Illinois: Quintessence, 2005: Maxillary Canine- X-ray Database.

but midroot lateral canals can also occur (see Figure 25). Mizutani et al. investigated the anatomical location of the apical foramen in 30 maxillary canines.⁷⁴ The root apex and the apical foramen were displaced distolabially in the majority of the specimens. The coincidence of the apical foramen and the root apex was found in only five (16.7%) of the specimens. The use of the electronic apex locator is more reliable than the radiograph in

Figure 24 Maxillary left canine with normal anatomy and numerous lateral canals on the mesial aspect of the root. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas* Version 3.0. Illinois: Quintessence, 2005: Maxillary Canine- X-ray Database.

determining the apical foramen or the constriction in most canine teeth.

The study by Green on the root apices of permanent anterior teeth found that the average diameter of the major foramen in the 50 maxillary canines studied was 0.5 mm, while the accessory foramina were 0.2 mm in diameter. The average distance of the major apical foramen from the anatomical root apex was found to be 0.3 mm. Approximately 12% of the maxillary canines exhibited accessory foramina.⁷³

VARIATIONS AND ANOMALIES

The maxillary canine usually presents few anatomical variations. When variations do occur, the root is more frequently affected than the crown. However, there are occasional reports in the literature of both coronal and radicular anomalies in the maxillary canine. The root can be dilacerated¹⁵ or can have extreme variations in length.^{2,3,5,12,15} One individual with an extremely long root length was reported by Booth in 1988

with canine teeth having an overall length of 41 mm.¹⁵⁵ This patient was a 5'2", 31-year-old female of Dutch origin.

Dens evaginatus, when present, can take the form of a tubercle or a talon cusp, and is most frequently found on the lingual surface of the crown. There are also reports of labial tubercles.¹⁵⁶ The total incidence of dens evaginatus has been shown to be approximately 1% in an extensive literature review and a radiographic review of 15,000 anterior teeth by Dankner et al.¹⁵⁷ Between 1970 and 1995, there were only four case reports of dens evaginatus in the maxillary canine in their review. The radiographic survey of 15,000 anterior teeth found no occurrences of dens evaginatus in the maxillary canine.

Other variations reported in the literature include case reports with two canals in a single root,¹⁵⁸ two roots,^{153,154} dens invaginatus^{97,147,159} (Figure 26), and bilateral, supernumerary canines in a nonsyndrome case.¹⁶⁰

Maxillary First Premolar

EXTERNAL ROOT MORPHOLOGY

The root anatomy of the maxillary premolar can vary depending on whether one, two, or three roots are present (Figures 27–34). The more common two-rooted form is illustrated in Figures 27–30. There are some common features to the various forms. The overall length of the maxillary first premolar is 22.5 mm with an average crown length of 8.5 mm and an average root length of 14 mm.³

Prominent root concavities are present on both the mesial and the distal surfaces of the root. The mesial

Figure 27 Buccal view of maxillary right first premolar. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary First Premolar- Rotations & Slices.

Figure 28 Mesial view of maxillary right first premolar. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Maxillary First Premolar- Rotations & Slices.

root concavity is more prominent and extends onto the cervical third of the crown.^{3,5,12,14,16,65,161} This results in a root that is broad buccolingually and narrow mesiodistally with a kidney shape when viewed in cross section at the cemento enamel junction.³ These anatomical features have implications in restorative dentistry and in periodontal treatment, and are common areas for endodontic root perforations.

Gher and Vernino examined the external root shape as it related to the development of periodontal defects.¹⁶² The palatal aspect of the buccal root tip of two-rooted maxillary first premolars usually has a deep longitudinal depression along its length. Seventy-eight percentage of the 45 teeth in their study exhibited a buccal furcation groove. They concluded that a buccal root furcation groove was a normal anatomical feature in these two-rooted maxillary first

premolars that have well-formed buccal and lingual roots. The groove was not generally found in these two-rooted specimens with a furcation located in the apical third of the root. A study by Joseph et al also found an incidence of the buccal furcation groove in 62% of teeth with bifurcated roots.¹⁶³

ROOT NUMBER AND FORM

The majority of anatomical studies found that the most common form of the maxillary first

Figure 34 Extracted maxillary right first premolar with three very fine roots (MB, DB and Palatal). Courtesy of Dr. W.H. Christie.

premolar is the two-rooted form^{4,21,57,164–173} (see Figures 27–30). There was a wide variation in the incidence of the number of roots in the anatomical studies cited. Figure 31 is an example of three canals in two fused buccal roots and a lingual root. The incidence of three-rooted maxillary first premolars ranged from 0%^{4,169,173} to 6%.¹⁶⁵ The ethnic background of the patients in many of the studies was not identified. The majority of studies reporting that the two-rooted form was the most common had a Caucasian cohort, forming the majority of the population.

The studies identifying ethnic background have demonstrated distinct differences between Asian and Caucasian populations. Single-rooted maxillary first premolars (see Figure 32) are the dominant form in Asian population,^{164,173} and three-rooted forms are rare^{164,169,173} (see Figures 33 and 34). Because of the significant influence of the ethnic background in the root number for this tooth, Table 11 reports the weighted averages for all studies and separates the data between Asian versus non-Asian populations.

In addition to ethnic differences, studies vary in their definition or do not identify what constitutes a bifurcated root. Walker utilized Turner's classification and did not consider a root to be separate unless it was a distinct and separate root for at least half of the overall root length.¹⁷³ Loh, however, grouped teeth into one root, two roots (including two-root distinct and two-root fused), and three roots. The two-root fused category was defined as teeth with roots joined almost to the apex and with two canals at their origin.¹⁶⁹

The normal external three-root anatomy configuration is that of a mesiobuccal, distobuccal, and palatal root. Sabala et al. studied aberrant root and root canal morphology in 501 patient records.²¹ The occurrence of the same aberration on the contralateral tooth varied according to the type of anomaly. Of the four patients, out of 501, who were found to have three-rooted maxillary first premolars, all were bilateral. Their study found that the rarer the anomaly, the greater the incidence of the anomaly occurring bilaterally. Those anomalies occurring less than 1% were found to occur bilaterally up to 90% of the time.

CANAL SYSTEM

The majority of maxillary premolars were found to have two canals, irrespective of whether the tooth has a single or a double root (Table 12). In the 15 anatomical studies assessed, over 75% of the teeth studied had two canals.^{4,6,7,10,36,57,165,167–174} Ethnicity was a factor in canal number. The incidence of a single canal was significantly higher in Asian populations compared to the mixed non-Asian population.^{169,173} The Vertucci and

	0	–						

Weine classification systems are useful in exploring canal systems with double canals in single roots.^{13,40}

All of the three-rooted first premolars in the anatomical studies were found to have a single canal in each root.^{165,166,168} The incidence of three canal maxillary premolar teeth was reported in these and other anatomical studies, and it ranged from 0%^{167,169,170,173} to 6%.¹⁶⁵ This finding is a rare occurrence in Asian populations.^{169,173} Regardless of the number of roots, the majority of maxillary first premolars (71.3%) had two separate canals and foramina at the apex.

VARIATIONS AND ANOMALIES

Ethnic differences were demonstrated for maxillary first premolar root number in the anatomical studies reported.^{81,164,169,173,175} The study by Loh reported a much lower incidence (50.6%) of the two-rooted maxillary first premolars in a Singaporean population compared to Sabala's study (98.4%) based in the United States.¹⁶⁹ Tratman⁸¹ reported that the two-rooted first premolar was very uncommon in Asian stock as did Petersen¹⁷⁵ in his study of the East Greenland Eskimo dentition. A large anatomical study of 3,202 maxillary first premolars by Aoki (Japanese patients) found that 65.7% of the specimens were single-rooted.¹⁶⁴

Three-rooted forms were reported to be a rare variation in Asian populations.^{176–178} Mattuella et al. reported a variation of the maxillary first premolar with a longitudinal sulcus on the buccal surface of the buccal root.¹⁷⁹ This variation resulted in a two-canal system in the buccal root and three canals in teeth with two roots. Geminatio of the maxillary first premolar is rarely reported in the literature.¹⁸⁰

Taurodontism is another rare anomaly in premolars, as a group, and less common in the maxillary premolars compared to their mandibular counterparts. Taurodontism of roots and canal systems is explained in greater detail in section "Maxillary First Molar." Llamas found only three taurodont-like maxillary premolars in a sample of 379 extracted maxillary and mandibular premolars.¹⁸¹ Of the 16 cases of taur-

odontism in Shifman's review of radiographs, over a 5-year period, none were maxillary first premolars.¹⁸² Madeira's study of 4,459 premolars found a total of 11 taurodont mandibular premolars (7 mandibular first premolars and 4 mandibular second premolars) but none in the maxillary premolars.¹⁸³ The Weine type IV root canal system, with a wide buccolingual canal that branches into two apical canals and foramina in the apical third, may sometimes be confused as a taurodont-like root canal anatomy, when it occurs in single-rooted maxillary premolar teeth.

Maxillary Second Premolar

EXTERNAL ROOT MORPHOLOGY

The cross-sectional root anatomy of the maxillary second premolar in the midroot area is described as oval- or kidney-shaped.^{1,3,5,12,14–16} Developmental depressions are often present on the mesial and the distal aspects of the root. The single root trunk is broad buccolingually and is narrower mesiodistally as illustrated in Figures 35–40. The root tip usually

Figure 35 Buccal view of maxillary left second premolar. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas* Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Premolar- Rotations & Slices.

ends as a single blunt apex, but it may be fine and divide into two or more, rarely three, apices. The curvature in the apical third is also not uncommon. The overall average length of the maxillary second

Figure 36 Mesial view of maxillary left second premolar. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Premolar- Rotations & Slices.

premolar is 22.5 mm with an average crown length of 8.5 mm and an average root length of 14 mm.³

ROOT NUMBER AND FORM

All of the anatomical studies cited found that the most common form of the maxillary second premolar is a single root as illustrated in Figures 35–40.^{4,57,153,164,184,185} The weighted averages for data from six anatomical studies of 8,513 teeth as illustrated in Table 13 result in a 90.7% incidence of single-rooted teeth. The incidence of two-rooted maxillary second premolars ranged from 5.5%¹⁶⁴ to 20.4%,⁵⁷ while the three-rooted form was a rare finding and ranged from 0%^{4,170,184,185} to 1%.⁵⁷ The bilateral symmetry of the three-rooted form may be expected in many patients as this anomaly is quite rare.²¹

CANAL SYSTEM

The maxillary second premolar has a single canal in approximately 50% of the 2743 teeth examined in 10 anatomical studies,^{6,10,13,36,57,167,168,174,184,185} as listed

Figure 38 Maxillary left second premolar with a single root and a single canal; lateral canals are visible in the middle and apical thirds of the root. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Premolar- X-ray Database.

Figure 39 Maxillary right second premolar with a single root and single canal; the apical third exhibits a curvature to the mesial. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Premolar- X-ray Database.

in Table 14. Therefore, even though over 90% of these teeth have a single root, a high proportion will have two canals present. Canal exploration of maxillary second premolar teeth should be done with fine curved files, keeping in mind the Vertucci or Weine classification of two canals in one root that may not be apparent on the radiograph. The incidence of three canals in the maxillary second premolar was low in each of the anatomical studies. The majority of the

Figure 40 Maxillary left second premolar with a single root and a single main canal; two lateral (accessory) canals are visible in the apical third of the root. teeth studied had a single canal (50.3%) and a single canal at the apex (61.4).

VARIATIONS AND ANOMALIES

Relatively few case reports of variations and anomalies in the maxillary second premolar have been published. These case reports include examples of dens

Table 13 Maxillary Second Premolar

invaginated,¹⁸⁶ a deep distal root concavity,¹⁸⁷ taurodontism,¹⁸² two roots and three canals⁵ (Figure 41), and the presence of three roots and three canals^{5,178,188–191} (Figure 42). Three-rooted maxillary second premolar teeth do not seem to be as common as in first premolars. This anomaly is often bilateral and should be considered by exposing radiographs taken at different angles. Both first and second premolar triple-canal system anomalies do occur, but rarely.¹⁷⁸

Figure 42 Maxillary right first and second premolars each have 3 roots (MB, DB and Palatal). Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Premolar- X-ray Database.

Maxillary First Molar

EXTERNAL ROOT MORPHOLOGY

The maxillary first molar normally has three roots as illustrated in Figures 43–48. The mesiobuccal root is broad buccolingually and has prominent depressions

Figure 43 Buccal view of maxillary right first molar. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary First Molar-Rotations & Slices.

or flutings on its mesial and distal surfaces.^{1,3,5,14-16} The internal canal morphology is highly variable, but the majority of the mesiobuccal roots contain two canals. The distobuccal root is generally rounded or

Figure 48 Maxillary left first molar with 3 roots and 4 canals (MB, ML, D and Palatal). Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Maxillary First Molar- X-ray Database.

ovoid in cross section and usually contains a single canal. The palatal root is more broad mesiodistally than buccolingually and ovoidal in shape but normally contains only a single canal. Although the palatal root generally appears straight on radiographs, there is usually a buccal curvature in the apical third.¹⁹² Depressions on the buccal and palatal surfaces of the palatal root can be present but are generally shallow. Gher and Vernino found prominent depressions on the distal aspect of the mesiobuccal roots.¹⁶² Depressions could also be found on the furcal side of the distobuccal and palatal roots. The overall average length of the maxillary first molar is 20.5 mm with an average crown length of 7.5 mm and an average root length of 13 mm.³

ROOT NUMBER AND FORM

The maxillary first molar root anatomy is predominantly a three-rooted form, as shown in all anatomical studies^{4,17,18,22} of this tooth (Table 15). The two-rooted form is rarely reported and may be due to the fusion of the distobuccal root to the palatal root

Table 15 Maxillary First Molar

Number of Roots	Number of Studies Cited	Number of Teeth	One Root	Two Roots	Three Roots
4	416	416	0.2% (1)	3.8% (16)	95.9% (399)

Table 16 Maxillary First Molar

	8	1714	6.2% (107)

Table 17 Maxillary First Molar

C-shaped Roots	Number of Studies Cited	Number of Teeth	Incidence of Fusion
	2	2480	0.12% (3)

or the fusion of the distobuccal root to the mesiobuccal root. The single root or the conical form of root anatomy in the first maxillary molar is very rarely reported.⁴ Over 95% (95.9%) of maxillary first molars had three roots and 3.8% had two roots in four studies that included 416 teeth. The four-rooted anatomy in its various forms is also very rare in the maxillary first molar and is more likely to occur in the second or the third maxillary molar.^{45,193}

The incidence of fusion (Table 16) of any two or three roots was approximately 6.2%.^{17-23,194} The C-shaped root canal system morphology (Table 17) is also a rare anomaly (0.12%).^{23,47}

CANAL SYSTEM

The internal root canal system morphology reflects the external root anatomy. The mesiobuccal root of the maxillary first molar contains a double root canal system more often than a single canal according to most of the anatomical studies (Table 18). This review contained the most data on the canal morphology of the mesiobuccal root with a total of 8,515 teeth from 37 studies.^{6-11,13,17,18,22,25,27,28,30-34,36-43,51,52,54-57,59,195,196}

The incidence of two canals in the mesiobuccal root was 57.1% and of one canal was 42.9% in a weighted average of all reported studies. The incidence of two canals in the mesiobuccal root was higher in laboratory studies (61.1%) compared to clinical studies (54.7%). Less variation was found in the distobuccal and palatal roots, and the results were reported from 15 studies consisting of 2,606 teeth. The distobuccal root had only one canal in 98.3% of teeth studied, while the palatal root had only one canal in over 99% of the teeth studied.²⁴

Table 18 Maxillary First Molar

	6	1381			98.1% (1355)	1.9% (26)

In vitro studies of the mesiobuccal root canal system are slightly more likely to report two canals in the maxillary first molar than do the vivo clinical studies, but the incidence of location of a two-canal system in clinical studies appears to be increasing with the routine use of the SOM and other aids during the modified endodontic access opening procedure.^{11,59}

The two-canal system of the mesiobuccal root of the maxillary first molar has a single apical foramen roughly twice as often (66.0%) in proportion to the two-canal and two-foramen morphology, in weighted laboratory studies (see Table 18).

The single-canal system and single apical foramen in the palatal and the distobuccal root of the maxillary first molar is the most predominant form, as reported in all studies, but multiple canals and more than one apical foramen variation do exist in 1–3% of these roots in the weighted studies reported (see Table 18).

VARIATIONS AND ANOMALIES

The root and root canal morphology of teeth varies greatly in the reported literature. Many studies provided no information on ethnic background, age or gender or possible explanations for variations observed.

Walker^{173,197,198} reported on the ethnic differences in the root anatomy of maxillary first premolars, mandibular first premolars, and the high incidence of three-rooted mandibular first molars in Asian patients. He did not, however, report on the incidence

of a second mesiobuccal canal (MB2) in the maxillary first molar. A study by Weine et al.³² determined that the incidence of MB2 in a Japanese population was similar to the incidence reported for other ethnic backgrounds.

Age was found to have an effect on the incidence of MB2. Fewer canals were found in the mesiobuccal root due to increasing age and calcification.^{38,42,55} Sert and Bayirli¹⁰ conducted a clearing study that identified gender, in a sample of 2800 teeth (1400 male and 1400 female) from Turkish patients. One hundred permanent teeth of each type (excluding third molars) for each gender were included in the study. Although they did not consider age in their study, they concluded that gender and race were important factors to consider in the preoperative evaluation of canal morphology for nonsurgical root canal therapy. Although only 100 of each type of tooth for each gender was included in their study, a single Vertucci Type I canal was present in the mesiobuccal root in only 3% of males compared to 10% of females. There are conflicting results with respect to gender and the number of canals.^{6,10,42,55}

Some studies^{39,51} compared in vivo versus in vitro techniques. Seidberg et al.³⁹ reported that 33.3% of the 201 teeth studied had a MB2 canal in their in vivo study. This increased to 62% in their in vitro study of 100 teeth. Similar results were reported in a study by Pomeranz and Fishelberg.⁵¹ Only 31% of 100 teeth studied had a MB2 canal in their in vivo study compared to 69% of 100 teeth in their in vitro study. The in vitro portion of this study described the samples as extracted maxillary molars and may represent pooled

data instead of maxillary first molar data alone. The definition of a canal as a treatable canal used in clinical studies^{11,42} versus the more complex canal configurations visible through clearing studies^{6,10,13,17,25} can also lead to different results.

The more common use of SOM or loupes in recent clinical studies has resulted in an increased prevalence of the clinical detection of the MB2 canal.^{11,31,41,43} The effect of magnification on the incidence of clinical location of MB2 was assessed in a clinical study by Buhrey et al.⁴¹ The MB2 canal was found in 41 of 58 teeth (71.1%) when using SOM. The group using loupes found MB2 in 55 of 88 teeth (62.5%). The lowest incidence of MB2 was in the group performing RCT without any magnification. MB2 was found in only 10 of 58 teeth (17.2%). A study by Sempira and Hartwell⁴³ found that the use of an SOM did increase the incidence of MB2. They attributed the lower incidence in their study to their characterization of a canal as one that must be negotiated and obturated to within 4 mm of the apex.

The incidence of many of the anomalies in case reports cannot be determined due to the lack of data collection. However, although rare, these anomalies can and do occur. There are reports of two palatal canals in three-rooted teeth,^{54,193,199,200} three palatal canals in a reticular palatal root,^{53,201} two palatal roots or four roots total,^{26,44,45,193,202} five roots (two palatal, two mesiobuccal, and one distobuccal),²⁶ C-shaped canals,^{46,47,203–205} single or multiple taurodont molar

teeth,^{58,182,206} root fusion,^{46–48,207} two canal systems in the distobuccal root,^{49,208} and a single-rooted tooth with a single canal.²⁰⁹ Other rare anomalies are illustrated below in Figures 49–51.

Of all the canals in the maxillary first molar, the MB2 can be the most difficult to find and negotiate in a clinical situation. The knowledge from laboratory

studies is essential to provide insight into the complex root canal anatomy. A study by Davis et al. in 1973²¹⁰ compared the post débridement anatomy of the canals of 217 teeth. Injection of silicone impression material into the instrumented canals revealed that standard instrumentation left a significant portion of the canal walls untouched. Fins, webbing, and canals were sometimes found to be not fully instrumented. Clinical instrumentation of this tooth, especially with respect to the mesiobuccal root, can be complicated. Failure to detect and treat the second MB2 canal system will result in a decreased long-term prognosis.⁵² Stropko¹¹ observed that by scheduling adequate clinical time, by using the recent magnification and detection instrumentation aids, and by having thorough knowledge of how and where to search for MB2, the rate of location can approach 93% in maxillary first molars.

Taurodontism or “bull-like” teeth was first described by Keith.²¹¹ Initially, it was considered to be a primitive trait found in Neanderthal skulls from Krapina and other archaeological sites. Shaw and others^{206,212,213} classified the “modern” molar form as cynodont and classified taurodontism into hypo-, meso- and hypertaurodontism. Many case reports appeared in the early dental literature with varying degrees of taurodontism. There are a few case reports to date that have described endodontic treatment on taurodont-like teeth.^{214–217} Other case reports link taurodontism with inherited syndromes as well.^{217,218}

Maxillary Second Molar

EXTERNAL ROOT MORPHOLOGY

The maxillary second molar normally has three roots, as shown in Figures 52–57. The relative shape of each of the roots is similar to the maxillary first molar, but the roots tend to be closer together and there is a higher tendency toward fusion of two or three roots.¹⁵ There is also usually more of a distal inclination to the root or roots of this tooth compared to the maxillary first molar.¹⁵

The mesiobuccal root is broad buccolingually and has prominent depressions or flutings on its mesial and distal surfaces.^{1,3,5,14–16} The internal canal morphology is variable and anatomical studies indicate that the mesiobuccal root has almost an equal incidence of one or two canals (Table 19). The distobuccal root is generally rounded or ovoid in cross section and usually contains a single canal. The palatal root is more broad mesiodistally than buccolingually

and ovoidal in shape but normally contains only a single canal. Depressions on its buccal and palatal surfaces can be present but are usually shallow. Gher and Vernino found prominent depressions on the distal aspect of the mesiobuccal roots.¹⁶² Depressions could also be found on the furcal side of the distobuccal and palatal roots. The overall average length of the maxillary second molar is 19 mm with an average crown length of 7 mm and an average root length of 12 mm.³

ROOT NUMBER AND FORM

The majority of maxillary second molars (88.6%) in the anatomical studies were found to be three-rooted,^{4,17,219} as listed in Table 20. However, this is

Figure 52 Buccal view of maxillary left second molar. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas* Version 3.0. Illinois: Quintessence, 2005: Maxillary Second Molar-Rotations & Slices.

a lower incidence than that found in the maxillary first molar. The closer proximity of the roots results in a higher incidence of root fusion (25.8%),^{17,19-21, 23,194,220} as listed in Table 21, and C-shaped canals

(4.9%) (Table 22) when compared to the maxillary first molar.²³

CANAL SYSTEM

The shape of the root provides an indication of the shape of the internal canal morphology.¹³ The broad

buccolingual and narrow mesiodistal dimension of the mesiobuccal root of the maxillary second molar may have one (see Figures 55 and 56) or two canals (Figure 57), as illustrated in Table 19. The anatomical studies found a wide range of canal incidence in the mesiobuccal root.^{6,7,10,11,13,17,25,27,28,31,34,36,38,51,54,57,221} Kulild and Peters³¹ reported a low incidence of a single canal of 5.3%, while Hartwell and Bellizzi⁵⁴ found a single canal in 81.8% of their specimens. It should be noted that the former was a laboratory study while the latter was clinical. The single canal is usually described as being kidney- or ribbon-shaped. Eskoz and Weine suggest that age and continued deposition of secondary dentin in the isthmus can cause narrowing and possible occlusion resulting in two canals.²²¹ There was a single apical foramen found in the mesiobuccal root over 68% of the time. The distobuccal and palatal roots exhibited a single canal over 99% of the time in the 10 anatomical studies reported.^{6,7,10,13,17,25,28,36,54,57}

VARIATIONS AND ANOMALIES

Other variations reported in the literature include four-rooted teeth with two palatal roots and one canal in each palatal root^{26,44,45,56,192,193,199,200,219,222,223}

Figure 58 Maxillary right second molar (buccal view) with bifurcated double palatal root type I. (Courtesy, Dr. W. H. Christie).

(Figure 58), a four-rooted tooth with one palatal, one mesiobuccal, and two distobuccal roots,²²⁴ taurodontism,⁵⁸ and a single-rooted specimen with a single canal.²²⁵ Other rare anomalies are illustrated below in Figures 59 and 60. Darwazeh et al.²²⁶ found the prevalence toward taurodontism in modern Jordanian patients to be highest in the maxillary second molar, while Shifman et al.¹⁸² reported the highest incidence in the mandibular second molar.

A review article on the double palatal root by Christie, Peikoff, and Fogel⁴⁵ studied a collection of 16 clinical cases from their practice and 8 teeth from 6 case reports^{56,192,193,199,219,223} from the literature to 1991. The highest occurrence of two palatal canals in double palatal roots (21/24 teeth) was found in the maxillary second molar tooth. The anomaly seemed to occur as three root anatomy types: first, the two

palatal roots being long and divergent; second, the two palatal roots being shorter, nearly parallel and comparable to the two buccal roots; and third, variations of root fusion that included a two-canal system

on the palatal aspect. Subsequent case reports have tended to support this observation.^{44,200,227,228} Di Fiore²²⁹ has reported on the complications that may arise in the restorative and periodontal treatment for the four-rooted maxillary molar tooth.

Mandibular Central Incisor

EXTERNAL ROOT MORPHOLOGY

The mandibular central incisor is single-rooted (Figures 61–64). The external form of the root is broad labiolingually and narrow mesiodistally. Longitudinal depressions are present on both the

Figure 61 Labial view of mandibular right central incisor. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular Central Incisor- Rotations & Slices.

mesial and the distal surfaces of the root. A cross section of the root is ovoid to hourglass in shape due to the developmental depressions on each side.^{3,5,12,14,16,65} The overall average length of the mandibular central incisor is 21.5 mm with an average crown length of 9 mm and an average root length of 12.5 mm.³

ROOT NUMBER AND FORM

All of the anatomical studies reviewed reported that 100% of the mandibular central incisors studied were single-rooted teeth, as listed in Table 23.^{4,6,10,36,230,231} Variations from this form have either not been reported or not found in a review of the literature.

CANAL SYSTEM

The canal system is either ovoid or ribbon-shaped.^{3,5,12,14,16,65,232} All the anatomical studies found the majority of mandibular central incisors to have a single canal. Table 24 shows that the anatomical studies found a single canal in 73.6% of the teeth

Figure 63 Root cross-sections of the mandibular right central incisor. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular Central Incisor- Rotations & Slices.

	6	1284	100% (1284)

studied. Two canals were found in 26% of the specimens.^{4,6,10,36,230,231,233–240} The incidence of three or more canals was quite rare (0.4%). A single apical foramen was found in 96.4% of the teeth in the studies. Therefore, even when two separate canals have been found, the majority of these canals will join and exit in a single foramen (Figures 65 and 66). Table 25 provides data from four studies that pooled mandibular central and lateral incisors.^{241–244} These data are reported to provide a comparison between the separate data reported for each of these teeth. The rationale reported for pooling data from these two teeth was that they were anatomically very similar.

A study by Green in 1956 on the root apices of anterior teeth found that the average diameter of the major foramen in the 200 pooled mandibular incisors was 0.3 mm, while the accessory foramina were 0.2 mm in diameter. Approximately 12% of the pooled mandibular incisors exhibited accessory foramina. The

average distance of the apical foramen from the anatomical root apex was found to be 0.2 mm.⁷³

VARIATIONS AND ANOMALIES

A few anomalies are reported for this tooth in the literature. The case reports of anomalies include an example of two canals and two separate foramina (Figure 67),²⁴⁵ dens invaginatus,^{97,246} fusion⁵ (Figure 68), gemination⁵ (Figure 69), and examples of dens evaginatus that includes a lingual talon cusp^{148,247} and a labial talon cusp.¹⁵⁶

Mandibular Lateral Incisor

EXTERNAL ROOT MORPHOLOGY

The mandibular lateral incisor is single-rooted (Figures 70–75) and is comparable in form to the mandibular central incisor. The external form of the root is broad labiolingually and narrow mesiodistally. Longitudinal depressions are present on both the

mesial and the distal midroot surfaces of the root. A cross section of the root is ovoid or hourglass in shape due to the developmental depressions on each side.^{3,5,12,14,16,65} The overall length of the average mandibular lateral incisor is 23.5 mm with an average crown length of 9.5 mm and an average root length of 14 mm.³ The major difference in tooth anatomy from the mandibular central incisor is at the incisal edge coronal anatomy. A slight angulation to the distolingual and the mesiolabial of the mandibular incisor's incisal edge should be compensated for when preparing an endodontic access opening and searching for the broader labiolingual canal system.

ROOT NUMBER AND FORM

All of the anatomical studies reviewed reported that 100% of the mandibular lateral incisors studied were single-rooted teeth, as listed in Table 26.^{4,6,10,36,230,231} Variations in root number from this form have either not been reported or not found in a review of the literature.

	14	2812	71.8% (2018)	28.1% (791)	0.1% (3)		
	9	1589				97.4% (1547)	2.6% (42)

of the teeth studied. Two canals were found in 28.1% of the specimens (Figure 76).^{4,6,10,36,230,231,233-240} The incidence of more than two canals was quite rare (0.1%). There was a single apical foramen found in 97.4% of the teeth included in the studies. Therefore, similar to the mandibular central incisors, even when two separate canals have been found, the majority of the canals will join and exit through a single foramen.

VARIATIONS AND ANOMALIES

Few anomalies are reported for this tooth. Case reports of anomalies include dens invaginatus,^{248,249} gemination⁵ (Figure 77), fusion^{5,250,251} (Figure 78), and two (bifid) roots.¹⁹²

Mandibular Canine

EXTERNAL ROOT MORPHOLOGY

The root of the mandibular canine in cross section is wider labiolingually and narrower mesiodistally, which is larger but similar to the shape of the other mandibular anterior teeth (Figures 79–83). Developmental depressions are normally present on both the mesial and the distal surfaces of the root. The depressions can be relatively deep. Normally a single-rooted tooth, one variation is a bifurcated root^{3,5,12,14,16,65} (Figure 84). When this occurs, the level of furcation dividing the labial and the lingual roots can be at any level on the root and usually results in a smaller lingual rootlet at the apical region. The overall average length of the mandibular canine is 27 mm with an average crown length of 11 mm and an average root length of 16 mm.³

ROOT NUMBER AND FORM

As described above, the most common form of the mandibular canine is one with a single root, as listed in Table 28.^{4,252,253} The three anatomical studies cited^{4,252,253} that reported on the mandibular canine

Figure 76 Mandibular right lateral incisor with two canals and one apical foramen (unpublished case report courtesy of Dr. W.H. Christie).

Figure 77 Mandibular left lateral incisor exhibiting gemination. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular Lateral Incisor- X-ray Database.

root number in certain populations found an incidence of two roots ranging from 1.7%²⁵³ to 6.2%.⁴

CANAL SYSTEM

The mandibular canine usually presents with a single-root canal system, as cited in Table 29.^{4,6,10,13,21,36,167,233,235,236,253} The incidence of a single canal is 89.4%. In the single-canal system, 96.9% have a single apical foramen.^{6,13,36,253,254} Therefore, when two canals

are present in a single-rooted mandibular canine, the most common configuration is the joining of the two canals before exiting at the apex (Vertucci Type II (2-1) or Vertucci Type III (1-2-1)).

A study by Green in 1956 on the root apices of the anterior teeth found that the average diameter of the major foramen, in the 50 mandibular canines studied, was 0.3 mm, while the accessory foramina were 0.2 mm in diameter. The average distance of the major apical foramen from the anatomical root apex

was found to be 0.35 mm.⁷³ Approximately 10% of the mandibular canines exhibited accessory foramina.

VARIATIONS AND ANOMALIES

The most frequent variation found in the mandibular canine is the presence of two canals.¹² One anthropology report by Alexandersen²⁵² showed a high incidence of two-rooted mandibular canine teeth in an Iron-Age Danish population. Although, the data from anatomical studies vary greatly with respect to the incidence of two roots, the mandibular canine has the highest incidence of all of the anterior teeth at 5.2%. Other variations reported in the literature include two canals and two roots^{255,256} (Figures 84 and 85), two canals with a single apical foramen^{5,257} (Figure 86), dens evaginatus,¹⁵⁷ three canals in a single root,²⁵⁸ fusion with a lateral incisor,²⁵⁰ dens invaginatus⁵ (Figure 87), and gemination⁵ (Figure 88).

Mandibular First Premolar

EXTERNAL ROOT MORPHOLOGY

The mandibular first premolar is typically a single-rooted tooth that is wider buccolingually and narrower mesiodistally, although two-rooted varieties do occur fairly frequently^{1,3,5,14-16} (Figures 89–91). Developmental depressions or grooves are frequently found on both the mesial and the distal surfaces of the root resulting in an ovoid- or hourglass-shaped root. The depression on the distal root surface has been described as being deeper than the mesial root depression.²⁵⁹ The overall average length of the mandibular first premolar is 22.5 mm with an average crown length of 8.5 mm and an average root length of 14 mm.³

ROOT NUMBER AND FORM

The mandibular first premolar is normally a single-rooted tooth, as shown in Figures 92 and 93 (Table 30); however, eight anatomical studies did reveal an incidence in approximately 1.8% of bifurcated teeth (Figure 94).^{4,6,13,57,254,260–262}

Trope et al. found significant ethnic variations in the root anatomy when comparing African American and Caucasian patients.²⁶³ Their study found an incidence of two root canals of 5.5% in the Caucasian and 16.2% in the African American group of patients. Three-rooted mandibular first premolars are rare but are occasionally found in case reports²⁶⁴ (Figures 95–97). Scott and Turner²⁶⁵ describe the accessory root as “Tome’s root.” Their anthropological review of ethnic differences indicates that aboriginal Australians and sub-Sahara African population

have the highest incidence (>25%) of accessory roots. The lowest incidence (0–10%) of Tome's root occurred in American Arctic, New Guinea, Jomon, and Western Eurasian population.

CANAL SYSTEM

Slowey has suggested that the mandibular premolars may present with greatest difficulty of all teeth to treat endodontically.¹⁹² A University of Washington study assessed the failure rate of nonsurgical RCT in all teeth. It was highest for the mandibular first premolar at 11.45%.¹ The possible reasons for a high failure rate are the numerous variations in root canal morphology and difficult access to a second canal. There is usually a straight line access to the buccal canal, while the lingual canal branches at a sharp angle, potentially resulting in a missed canal. A study by Kartal and Yanikoglu, using pooled data (Table 31) that included first and second premolars, reported a 27.8% incidence of mandibular premolars with more than one canal.²⁶⁶ Serman and Hasselgren examined full mouth series of radiographs for 547 patients and found that 15.7% of patients had at least one mandibular first premolar with either a divided canal or a root.²⁶⁷ The second premolars had an incidence of 7% in this study.

The data from 16 anatomical studies of the canal system that included only mandibular first premolars (Table 32) resulted in a weighted average of a single

African American group of 400 patients was 32.8%, while the incidence in the Caucasian group of 400 patients was 13.7%. A study of 1,000 full mouth radiographic surveys by Amos in 1955 also found ethnic differences between African American and Caucasian patients.²⁷³ Although the number of patients in each ethnic group was not identified, Amos reported that 16% of the Caucasian patients had bifurcated canals compared to 21.6% of the African American patients. Sert and Bayirli's study of Turkish patients found an incidence of two or more canals in 35% of the males and 44% of the females, further reinforcing the importance of ethnic differences as well as gender differences.¹⁰

VARIATIONS AND ANOMALIES

Anomalies associated with mandibular first premolars include gemination,²⁷⁴ dens evaginatus,²⁷⁵ dens invaginatus,²⁷⁶⁻²⁷⁸ two roots,²⁷⁹ three roots (see Figures 95–97) two canals in a single root,²⁸⁰⁻²⁸³ three canals with fused roots,²⁸⁰ three canals in a single root^{282,284,285} (Figure 98), three canals and two roots²⁸⁶ (Figure 99), three canals and three roots,^{264,287} three canals, and one case of aberrant root development and multiple roots in all mandibular premolars.²⁸⁸

A study of 45 X-chromosome females in Finland found more than one canal in one or more of the

Figure 98 Mandibular right first premolar exhibiting 3 canals in a single root. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular First Premolar- X-ray Database.

mandibular premolars in almost half of the 87 patients studied. Separate canals were found in 23% of the mandibular first premolars and 25% of the mandibular second premolars.²⁸⁹ The study concluded that X chromosomes have a gene or genes with a regulatory function in root development.

Mandibular Second Premolar

EXTERNAL ROOT MORPHOLOGY

The mandibular second premolar is normally a single-rooted tooth (Figures 100–104) like the mandibular

Figure 100 Buccal view of mandibular left second premolar. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular Second Premolar- Rotations & Slices.

first premolar.^{1,3,5,14–16} The root is described as flat or convex on its mesial surface, while the distal surface often (73%) has a longitudinal developmental depression.²⁵⁹ A cross section of the root is usually ovoid in shape.¹⁵ The overall average length of the mandibular second premolar is 22.5 mm with an average crown length of 8 mm and an average root length of 14.5 mm.³

ROOT NUMBER AND FORM

The mandibular second premolar is normally a single-rooted tooth. Trope et al. compared the root and root canal morphology in Caucasian and African American patients and found a 1.5% incidence of two roots in second premolar teeth in Caucasian and a 4.8% incidence in African American patients.²⁶³ These differences were not statistically significant in contrast to the differences found

Figure 103 Mandibular left second premolar with a single root and single canal; multiple lateral canals are visible on the distal aspect of the apical third of the root. between these two groups in the mandibular first premolars.

The eight anatomical studies cited found multi-rooted mandibular second premolars to be quite rare^{4,6,10,57,260,269,271,290} (Table 33). Two-rooted varieties comprised 0.3% of the 2985 teeth in the studies. Three-rooted forms were rarely found and comprised 0.1% of these teeth.

CANAL SYSTEM

The anatomical studies found a single canal in 91.1% of the 2983 mandibular second premolars^{4,6,10,36,57,167,236,260,269,271} (Table 34). When a second canal system is located, it is usually fine and branches toward the lingual surface in the middle or the apical third of the main canal. The incidence of two or more canals was 8.9%. There was a single apical foramen 91.6% of the time. Serman and Haselgren's study of full mouth radiographic series of 547 patients found that second mandibular premolars had an incidence of a divided canal or a root of 7%.²⁶⁷ Trope et al. found ethnic differences between African American and Caucasian patients.²⁶³ The incidence of mandibular second premolars with two or more canals in

Table 33 Mandibular Second Premolars

common occurrence in Asians and is usually found in mandibular premolars. Merrill reported a high incidence (4.5%) of this anomaly in Alaskan Eskimos and

Figure 111 Mandibular left second premolar with 2 roots and 3 canals. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Mandibular Second Premolar- X-ray Database.

Indians, an observation serving to illustrate Alaskan natives' ties to their Asian heritage.³⁰⁶

Mandibular First Molar

EXTERNAL ROOT MORPHOLOGY

The mandibular first molar is typically a two-rooted tooth,^{1,3,5,14-16} as shown in Figures 112–117. The mesial and the distal roots are normally widely separated with a furcation level buc-

Figure 112 Buccal view of mandibular right first molar. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Mandibular First Molar- Rotations & Slices.

Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular First Molar- X-ray Database.

cally and lingually at approximately 3 and 4 mm, respectively.³ Both roots are broader buccolingually than mesiodistally. The mesial root has concavities on both its mesial and distal surfaces and is angled slightly mesially before curving distally approximately midroot. The mesial root is slightly rotated and tapers distally from buccal to lingual. The distal root is generally more ovoid in its cross-sectional shape.³ The overall average length of the mandibular first molar is 21.5 mm with an average crown length of 7.5 mm and an average root length of 14 mm.³

ROOT NUMBER AND FORM

The mandibular first molar is typically a two-rooted form with a mesial and a distal root, as listed in Table 35.^{4,57,60,198,307-320} This form has an overall incidence of 85.2%. However, there are significant differences when comparing Asian^{60,198,307,309-312,}

Table 35 Mandibular First Molar

Number of Roots	Number of Studies Cited	Number of Teeth	Fused Roots (Grades I, II, and III)				
			One Root	Two Roots	Three Roots	Four Roots	
All studies	18*	10,044	0.03% (3)	0.2% (19)	85.2% (8555)	14.6% (1465)	0.02% (2)
Non-Asian population	10	3,263	0.09% (3)	–	96.9% (3163)	2.97% (97)	–
Asian population	10	6,781	–	0.3% (19)	79.5% (5392)	20.2% (1368)	0.03% (2)

*Curzon's study³⁸ and de Souza-Freitas' study⁴⁶ included a Asian and a non-Asian population.

^{316,318,320} with non-Asian populations.^{4,57,307,308,313–315,317,319,320} Non-Asian populations have an incidence of two roots of 96.9% while the Asian populations have an incidence of 79.5%. Therefore, three roots may occur in one of five patients from Asian populations. The 18 anatomical studies of over 10,000 teeth found that the three-rooted variety, with a bifurcated mesial or distal root or an additional supplementary root, had the next highest incidence of 14.6%. Single-rooted forms and fusion and four-rooted forms were found to be extremely rare and occurred less than 1% of the time in all population groups studied. There is a higher incidence of three roots in Asian population that includes North American Aboriginal people.^{321,322} Ten of the 18 anatomical studies, which specifically included Asian populations, showed a variation in incidence even within these population groups. The incidence of three-rooted mandibular first molars in these studies ranged from 10.1% in the Burmese³⁰⁹ to 26.8% in the Japanese.³¹² The range of this occurrence in non-Asian groups ranged from a low of 0%^{4,319} to a high of 6.0% in a Saudi Arabian population.³⁰⁸

CANAL SYSTEM

The mandibular first molar typically has two mesial canals and one distal canal, as shown by the anatomical studies of the two-rooted form in Table 36. The two-rooted forms have two canals in the mesial root 95.8% of the time.^{6,13,36,54,57,60,195,196,254,308,309,313,314,316,323,324} The mesial root canals may have a common exit foramen or can exit separately as two or more apical foramina.¹⁹² Slowey indicated that the mesio-buccal canal usually has a distinct buccal curvature at the floor of the chamber while the mesiolingual canal is straighter in the long axis to the root.¹⁹² The distal root usually has a single broad canal but a two-canal system can occur in nearly one-third of the distal roots.

The three-rooted forms had two canals in the mesial root 100% of the time in a weighted average of the three anatomical studies reported^{160,309,316} (Table 37). However, there was a single apical foramen 93.1% of the time. The distobuccal root had one canal 97.6% of the time and the distolingual or third root had a single canal 100% of the time.

Table 36 Two-rooted Mandibular First Molars

Number of Canals and Apices	Number of Studies Cited	Number of Teeth (Canal Studies)	Number of Canals			
			One Canal	Two or More Canals	One Canal at Apex	Two or More Canals at Apex
Mesial root	16	3375	4.2% (143)	95.8% (3232)		
	13	1731			46.3% (802)	53.7% (929)
Distal root	15	3304	68.3% (2256)	31.7% (1048)		
	13	1805			82.4% (1488)	17.6% (317)

Distolingual root	3	208	100% (208)	–		
	2	29			100% (29)	–

VARIATIONS AND ANOMALIES

There are numerous case reports of anomalies in the literature. The most frequent anomaly relates to additional canals in one or more of the roots. There are reports of an extra canal^{323,325–330} (Figure 118), supernumerary roots and canals^{295,331,332} (Figures 119 and 120), taurodontism^{182,206} (Figure 121), and C-shaped canals.^{58,205,327,333}

Mandibular Second Molar

EXTERNAL ROOT MORPHOLOGY

The mandibular second molar normally has two roots^{1,3,5,14–16} (Figures 122–127). The mesial and the distal roots are usually closer together or have a longer root trunk and are more frequently fused, compared to the mandibular first molar. The roots are broader buccolingually than mesiodistally. Root concavities are usually present on the mesial surfaces of both the mesial and the distal roots and the distal surface of the mesial root¹⁵ (see Figure 124). The overall average length of the mandibular second molar is

Figure 118 Mandibular right first molar with extra canal in the distal root; 2 canals are present in the mesial roots and 2 canals are present in the distal root. 20 mm with an average crown length of 7 mm and an average root length of 13 mm.³

ROOT NUMBER AND FORM

The mandibular second molar is two-rooted approximately 76% of the time according to the anatomical studies reported in Table 38.^{4,5,7,60,309,312,313,334-336}

Root fusion that becomes a single-root, conical, or “C-shape” form has an incidence of approximately 21.8%.

The incidence of a third root, usually the distolingual root, in mandibular second molars (2.2%) is not as high as in first mandibular molars (14.6), as shown by the anatomical studies cited in Table 38. Asian

Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Mandibular Second Molar- X-ray Database.

population reports a higher incidence of third root anatomy.²⁶⁵

CANAL SYSTEM

The mandibular second molar, like the mandibular first molar, typically has two mesial canals and one distal canal, as listed in Table 39.^{6,10,13,54,57,60,309,313}

The mesial root of the mandibular second molar has a higher incidence of one canal (14%) than does the mesial root of the mandibular first molar (4.2%). Mesial root canals may have a common foramen or may exit separately as two or more foramina, but the joining of the two canals is the most common form.¹⁹²

Due to the higher incidence of root fusion in the mandibular second molar, C-shaped canals are frequent. The incidence of root fusion is generally higher in studies of Asian patients,^{194,335} with Hou and Tsai reporting an incidence of 51.6% in a study of 64 patients. As would be expected, the incidence of C-shaped canals is often higher in Asian patients as well.⁸¹ Seo and Park³³⁷ reported an incidence of C-shaped canals of 32.7% in Korean patients and

Table 38 Mandibular Second Molar

Number of Roots	Number of Studies Cited	Number of Teeth	Total Incidence of Fused Roots (Grade I, II, and III) % (Number of Teeth)*	One Root (Conical)	One Root (C-shaped)	Two Roots	Three Roots	Four Roots
	9	997	21.8% (217)			76.2% (760)	2.2% (22)	–
	6 (studies reporting single conical root and C-shaped data)	674		8.3% (56)	8.5% (57)			

*In this table, data for fused teeth, C-shaped roots, and single conical roots are all considered to be a form of fusion; therefore, this column represents the sum of data reported in these categories.

Table 39 Mandibular Second Molars (Two-Rooted Teeth)

Number of Canals and Apices	Number of Studies Cited	Number of Teeth (Canal Studies)	One Canal	Two or More Canals	One Canal at Apex	Two or More Canals at Apex
Mesial root	8	1194	14% (167)	86% (1027)		
	7	778			60.3% (469)	39.7% (309)
Distal root	8	1194	85.1% (1016)	14.9% (178)		
	7	778			95% (739)	5% (39)

Gulibivala et al.³⁰⁹ reported an incidence of 22.4% in the Burmese. Manning³³⁴ reported an incidence of C-shaped canals of 12.7%, and Caucasians formed the majority of the patients in his study. The studies in the United States by Weine et al.^{336,338} and Sabala, Benenati, and Neas²¹ reported incidences of single root or C-shape of less than 10%. Ethnicity was not identified in either of these studies, but it is likely that non-Asian patients formed the majority of the patients in both studies. The data from the six anatomical studies that differentiated single conical and C-shaped roots indicate that the incidence of these two canal systems is approximately equal (8.3% and 8.5%, respectively).^{57,60,309,312,334,336}

VARIATIONS AND ANOMALIES

A variation in canal and root morphology was first termed the “C-shaped canal” by Cooke and Cox in 1979.³³⁹ This canal shape results from the fusion of the mesial and distal roots on either the buccal or the lingual root surface. Melton et al.³⁴⁰ described three categories of C-shaped canals and Haddad’s group³⁴¹ added to the initial description. Category I is described as a continuous C-shaped canal from the pulp chamber to the apex. Category II is described as a “semi-colon” where one canal was separated by dentin from the C-shaped canal. Category III C-shaped anatomy is described as having a C-shaped orifice with two or more distinct and separate canals. Although there have been reported cases of C-shaped canals in other teeth such as the maxillary lateral incisor, maxillary first molar,^{46,47,203–205} maxillary second molar,^{342,343} maxillary third molar,³⁴⁴ mandibular first premolar,^{268,345} mandibular first

Figure 128 Mandibular left second molar exhibiting fused roots; 3 canals are present; distal canal divides into two canals with separate apical foramina. Reprinted with permission from Brown P, Herbranson E. *Dental Anatomy & 3D Tooth Atlas Version 3.0*. Illinois: Quintessence, 2005: Mandibular Second Molar- X-ray Database.

molar,^{205,327,333} and the mandibular third molar,^{339,344,346} the most numerous reports are of C-shaped mandibular second molars.^{60,309,334,337–341,346–358} The incidence of C-shaped canals is reported to be highest in the mandibular second molar.^{339,359}

Other reported anomalies of mandibular second molars include supernumerary roots,^{295,360} taurodontism,^{58,182,206} fused or single roots (Figures 128 and 129),^{4,5,20,194,225,309,334,335,358,361} additional canals in one or more of the roots (Figure 130),^{5,326,362,363} and two canals (Figure 131).⁵

Figure 129 Mandibular left second molar with 1 root and 1 canal; multiple lateral canals are visible in the apical third. Reprinted with permission from Brown P, Herbranson E. Dental Anatomy & 3D Tooth Atlas Version 3.0. Illinois: Quintessence, 2005: Mandibular Second Molar- X-ray Database.

Figure 131 Mandibular right second molar with 2 roots and 2 canals; apical third of the mesial root has a significant mesial curvature on exit of the apical foramen. CHAPTER 7

MICROBIOLOGY OF ENDODONTIC DISEASE

J. CRAIG BAUMGARTNER, JOSÉ F. SIQUEIRA JR., CHRISTINE M. SEDGLEY, ANIL KISHEN

Microorganisms cause virtually all pathoses of the pulp and periapical tissues. To effectively treat endodontic infections, clinicians must recognize the cause and effect of microbial invasion of the dental pulp space and the surrounding periapical tissues. Once bacterial invasion of pulp tissues has taken place, both non-specific inflammation and specific immunologic response of the host have a profound effect on the progress of the disease. Knowledge of the microorganisms associated with endodontic disease is necessary to develop a basic understanding of the disease process and a sound rationale for effective management of patients with endodontic infections. Although the vast majority of our knowledge deals with bacteria, we are now aware of the potential for endodontic disease to be associated with fungi and viruses.¹⁻⁹ The topics of this chapter are directed toward the role of microorganisms in the pathogenesis of endodontic disease. Owing to a recently resurrected controversy over the “theory of focal infection,” an update on this issue will be presented.

Theory of Focal Infection (Revisited)

A focus of infection contains pathogenic microbes and can occur anywhere in the body. Foci of infection have been associated with tonsils, adenoids, sinuses, the oral cavity, the prostate, appendix, gallbladder, and the kidney.¹⁰ In 1890, W. D. Miller associated the presence of bacteria with pulpal and periapical disease. He described “focal infection” and recommended treating and filling root canals. The first reported claim of a cure for a disease associated with focal infection was by Hippocrates¹¹ who believed he cured a case of arthritis by tooth extraction. In 1904, F. Billings reported a series of cures of afflictions by tonsillectomies and dental extractions. He described

that cultured bacteria from septic arthritis patient could produce arthritis in rabbits.^{12,13} One of his students was E. C. Rosenow, who in 1909 described the “Theory of Focal Infection” as a localized or generalized infection caused by bacteria traveling through the bloodstream from a distant focus of infection. He also introduced the concepts of “elective localization” whereby bacteria would have affinity for specific body organs. He also described “transmutation” as the process of one species of bacteria spontaneously changing into another species.^{14,15} Transmutation was used to explain why other researchers could not reproduce his results. Numerous prominent physicians began advocating the removal of tonsils, adenoids, and teeth as a remedy for diseases caused by microbes and virulence factors from a distant focal infection.¹⁶

In 1910, a British physician, William Hunter, presented a lecture on the role of sepsis and antisepsis in medicine to the faculty of McGill University. He condemned the practice of dentistry in the United States, which emphasized restorations instead of tooth extraction. Hunter stated that the restorations were “a veritable mausoleum of gold over a mass of sepsis.” He believed that this was the cause of Americans’ many illnesses, including pale complexion, chronic dyspepsias, intestinal disorders, anemias, and nervous complaints.¹⁷ This led to an “orgy of extractions” and the recommendation of extraction for all endodontically treated teeth by the “100 percenters.”¹⁸ Many of the studies were “reverse investigation” which start with a conclusion and gather information to support it.

Weston Price began a 25-year study of pulpless and endodontically treated teeth and their association with focal infection. He published a series of rabbit experiments and case reports purporting remarkable improvement after dental extraction of non-vital teeth (teeth with non-vital pulps).^{19,20} During that time

frame, the dental literature contained numerous testimonials reporting cures of illnesses following tooth extraction. These reports were empirical and without adequate follow-up. However, they wrongfully supported the continued extraction of teeth without scientific reason. In many cases, diseases reoccurred, and the patients had to face the additional difficulty of living with mutilated dentitions. In the 1920s, the theory of focal infection was widely accepted and endodontic education was virtually eliminated from dental education. In the 1930s, reports began to be published critical of the theory of focal infection. Cecil and Angevine²¹ reported on 200 cases of rheumatoid arthritis, which showed no benefit from tonsillectomy or dental extractions. In 1940, a critical publication by Reimann²² raised several issues related to the theory of focal infection. They included (1) the theory of focal infection was not proved; (2) the infectious agents were unknown; (3) large groups of people with tonsils were no worse than those that had their tonsils removed; (4) patients having their teeth or tonsils removed were no better off after surgery; (5) beneficial effects could seldom be associated with the surgery; (6) harmful effects of the surgery often outweighed and benefit of surgery; (7) foci of infection often heal after recovery from a systemic disease or improved hygiene and dietary measures.

In the 1930s and 1940s, editorials and research refuted the theory of focal infection and called for a return to constructive rather than destructive dental treatment.^{18,23} The studies by Rosenow and Price were flawed by inadequate controls, the use of massive doses of bacteria, and bacterial contamination of endodontically treated teeth during tooth extraction. In 1939, Fish²⁴ recognized four zones of reaction formed in response to bacteria implanted in the jaws of guinea pigs. He described the bacteria as being confined by polymorphonuclear neutrophil leukocytes to a zone of infection. Outside the zone of infection is the zone of contamination containing inflammatory cells, but no bacteria. Next, the zone of irritation contained histocytes and osteoclasts. On the outside was a zone of stimulation with mostly fibroblasts, capillary buds, and osteoblasts. Fish²⁴ theorized that removal of the nidus of infection would lead to resolution of the infection. This theory became the basis for successful root canal treatment.

Today, the medical and dental professions agree that there is no relationship between endodontically treated teeth and the degenerative diseases implicated in the theory of focal infection. However, recent publications have resurrected the focal infection theory based on the poorly designed and outdated studies by

Rosenow and Price.^{25,26} This body of research has been evaluated and disproved. Unfortunately, uninformed patients may receive this outdated information and believe it to be credible new findings.

Endodontic infections may be associated with metastatic infections by direct extension of the infection, via microbes carried through the blood (bacteremia), and by the release of bacterial products and inflammatory mediators. The direct extension of a periapical abscess may reach the maxillary sinuses, cavernous sinus, orbit, brain, or via parapharyngeal pathways produce Ludwig's angina.

Both non-surgical root canal instrumentation and endodontic surgery may produce bacteremia.²⁷⁻³² One study found that if the endodontic instrument was confined to inside the root canal 1 mm short of the apical foramen, the incidence of bacteremia was 4 in 13 (31%). If the instruments (sizes 15, 20, and 25) were deliberately used to a level 2 mm beyond the apical foramen, the incidence of bacteremia was 7 in 13 (54%). Ribotyping with restriction enzymes showed identical characteristics for the clinical isolates from the root canals and for the bacteria isolated from the blood. This typing method shows that the microorganisms recovered from the bloodstream during and after endodontic treatment had the root canal as their source.

Another study using both cultivation and the polymerase chain reaction (PCR) detected bacteremia in 9/30 (30%) patients undergoing non-surgical endodontic treatment.³² Anaerobic bacteria were the predominant microbe detected in blood samples taken during endodontic treatment. In clinical practice, it is impossible to know that endodontic instruments are always confined to the canal system. In addition, infected canal debris may be extruded beyond the apical foramen. However, non-surgical endodontics is less likely to produce bacteremia than tooth extraction or surgical endodontics.^{28,29} Simple tooth extraction produces an extensive bacteremia 100% of the time.^{27,28} Endodontic therapy should be the treatment of choice instead of tooth extraction for patients believed to be susceptible to infective endocarditis following a bacteremia.

In a study of 20,747 positive blood cultures, 2.8% were viridens group streptococci and 4.4% were obligate anaerobes.³³ These data suggest that oral microbes are only a small percentage of the bacteria detected in blood cultures. It is also known that bacteremias from tooth brushing, flossing, and mastication produce daily bacteremias approaching that of various dental treatments.³⁴ There is no data on the necessary inoculum size to initiate a metastatic (focal) infection and little on

the magnitude [colony-forming units (CFUs)] of a bacteremia produced by various dental procedures.³⁴ Currently, the most documented examples of focal infection are bacterial endocarditis, brain abscess, and prosthetic joint infections.¹⁰ The actual risk to patients from dental treatment induced bacteremia appears to be very less.³⁵ The approximate risk for acquiring bacterial endocarditis from a single dental treatment ranges from 1/95,058 for a patient with previous endocarditis to 1/1,096,824 for a patient with mitral valve prolapse with regurgitation.³⁴ Considering a 16/1,000,000 mortality rate from penicillin anaphylaxis, penicillin prophylaxis might result in a net loss of life.³⁴ In addition, there is no clear mechanism of how antibiotic prophylaxis reduces bacteremias.³⁶ Penicillin and cephalosporin require actively dividing bacteria to be effective, and bacteriostatic antibiotics take hours to produce their effects by affecting protein synthesis. In fact, it has been shown that prophylactic antibiotics do not significantly reduce the incidence of bacteremias.^{37,38} It has been proposed that antibiotic prophylaxis may prevent adherence of bacteria to valvular vegetation or eliminate the bacteria once they have attached.^{39,40} Guidelines for the use of prophylactic antibiotics are found in Chapter 24.

It is believed that cardiovascular disease begins with the formation of an atheroma in response to an injury. Microorganisms may be deposited in the area and produce proinflammatory cytokines.⁴¹ However, cardiovascular disease has many risk factors that control the progress of the atheromas and thrombogenesis.⁴¹ Risk factors include coronary lipid profile, hypertension, diabetes mellitus, obesity, sex, age, socioeconomic factors, lifestyle stress, homocysteine levels, smoking, and genetics. Epidemiologic studies have found relationships between periodontal disease and coronary heart disease, strokes, and preterm low birth rate.^{42,43} More recent studies have shown only a very limited association between periodontal disease and cardiovascular disease.⁴⁴⁻⁴⁹ It must be kept in mind that epidemiologic research can identify relationships, but not causation.

In a health professionals' follow-up study using root canal therapy as a surrogate for pulpal inflammation, an association was found between dentists with root canal therapy and coronary heart disease.⁴⁹ Interestingly, there was no association among non-dentists in the study. Another longitudinal study evaluated whether patients with radiographic lesions of endodontic origin were more likely to develop coronary heart disease.⁵⁰ Among those patients less than 40 years old, periapical lesions of endodontic origin

were associated with future diagnosis of coronary heart disease.

Further research may show that endodontic or periodontal disease constitutes an oral component of a systemic disorder or has etiologic features in common with medical diseases. They may occur without necessarily indicating a cause-effect relationship. To demonstrate cause and effect, interventional studies must be undertaken that show that elimination of a variable alters the incidence or course of the disease. More research is needed to determine the impact that endodontic disease may have on overall health of our patients.

Endodontic infections can spread to other tissues. An abscess or cellulitis may develop if bacteria invade periapical tissues, and the patient's immune system is not able to stop the spread of bacteria and bacterial by-products. This type of infection/inflammation spreads directly from one anatomic space to an adjacent space. This is not an example of the theory of focal infection, whereby bacteria travel through the circulatory system and establish an infection at a distant site.

Successfully completed root canal therapy should not be confused with an untreated infected root canal system or a tooth with a periapical abscess that may be a source of a bacteremia. Bacteremias occur every day as a result of a patient's normal daily activities. To show a causal relationship between an oral infection and systemic disease, it is not adequate to show only a potential relationship via a bacteremia. Hard evidence is needed to show that the organism in the no-oral site of infection actually came from the oral cavity. If possible, Koch's postulates should be fulfilled to establish a causal role of the microorganism from the oral cavity. Endodontics has survived the theory of focal infection because of recognition by the scientific community that successful root canal treatment is possible without endangering systemic health.

Endodontic Infections

Colonization is the establishment of microbes in a host if appropriate biochemical and physical conditions are available for growth. Normal oral microbiota is the result of a permanent microbial colonization in a symbiotic relationship with the host. Although the microbes in the normal oral microbiota participate in many beneficial relationships, they are opportunistic pathogens if they gain access to a normally sterile area of the body such as the dental pulp or periapical tissues and produce disease. An infectious disease

(infection) is the result of invasion of the tissues by microbes and the reaction of the tissues to their presence which produces clinical signs and symptoms. Pulpal and periapical pathoses (diseases) result from opportunistic pathogens infecting the pulp and periapical tissues. The steps in the development of an endodontic infection include microbial invasion, multiplication, and pathogenic activity. Much of the pathogenic activity is associated with host response.

Pathogenicity is a term used to describe the capacity of a microbe to produce disease, whereas virulence describes the degree of pathogenicity. Bacteria have a number of virulence factors that may be associated with disease. They include pili (fimbriae), capsules, extracellular vesicles, lipopolysaccharides (LPS), enzymes, short-chain fatty acids, polyamines, and low molecular weight products such as ammonia and hydrogen sulfide. Pili may be important for attachment to surfaces and interaction with other bacteria in a polymicrobial infection. Bacteria including gram-negative dark-pigmented bacteria may have capsules that enable them to avoid or survive phagocytosis.⁵¹

Association of Microbes with Endodontic Disease

Antony van Leewenhoek,⁵² the inventor of single-lens microscopes, was the first to observe oral microbiota. His description of the “animalcules” observed with his microscopes included those from dental plaque and from an exposed pulp cavity. W. D. Miller is considered to be the father of oral microbiology. In 1890, he authored a book, *Microorganisms of the Human Mouth*, which became the basis for dental microbiology in this country. In 1894, Miller⁵³ became the first researcher to associate the presence of bacteria with pulpal disease.

The true significance of bacteria in endodontic disease was shown in the classic study by Kakehashi et al.⁵⁴ in 1965. They found that no pathologic changes occurred in the exposed pulps or periapical tissues in germ-free rats (Figure 1A). In conventional animals, however, pulp exposures led to pulpal necrosis and periapical lesion formation (see Figure 1B). In contrast, the germ-free rats were healed with dentinal

Figure 1 Role of bacteria in dentin repair following pulp exposure. **A**, Germ-free specimen obtained 100 days after pulp exposure. Normal pulp tissue can be observed beneath the dentin bridge (arrow). **B**, Exposure of pulp in control rat with normal oral flora produced pulp necrosis and Abscess formation (arrow). **A**, Reproduced with permission from Kakehashi S, Stanley HR, Fitzgerald RJ. *Oral surg* 1965; **20**: 340. **B**, reproduced with permission from Clark JW, Stanley HR, Fitzgerald RJ. *Clinical Dentistry*. Figure 2 Coccal forms of bacteria (arrow) seen in cross-section of a fractured dentinal tubule ($\times 5000$ original magnification). Courtesy C. Baumgartner.

bridging regardless of the severity of the pulpal exposure.⁵⁴ Thus, the presence or absence of a microbiota was the major determinant for the destruction or healing of exposed rodent pulps.

Invasion of the pulp cavity by bacteria is most often associated with dental caries. Bacteria invade and multiply within the dentinal tubules (Figure 2). Dentinal tubules range in size from 1 to 4 μm in diameter, whereas the majority of bacteria are less than 1 μm in diameter. If enamel or cementum is missing, microbes may invade the pulp through the exposed tubules. A tooth with a vital pulp is resistant to microbial invasion. Movement of bacteria in dentinal tubules is restricted by viable odontoblastic processes, mineralized crystals, and various macromolecules within the tubules. Caries remains the most common portal of entry for bacteria and bacterial by-products into the pulpal space. However, bacteria and their by-products have been shown to have a direct effect on the dental pulp even without direct exposure.^{55,56} These studies demonstrated inflammatory reactions adjacent to the exposed dentinal tubules. Although the inflammatory reactions could result in pulpal necrosis, the majority of pulps were able to undergo healing and repair.⁵⁵⁻⁵⁸

Following trauma and direct exposure of the pulp, inflammation, necrosis, and bacterial penetration are no more than 2 mm into the pulp after 2 weeks.⁵⁷ In contrast, a necrotic pulp is rapidly invaded and colonized. Peritubular dentin and reparative dentin may impede the progress of the microorganisms. However, the “dead tracts” of empty dentinal tubules following dissolution of

the odontoblastic processes may leave virtual high-ways for the microbes’ passage to the pulp cavity. Microbes may reach the pulp via direct exposure of the pulp from restorative procedures or trauma injury and from pathways associated with anomalous tooth development. It is believed that the egress of irritants from an infected root canal system through tubules, lateral or accessory canals, furcation canals, and the apical foramina may directly affect the surrounding attachment apparatus. However, it is debatable whether periodontal disease directly causes pulpal disease.⁵⁹⁻⁶² The presence of pulpitis and bacterial penetration into exposed dentinal tubules following root planing in humans has been demonstrated.⁶³ Langeland et al.⁶⁰ found that changes in the pulp did occur when periodontal disease was present, but pulpal necrosis occurred only if the apical foramen was involved. Kobayashi et al.⁶⁴ compared the bacteria in root canals to those in periodontal pockets. The authors believe that bacteria concurrent in both areas suggest that the sulcus or periodontal pocket is the source of the bacteria in root canal infections. To differentiate an abscess of periodontal origin from that of endodontic origin, the enumeration of spirochetes has been recommended.⁶⁵ Abscesses of periodontal origin contained 30% to 58% spirochetes, whereas those of endodontic origin were 0% to 10% spirochetes.

Anachoresis is a process by which microbes may be transported in the blood or lymph to an area of inflammation such as a tooth with pulpitis, where they may establish an infection. The phenomenon of anachoresis has been demonstrated in animal models, both non-dental inflamed tissues and inflamed dental pulps.⁶⁶⁻⁶⁸ However, the localization of blood-borne bacteria in instrumented but unfilled canals could not be demonstrated in an animal model.^{69,70} Infection of unfilled canals was possible only with over-instrumentation when bacteremia occurs to allow bleeding into the canals.⁷⁰ Anachoresis may be the mechanism through which traumatized teeth with intact crowns become infected.⁷¹ The process of anachoresis has been especially associated with bacteremias and infective endocarditis.

Once the dental pulp becomes necrotic, the root canal system becomes a “privileged sanctuary” for clusters of bacteria, bacterial by-products, and degradation products of both the microorganisms and the pulpal tissue.⁷²⁻⁷⁴

Polymicrobial interactions and nutritional requirements make the cultivation and identification of all organisms from endodontic infections very difficult.

Prior to 1970, very few strains of strict anaerobes were isolated and identified because of inadequate anaerobic culturing methods. The importance of anaerobic bacteria in pulpal and periapical pathoses has been revealed with the development of anaerobic culturing methods and the use of both selective and non-selective culture media. However, even with the most sophisticated culturing methods, there are still many microorganisms that remain uncultivable. The bacteria in an infected root canal system are a restricted group compared to the oral microbiota.

Most of the bacteria in an endodontic infection are strict anaerobes. These bacteria grow only in the absence of oxygen but vary in their sensitivity to oxygen. They function at low oxidation-reduction potentials and generally lack the enzymes superoxide dismutase and catalase. Microaerophilic bacteria can grow in an environment with oxygen but predominantly derive their energy from anaerobic energy pathways. Facultative anaerobes grow in the presence or absence of oxygen and usually have the enzymes superoxide dismutase and catalase. Obligate aerobes require oxygen for growth and possess both superoxide dismutase and catalase.

Most species in endodontic infections have also been isolated from periodontal infections, but the root canal microbiota is not complex.⁶⁴ Using modern cultivation techniques, five or more species of bacteria are usually isolated from root canals with contiguous apical rarefactions. The number of CFUs in an infected root canal is usually between 10^2 and 10^8 . A positive correlation exists between an increase in size of the periapical radiolucency and both the number of bacteria species and CFUs present in the root canal.^{75,76}

The dynamics of bacteria in infected root canals have been studied in monkeys.^{72,77,78} After infecting the monkey root canals with indigenous oral bacteria, the canals were sealed and then sampled for up to 3 years. Initially, facultative bacteria predominated; however, with increasing time, the facultative bacteria were displaced by anaerobic bacteria.^{72,77,78} The results indicate that a selective process takes place that allows anaerobic bacteria an increased capability of surviving and multiplying. After almost 3 years (1,080 days), 98% of the cultivable bacteria were strict anaerobes.

The root canal system is a selective habitat that allows the growth of certain species of bacteria in preference to others. Tissue fluid and the breakdown products of necrotic pulp provide nutrients rich with polypeptides and amino acids. These nutrients, low

oxygen tension, and bacterial by-products determine which bacteria will predominate.

Antagonistic relationships between bacteria may occur. Some metabolites (eg., ammonia) may be either a nutrient or a toxin, depending on the concentration. In addition, bacteria may produce bacteriocins, which are antibiotic-like proteins produced by one species of bacteria to inhibit another species of bacteria. When Sundqvist et al.⁷⁹ cultured intact root canals, 91% of the organisms were strict anaerobes. When Baumgartner et al.⁸⁰ cultured the apical 5 mm of root canals exposed by caries, 67% were found to be strict anaerobes. A polymicrobial ecosystem seems to be produced that selects for anaerobic bacteria over time. Gomes et al.^{81,82} and Sundqvist^{74,83} used odds ratios to show that some bacteria tend to be associated in endodontic infections. This suggests a symbiotic relationship that may lead to an increase in virulence by the organisms in that ecosystem. Clinicians may consider chemomechanical cleaning and shaping of the root canal system as total disruption of that microbial ecosystem.

Although no absolute correlation has been made between any species of bacteria and severity of endodontic infections, several species have been implicated with some clinical signs and symptoms. Those species include dark-pigmented bacteria, *Peptostreptococcus*, *Eubacterium*, *Fusobacterium*, and *Actinomyces*.^{76,79,82,84-95} Table 1 summarizes the percentage of incidence of bacteria isolated from intact root canals from five combined studies.^{76,79,96-98} Table 2 summarizes the taxonomic changes that have taken place with the bacteria formerly in the genus *Bacteroides*.

Dark (black)-pigmented bacteria have been associated with clinical signs and symptoms in several studies.^{76,79,84,86-88,90,92,94} Unfortunately, taxonomic revision based on deoxyribonucleic acid (DNA) studies has made the interpretation of previous research results based on conventional identification of the bacteria at the very least confusing and in many cases impossible. Conventional identification of microbes based on Gram stain, colonial morphology, growth characteristics, and biochemical tests is often inconclusive and yield presumptive identifications. Dark-pigmented bacteria range from being tan to black colonies depending on the media and environment of incubation in the laboratory. Previously, *Prevotella intermedia* was the species of dark-pigmented bacteria most commonly isolated from endodontic infections. In 1992, isolates previously thought to be *P. intermedia* were shown to be a closely related species now

were determined to be *Prevotella tanneriae* using the PCR.¹⁰³

Several studies of endodontically treated teeth requiring re-treatment have shown a prevalence of facultative bacteria, especially *Enterococcus faecalis*, instead of strict anaerobes.^{104–108} Studies using molecular methods have detected numerous other species in root canals that have failed to heal.^{109–111} In addition, fungi have been shown to be associated with failed root canal treatment.^{7,112} Infection at the time of refilling and the size of the periapical lesion were factors that had a negative influence on the prognosis for re-treatment.¹⁰⁸

Microbiological Diagnostic Techniques

Interest in endodontic microbiology has boomed after the recognition that apical periodontitis lesions are inflammatory diseases caused by microorganisms. The growing interest in this area has become even more pronounced after the recent introduction of and further fast paced advances in methods based

on detection and analysis of microbial nucleic acids. Traditionally, microorganisms involved with endodontic infections have been studied by means of culture-dependent techniques, which have been demonstrated to have several limitations when it comes to microbiological diagnosis.¹¹³ Findings from culture-dependent methods with regard to the microbiota living in diverse ecosystems have been supplemented and significantly expanded with molecular biology techniques, and the impact of these methods on the knowledge of the endodontic microbiota in diverse clinical conditions has been astonishing.¹¹¹

Several methodologies have been used or have the potential to be used for the study of endodontic infections. No single method can provide all the information, and the choice for a given method is indeed based on the answers the researcher or clinician is looking for. As a matter of fact, data obtained from different methods should be compiled, interpreted, and collated so that evidence can be mounted. In this regard, it is important for students, clinicians, and researchers to understand the principles behind the methodologies currently in use as well as their advantages and limitations, so that the impact of the information brought about by different methods can be properly weighed. To shed some light on these aspects, the following discussion highlights the main methods currently in use for endodontic microbiology research.

Culture

Traditionally, microbial culture has been the preferred means for examination of the endodontic microbiota. Culture is the process of propagating microorganisms

in the laboratory by providing them with proper environmental conditions. Ingredients necessary for microbial pathogens can be supplied by living systems (eg., growth in an animal host or in cell culture) or artificial systems (by gathering the required conditions for growth). Artificial systems have been widely used for microbiological diagnosis of most bacterial and fungal infections that afflict humans. In order for microorganisms to multiply on/in artificial media, they must have available the required nutrients and proper physicochemical conditions, including temperature, moisture, atmosphere, salt concentration, ionic strength of the medium, and pH.¹¹⁴

In microbial culture, samples are collected and transported to the laboratory in a viability preserving, non-supportive, and anaerobic medium. They are then dispersed by sonication or by vortex mixing, distributed onto various types of agar media, and cultured under aerobic or anaerobic conditions. After a suitable period of incubation, individual colonies are subcultured and identified on the basis of multiple aspects including colony and cellular morphology, Gram-staining pattern, oxygen tolerance, comprehensive biochemical characterization, and metabolic end-product analysis by gas-liquid chromatography. The outer cellular membrane protein profile as examined by gel electrophoresis, fluorescence under ultraviolet light, and susceptibility tests to selected antibiotics can also be of great value for the identification of some species. Marketed packaged kits that test for preformed enzymes have been used for rapid identification of some species, but they can show a relatively low accuracy for identification of many anaerobes, requiring further testing.¹¹⁵

Advantages and limitations of culture-dependent methods are summarized in Table 3. The difficulties in

Table 3 Advantages and Limitations of Culture Methods

Culture Techniques	
Advantages	Limitations
<ol style="list-style-type: none"> 1. Broad-range nature, identification of unexpected species 2. Allow quantification of all major viable microorganisms in the samples 3. Allow determination of antimicrobial susceptibilities of the isolates 4. Physiological studies are possible 5. Pathogenicity studies are possible 6. Widely available 	<ol style="list-style-type: none"> 1. Impossibility of culturing a large number of extant bacterial species 2. Not all viable bacteria can be recovered 3. Once isolated, bacteria require identification using a number of techniques 4. Misidentification of strains with ambiguous phenotypic behavior 5. Low sensitivity 6. Strict dependence on the mode of sample transport 7. Samples require immediate processing 8. Costly, time-consuming, and laborious 9. Specificity is dependent on the experience of the microbiologist 10. Extensive expertise and specialized equipment needed to isolate strict anaerobes 11. Take several days to weeks to identify most anaerobic bacteria

culturing or in identification are of great importance and deserve additional discussion.

DIFFICULTIES IN CULTURING: THE HUGE AS-YET-UNCULTIVATED MAJORITY

Not all microorganisms can grow and be maintained under artificial conditions in the laboratory. In fact, there are several instances of microbial ecosystems that were thought to be well characterized by culture-dependent approaches, but which proved to be far different when assessed by culture-independent molecular biology techniques.¹¹⁶ Investigations of many aquatic and terrestrial environments using culture-independent methods have revealed that the cultivable members of these systems represent less than 1% of the total extant population.^{117,118} Novel culture-independent methods for microbial identification that involve amplification of the 16S *rRNA* gene followed by cloning and sequencing (discussed in “PCR and Its Derivatives”) have recently been used to determine the bacterial diversity within different environments, including human diseased and healthy sites.^{119–129} Perhaps not surprisingly, the number of recognized bacterial phyla has expanded from the original estimate of 11 in 1987 to 36 in 1998.¹³⁰ The latest tally of bacterial phyla is now probably near 53, of which one-half are as-yet-uncultivated representatives.^{131,132} Taking into consideration that known bacterial pathogens fall within 7 out of the 53 candidate bacterial phyla and that culture-independent approaches have shown that 50% to 80% of the human microbiota in different sites are composed of as-yet-uncultivated bacteria,^{120,121,124,128,133} it is fair to realize that there can be many human pathogens which remain to be identified.

There are many possible reasons for bacterial “unculturability.” They include (1) lack of essential nutrients or growth factors in the artificial culture medium; (2) overfeeding conditions; (3) toxicity of the culture medium itself, which can inhibit bacterial growth; (4) production of substances inhibitory to the target microorganism by other species present in a mixed consortium; (5) metabolic dependence on other species for growth; and (6) disruption of bacterial intercommunication systems induced by separation of bacteria on solid culture media.^{134,135} In addition, under certain stressful environmental conditions, such as starvation, some bacterial cells can be in a state of low metabolic activity and be unable to divide or form colonies onto agar plates without a preceding resuscitation phase. This state is referred to as bacterial dormancy or “viable but non-cultivable” state.¹³⁶

Obviously, if microorganisms cannot be cultured, they cannot be identified by phenotype-based methods. While we stay relatively ignorant on the requirements of many bacteria to grow, identification methods that are not based on bacterial culturability are required. This would avoid that many pathogens pass unnoticed when one is microbiologically surveying clinical samples.

It is worth pointing out the fact that a given species is hitherto uncultivated does not necessarily imply that this species is impossible to cultivate. A myriad of strict anaerobic bacteria were uncultivated a hundred years ago, but further developments in culturing techniques have to a large extent helped solve this problem. For instance, the huge majority of anaerobic bacteria isolated from infected root canals were unnoticed in microbiologic analysis of endodontic infections before the 1970s. There is a growing trend to develop approaches and culture media that allow cultivation of as-yet-uncultivated bacteria,^{137,138} allowing a better understanding of their role in nature.

DIFFICULTIES IN IDENTIFICATION: KNOWN SPECIES WITH UNCOMMON PHENOTYPES

Culture-dependent identification is based on phenotypic traits. The fact that the phenotype is inherently mutable and subject to biases of interpretation can lead culturing procedures to misidentification.¹³⁹ Interpretation of results from culturing methods is based on characteristics observed in reference strains, with predictable biochemical and physical properties under optimal growth conditions. Phenotypic characteristics are not static and can change under some conditions, including stress.¹⁴⁰ Thus, when common microorganisms with uncommon phenotypes are present, reliance on phenotypic traits can compromise accurate identification. Technologist bias or inexperience with an unusual phenotype or isolate may also compromise identification when results of biochemical tests are interpreted to fit expectations. Thus, one should be mindful that in some circumstances even the successful culturing of a given microorganism does not necessarily mean that this microorganism can be successfully identified.

Molecular biology technology has emerged as a more effective, accurate, and reliable means for the identification of bacteria that are difficult to identify by conventional techniques.^{139,141,142} The 16S *rRNA* gene sequencing approach was first proposed to identify uncultivated bacteria without the need for

cultivation, but it has also been widely used for identification of cultivable bacteria that shows uncommon phenotypic behavior and cannot be accurately identified by culture-dependent approaches.^{142–144}

In the light of the discussion above, it may appear that the reputation of culture-dependent methods is somewhat tarnished. In addition to its historic importance and undeniable contribution to the knowledge of endodontic infections and not withstanding its numerous shortcomings, culture still has a place in studies of endodontic microbiology, particularly for the identification of microorganisms in unusual clinical conditions, after antimicrobial treatment and in situations where pure cultures are needed for additional analysis, including antibiotic susceptibility and pathogenicity tests.

Microscopy

Direct microscopic examination represents a quick, easy, and inexpensive means of screening microbial samples for major morphotypes and staining patterns. Nevertheless, microscopic findings regarding bacterial morphology may be misleading, because many species can be pleomorphic and conclusions can be influenced by subjective interpretation of the investigator. In addition, microscopy has limited sensitivity and specificity to detect microorganisms in clinical samples. Limited sensitivity is because a relatively large number of microbial cells are required before they are seen under microscopy (eg., 10^4 bacterial cells/mL of fluid).¹⁴⁵ Some microorganisms can even require appropriate stains and/or approaches to become visible. Limited specificity is because species cannot be distinguished.

Immunological Methods

Immunological methods employ antibodies that recognize specific microbial antigens to directly detect target species. Antibodies targeting host immunoglobulins specific to a target species can also be used for indirect detection assays. The reaction can be visualized using a variety of techniques and reactions, including direct and indirect immunofluorescence, flow cytometry, and enzyme-linked immunosorbent assay.¹⁴⁶ These methods may require the use of monoclonal antibodies to assure high specificity. Sensitivity is not significantly higher when compared to culture-dependent approaches.

Table 4 Advantages and Limitations of Immunological Methods

Immunological Techniques	
Advantages	Limitations
1. Rapid—no more than a few hours to identify a microbial species	1. Detect only the target species
2. Easily standardized	2. Low sensitivity
3. Low cost	3. Specificity is variable and depends on the type of antibodies used
4. Detect dead microorganisms	4. Detect dead microorganisms

Advantages and limitations of immunological methods are summarized in Table 4.

Molecular Biology Methods

The development of molecular biology techniques to investigate ecological microbial communities has provided a vast array of new techniques for study of the human microbiota in health and disease. In this regard, a significant contribution of molecular biology methods relates to the identification of previously unknown and uncharacterized human pathogens.^{147–151} Moreover, molecular studies have revealed a previously unanticipated diversity of the human microbiota, with as-yet-uncultivated bacteria corresponding to more than 50% of the taxa found in the microbiota associated with diverse oral sites,^{123,124,152} stomach,¹³³ skin,¹⁵³ and vaginosis.¹⁵⁴ About 80% of the taxa present in the intestinal microbiota remain to be cultivated and characterized.^{120,128} As a consequence, it is fair to assume that there can exist a number of as-yet-unknown pathogens in the uncultivated segment of the human microbiota.

Several genes have been chosen as targets for bacterial identification. Some of these genes are shared by a vast majority, if not all, of bacterial species. Genes proposed for bacterial identification include the *16S rRNA* and *23S rRNA* genes, the *16S-23S rRNA* gene internal transcribed sequences, the *rpoB* gene encoding the β -subunit of RNA polymerase, the *groEL* gene encoding the heat-shock protein, the *gyrB* gene encoding the β -subunit of DNA gyrase, and homologous recombination-encoding *recA*.¹⁵⁵ Of these, the *16S rRNA* gene (or *16S rDNA*) has been the most widely used target because it is universally distributed among bacteria, is long enough to be highly

informative and short enough to be easily sequenced, possesses conserved and variable regions, and affords reliability for inferring phylogenetic relationships.¹⁵⁶ Similarly, the *18S rRNA* gene of fungi and other eukaryotes have also been extensively used for identification of these organisms.

There are a plethora of molecular methods for the study of microorganisms, and the choice of a particular approach depends on the questions being addressed. Broad-range PCR followed by cloning and sequencing can be used to unravel the breadth of microbial diversity in a given environment. Microbial community structures can be analyzed via fingerprinting techniques, such as denaturing gradient gel electrophoresis (DGGE) and terminal restriction fragment length polymorphism (T-RFLP). Fluorescence in situ hybridization (FISH) can measure abundance of target species and provide information on their spatial distribution in tissues. Among other applications, DNA-DNA hybridization arrays, species-specific PCR, nested PCR, multiplex PCR, and quantitative real-time PCR can be used to survey large numbers of clinical samples for the presence of target species. Variations in PCR technology can also be used to type microbial strains. The following section will focus on the most commonly used approaches applied in the research of the endodontic microbiota.

PCR AND ITS DERIVATIVES

The PCR method is based on the *in vitro* replication of DNA through repetitive cycles of denaturation, primer annealing, and extension steps carried out in automated devices called thermocyclers. The target DNA serving as template denatures at high temperatures generating single strands of DNA. The temperature then decreases so that two short oligonucleotide primers can anneal to their complementary sequences on opposite strands of the target DNA. Primers are selected to encompass the desired genetic material, flanking the ends of the stretch of DNA to be copied. In sequence, a complementary second strand of new DNA is synthesized through the extension of each annealed primer by a thermostable DNA polymerase in the presence of excess deoxyribonucleoside triphosphates. All previously synthesized products act as templates for new primer-extension reactions in each ensuing cycle. The result is an exponential amplification of the DNA fragment flanked by the primers, which confers extraordinary sensitivity in detecting the target DNA.

PCR has unrivaled sensitivity (the lowest number of cells detected in a sample). While PCR can detect as few as 10 bacterial cells in a sample (with potential sensitivity to the one-cell level), other methods of identification show too higher detection limits. Culture using non-selective media can detect 10^4 to 10^5 cells in a sample, and when selective media are used, the sensitivity of culture method increases to 10^3 cells.¹⁵⁷ Immunological methods have a detection limit ranging from 10^3 to 10^4 cells. DNA-DNA hybridization assays can detect 10^2 to 10^4 cells in a sample. Thus, PCR methodology is at least 10 to 100 times more sensitive than the other more sensitive identification method.¹⁵⁸

Numerous derivatives of the conventional PCR technology have been developed since its inception. The most used PCR-derived assays are described below.

Touchdown PCR

Touchdown PCR is a strategy to increase the specificity of the assay. The annealing temperature in the initial PCR cycle is set several degrees above the T_m of the primers. In subsequent cycles, the annealing temperature is decreased in steps of 0.5 to 2 °C per cycle until a temperature is reached that is equal to, or 2 to 5 °C below, the T_m of the primers. Touchdown techniques have been considered useful to avoid the amplification of spurious DNA fragments (non-target gene fragments and/or fragments with improper sizes).¹⁵⁹

Nested PCR

Nested PCR consists of two rounds of amplification using different sets of primers in each round. A target region of DNA is amplified with an outer primer pair in an initial reaction, followed by a second amplification using an internal primer pair. This approach has been devised mainly to have increased sensitivity,¹⁶⁰ but can also exhibit increased specificity.¹⁵⁸

Multiplex PCR

In multiplex PCR, two or more sets of primers specific for different targets are concomitantly used in the same reaction.¹⁶¹ Thus, contrary to conventional PCR approaches, which can detect only one target at a time, multiplex PCR assays permit the simultaneous detection of different species in a sample.

Reverse Transcriptase PCR

Reverse transcriptase PCR (RT-PCR) was developed to amplify RNA targets and to exploit the use of the

enzyme reverse transcriptase, which can synthesize a strand of complementary DNA (cDNA) from an RNA template. Most RT-PCR assays employ a two-step approach. In the first step, reverse transcriptase converts RNA into single-stranded cDNA. In the second step, PCR primers, DNA polymerase, and nucleotides are added to create the second strand of cDNA. Once the double-stranded DNA template is formed, it can be used as template for amplification as in conventional PCR.¹⁶² The RT-PCR process may be modified into a one-step approach by using it directly with RNA as the template. In this approach, an enzyme with both reverse transcriptase and DNA polymerase activities is used, such as that from the bacteria *Thermus thermophilus* (*Tth*).

PCR-Based Microbial Typing

PCR technology can be used for clonal analysis and comparison of microbial isolates through PCR-generated fingerprinting profiles. Examples of PCR techniques used for this purpose include the arbitrarily primed PCR (AP-PCR, also referred to as random amplified polymorphic DNA, or RAPD),^{163,164} which uses a single random-sequence primer at low stringency, and other assays using primers that target known genetic elements, such as enterobacterial repetitive intergenic consensus sequences (ERIC-PCR)^{165,166} and repetitive extragenic palindromic sequences (REP-PCR).¹⁶⁷

Real-Time PCR

PCR assays are usually qualitative or can be adjusted to be semi-quantitative. One exception is the real-time PCR, which allows the quantification of the amount of DNA in the sample by monitoring the release of fluorescence with each amplification cycle. Accumulation of PCR products is measured automatically during each cycle in a closed tube format using a thermocycler combined with a fluorimeter. Real-time PCR assays allow the quantification of individual target species as well as total bacteria in clinical samples. The advantages of real-time PCR are the rapidity of the assay (30 to 40 minutes), the ability to quantify and identify PCR products directly without the use of agarose gels, and the fact that contamination can be limited due to avoidance of postamplification manipulation.¹⁶⁸ There are several different real-time PCR approaches, but the most commonly used chemistries include SYBR-Green,¹⁶⁹ *TaqMan*,¹⁷⁰ and molecular beacons.¹⁷¹

Broad-Range PCR

PCR technology can be used to investigate the breadth of microbial diversity in a given environment. In broad-range PCR, primers are designed that are complementary to conserved regions of a particular gene shared by a group of microorganisms. For instance, primers that are complementary to conserved regions of the *16S rRNA* gene have been used with the intention of exploiting the variable internal regions of the amplified sequence for sequencing and further identification.¹⁷² Initially, bacterial DNA is extracted directly from samples, and the *16S rRNA* gene is isolated via PCR amplification with oligonucleotide primers specific for conserved regions of the gene (universal or broad-range primers). Amplification with universal primers results in a mixture of the *16S rRNA* genes amplified from virtually all bacteria present in the sample. In mixed infections, direct sequencing of the PCR products cannot be performed because there are mixed products from the different species composing the consortium. PCR products are then cloned into a plasmid vector, which is used to transform *Escherichia coli* cells, establishing a clone library of *16S rRNA* gene from the sample. Cloned genes are then sequenced individually, and preliminary identification can be done by using similarity searches in public databases. Phylogenetic analysis should also be accomplished for accurate identification.^{173,174} Broad-range PCR can detect the unexpected bacterial diversity in a sample, and in this regard, it is far more effective and accurate than culture. Broad-range PCR has allowed the identification of several novel fastidious or as-yet-uncultivated bacterial pathogens directly from diverse human sites.^{113,134,175}

Broad-range PCR products from samples can be alternatively analyzed by fingerprinting techniques, such as DGGE and T-RFLP. Genetic fingerprinting techniques can be used to determine the structure and diversity of microbial communities living in a given environment and to monitor changes in the community over time.

DGGE The analysis of broad-range PCR products by DGGE is a useful strategy to fingerprint bacterial communities. In DGGE, DNA fragments of the same length but with different nucleotide sequences can be separated in polyacrylamide gels containing a linearly increasing gradient of DNA denaturants.^{176,177} As the PCR product migrates in the gel, it encounters increasing concentrations of denaturants and becomes

partially or fully denatured. DNA fragments with different sequences may have a different melting behavior and will stop migrating at different positions in the gel. Therefore, when PCR products from mixed microbial communities are subjected to DGGE, the result is a fingerprint with several different bands where, at least theoretically, each band corresponds to a single species. In DGGE, multiple samples can be analyzed concurrently, making it possible to compare the structure of the microbial community of different samples and to follow changes in microbial populations over time, including after antimicrobial treatment.¹⁷⁸ Specific bands can also be excised from the gels, re-amplified, and sequenced to allow species identification.

T-RFLP T-RFLP can also provide insight into the structure and function of bacterial communities.¹⁷⁹ In T-RFLP, the *16S rRNA* gene from different bacterial species in a community is PCR amplified using one of the universal PCR primers labeled with a fluorescent dye.¹⁸⁰ The mixture of PCR products is then digested with one or more restriction enzymes that have four-basepair recognition sites, generating different fluorescently labeled terminal fragment lengths, whose sizes and relative abundances are determined using an automated DNA sequencer.^{181,182} The use of a fluorescently labeled primer limits the analysis to only the terminal fragments of the enzymatic digestion. All terminal fragment sizes generated from digestion of PCR products can be compared with the terminal fragments derived from sequence databases in order to infer species identification. Through application of automated DNA sequencer technology, T-RFLP has considerably greater resolution than DGGE.^{179,180}

DNA-DNA HYBRIDIZATION

DNA-DNA hybridization methodology is the process of annealing the complementary bases of two single-stranded DNA molecules. It employs labeled DNA probes that can locate and bind to a target sequence, forming a new duplex molecule. The labeled duplex can then be detected.¹⁸³ Probes are segments of single-stranded DNA labeled with detection molecules that can be constructed from either whole genomic DNA or oligonucleotides. Whole genomic probes are more likely to cross-react with non-target microorganisms due to the presence of homologous sequences between different species. Oligonucleotide probes based on signature sequences of specific genes (such as the *16S rRNA* gene) may display limited or no cross-reactivity with non-target microorganisms when under optimized conditions. In addition, oligonucleotide

probes can differentiate between closely related species or even subspecies and can be designed to detect as-yet-uncultivated bacteria.

Hybridization methods developed for large-scale studies include the checkerboard DNA-DNA hybridization and DNA microarray techniques. The Checkerboard DNA-DNA hybridization technique was introduced by Socransky et al.¹⁸⁴ for hybridizing large numbers of DNA samples against large numbers of digoxigenin-labeled whole genomic DNA or *16S rRNA* gene-based oligonucleotide probes on a single support membrane. Briefly, denatured DNA from clinical samples is placed in lanes on a nylon membrane using a Minislot apparatus. After fixation of the samples to the membrane, the membrane is placed in a Miniblotter 45 apparatus with the lanes of samples at 90° to the lanes of the device. Digoxigenin-labeled whole genomic DNA probes are then loaded in individual lanes of the Miniblotter. After hybridization, the membranes are washed at high stringency and the DNA probes detected using antibody to digoxigenin conjugated with alkaline phosphatase and chemifluorescence or chemiluminescence detection. The checkerboard method permits the simultaneous determination of the presence of a multitude of bacterial species in single or multiple clinical samples. A modification of the checkerboard method was proposed by Paster et al.¹⁸⁵ and consists of a PCR-based, reverse-capture checkerboard hybridization methodology. The procedure circumvents the need for in vitro bacterial culture, necessary for preparation of whole genomic probes. Up to 30 reverse-capture oligonucleotide probes that target regions of the *16S rRNA* gene are deposited on a nylon membrane in separate horizontal lanes using a Minislot apparatus. Probes are synthesized with a poly-thymidine tail, which are cross-linked to the membrane via ultraviolet irradiation or heat, leaving the probes available for hybridization. The *16S rRNA* gene from clinical samples is PCR amplified using a digoxigenin-labeled primer. Hybridizations are performed in vertical channels in a Miniblotter apparatus with digoxigenin-labeled PCR amplicons from up to 45 samples. Hybridization signals are detected using chemifluorescence or chemiluminescence procedures.

DNA microarrays were first described in 1995¹⁸⁶ and consist of a high-density matrix of DNA probes which are printed or synthesized on a glass or silicon slide (chip).¹⁸⁷ Targets incorporate either a fluorescent label or some other moiety, such as biotin, that permits subsequent detection with a secondary label. Targets are applied to the array, and those that hybridize to complementary probes are detected using some type of reporter molecule. Following hybridization, arrays are imaged using a high-resolution scanner and analyzed

by sophisticated computer software programs. DNA microarrays can be used to enhance PCR product detection and identification. When PCR is used to amplify microbial DNA from clinical specimens, microarrays can then be used to identify the PCR products by hybridization to an array that is composed of species-specific probes.¹⁸⁸ Using broad-range primers, such as those that amplify the *16S rRNA* gene, a single PCR can be used to detect hundreds to thousands of bacterial species simultaneously.¹⁸⁹ When coupled to PCR, microarrays have detection sensitivity equal to conventional methods with the added ability to discriminate several species at a time.

FISH

This method uses fluorescently labeled rRNA probes and fluorescence microscopy to detect intact microbial cells directly in clinical specimens.¹⁸⁹ In addition to provide identification, FISH gives information about presence, morphology, number, organization, and spatial distribution of microorganisms.¹⁹⁰ Because oligonucleotide probes can be designed for use, FISH not only allows the detection of cultivated microbial species, but also of as-yet-uncultivated microorganisms.^{191,192} A typical FISH protocol includes four steps: fixation and permeabilization of the sample; hybridization with the respective probes for detecting the respective target sequences; washing steps to remove unbound probe; and detection of labeled cells by microscopy or flow cytometry.¹⁹³

DRAWBACKS OF MOLECULAR BIOLOGY METHODS

As with any other method, molecular methods have also limitations. The methods are summarized in Table 5. However, the issues related to the ability of PCR to detect either an extremely low number of cells or dead cells are of special interest when one interprets the results of PCR identification procedures in endodontic microbiology research. Therefore, these issues are worth a separate discussion.

THE "TOO-HIGH SENSITIVITY" ISSUE

The high detection rate of PCR may be a reason of concern, specifically when non-quantitative assays are employed. It has been claimed that because PCR can detect a very low number of cells of a given microbial species, the results obtained by this method may have no significance with regard to disease causation. However, the method's high sensitivity can represent a great advantage for microbiological diagnosis in endodontics.

When taking samples from endodontic infections, difficulties posed by the physical constraints of the root canal system and by the limitations of the sampling techniques can make it hard for the attainment of a representative sample from the main canal.¹³⁵ If cells of a given species are sampled in a number below the detection rate of the diagnostic test, species prevalence will be underestimated.

Table 5 Advantages and Limitations of Molecular Biology Methods

Molecular Biology Techniques	
Advantages	Limitations
1. Detect both cultivable and as-yet-uncultivated species or strains.	1. Most assays are qualitative or semi-quantitative (exceptions: real-time PCR, microarray)
2. High specificity and accurate identification of strains with ambiguous phenotypic behavior	2. Most assays only detect one species or a few different species at a time (exceptions: broad-range PCR, checkerboard, microarray)
3. Detect species directly in clinical samples	3. Most assays detect only the target species and fail to detect unexpected species (exception: broad-range PCR)
4. High sensitivity	4. Some assays can be laborious and costly (eg., broad-range PCR)
5. Rapid—most assays take no more than minutes to a few hours to identify a microbial species	5. Biases in broad-range PCR introduced by homogenization procedures, preferential DNA amplification, and differential DNA extraction
6. Do not require carefully controlled anaerobic conditions during sampling and transportation	6. Hybridization assays using whole genome probes detect only cultivable species
7. Can be used during antimicrobial treatment	7. Can be very expensive
8. Anaerobic handling and expertise not required	8. Detect dead microorganisms
9. Samples can be stored frozen for later analysis	
10. DNA can be transported easily between laboratories	
11. Detect dead microorganisms	
PCR, polymerase chain reaction.	

It is also important to take into consideration the analytical sensitivity needed for the specific clinical sample. For example, a sensitivity of no more than 10^4 microbial cells per mL is required for urine, while a sensitivity of one cell may be of extreme relevance for blood samples or cerebrospinal fluid.¹⁹⁴ There is no clear evidence as to the microbial load necessary for apical periodontitis to be induced. Endodontic infections are characterized by a mixed community, and individual species can play different roles in the consortium or dominate various stages of the infection. At least theoretically, all bacterial species established in the infected root canal have the potential to be considered endodontic pathogens.¹⁹⁵ Based on this, it would be glaringly prudent to use the method with the highest sensitivity to detect all species colonizing the root canal.

PCR detection of very low numbers of cells in clinical samples may not be as common as anticipated. There are numerous factors that can influence PCRs, sometimes dramatically reducing sensitivity for direct microbial detection in clinical samples. Thus, the analytical sensitivity of the method does not always correspond to its "clinical" sensitivity. It is well known that the effects of inhibitors are magnified in samples with low number of target DNA and therefore can significantly decrease the sensitivity of the method.¹⁹⁶ Another impediment refers to the aliquots of the whole sample used in PCRs. Most of the PCR assays that have been used so far in endodontic research have an analytical sensitivity of about 10 to 100 cells. If one takes into account the dilution factor dictated by the use of small aliquots (5% to 10%) of the whole sample in each amplification reaction, the actual sensitivity of the assay is 100 to 200 to 1,000 to 2,000 cells in the whole sample, without discounting the effects of inhibitors.¹⁵⁸ These numbers are still lower than the detection limits of other methods, but can represent more significance with regard to pathogenicity.

Therefore, the use of highly sensitive techniques is welcomed in the study of endodontic infections, decreasing the risks for potentially important species to pass unnoticed during sample analysis. Although qualitative results do not lack significance, the use of quantitative molecular assays, like the real-time PCR, can allow inference of the role of a given species in the infectious process while maintaining high sensitivity

and the ability to detect fastidious or as-yet-uncultivated microbial species.

THE "DEAD-CELL" ISSUE

Detection of dead cells by a given identification method can be at the same time an advantage and a limitation. On the one hand, this ability can allow detection of hitherto uncultivated or fastidious bacteria that can die during sampling, transportation, or isolation procedures.^{135,197,198} On the other hand, if the bacteria were already dead in the infected site, they may also be detected, and this might give rise to a false assumption of their role in the infectious process.^{199,200}

Several studies show that bacterial DNA is rapidly cleared from the host sites after bacterial death and that DNA from different species may differ as to the elimination kinetics at different body sites.^{201–204} It remains to be clarified how long bacterial DNA from dead cells can remain detectable in the infected root canal system.

It is true that detection of microbial DNA sequences in clinical specimens does not indicate viability of the microorganism. However, this issue should be addressed with common sense and without any sort of biases. The fact that some microorganisms die during the course of an infectious process does not necessarily imply that in a determined moment these microorganisms did not participate in the pathogenesis of the disease. In addition, the fate of DNA from microorganisms that have entered and not survived in root canals is unknown. DNA from dead cells might be adsorbed by dentine due to affinity of hydroxyapatite (HAP) to this molecule.²⁰⁵ However, it remains to be shown if DNA from microbial dead cells can really be adsorbed in dentinal walls, and, if even, it can be retrieved during sampling with paper points. In fact, it is highly unlikely that free microbial DNA can remain intact in an environment colonized by living microorganisms. The half-life of the DNA released in the environment is considered to be very short owing to the presence of DNases in a complex background like the infected root canal. DNases released by some living species as well as at cell death can degrade free DNA in the environment. It has been reported that the presence of DNase activity on whole bacterial cells and vesicles thereof can degrade DNA.²⁰⁶ These bacteria include common putative endodontic pathogens, such as *Porphyromonas endodontalis*, *Porphyromonas gingivalis*, *Tannerella forsythia*, *Fusobacterium* spp, *P. intermedia*, and *P. nigrescens*.

Thus, the DNA molecule faces an onslaught of microorganisms that can degrade macromolecules.²⁰⁷ Indeed, DNases are of concern during sample storage, as they can be carried along with the sample and cause DNA degradation, with consequent false negative results after PCR amplification.

Under rare circumstances, such as when the tissue becomes rapidly desiccated after host death or the DNA becomes adsorbed to a mineral matrix, like bone or teeth, DNA may escape enzymatic and microbial degradation. Even so, slower but still relentless chemical processes start affecting the DNA. Many of these processes are similar to those that affect the DNA in the living cell, with the difference that, after cell death, these processes are not counterbalanced by cellular repair processes. Thus, damage accumulates progressively until the DNA loses its integrity and decomposes, with an irreversible loss of nucleotide sequence information.²⁰⁷

DNA is not a stable molecule, and chemical processes, like oxidation and hydrolysis, damage DNA over time. As a result, the DNA becomes fragmented and difficult or even impossible to be detected and/or analyzed. In palaeomicrobiology, certain strategies have to be developed for successful detection of ancient DNA. One of the most important strategies consists of using primers that will amplify a small DNA target size, preferably below 200 bp. Even so, the sample has to be well preserved, usually frozen or mummified. It has been stated that it is not the age of the DNA but the environmental conditions that are critical in preservation.²⁰⁸ Thus, any comparisons between the use of molecular methods in palaeomicrobiology and endodontics can be considered inappropriate at best.

Based on the discussion above, although there is a possibility of detecting DNA from dead cells in endodontic infections, this possibility is conceivably low. In the event, DNA from dead cells is detected, the results by no means lack significance with regard to participation in disease causation. Nonetheless, the ability to detect DNA from dead cells poses a major problem when one is investigating the immediate effectiveness of antimicrobial intracanal treatment, as DNA released from cells that have recently died can be detected. To circumvent or at least minimize this problem, one can use some adjustments in the PCR assay or take advantage of PCR technology derivatives, such as RT-PCR. Because smaller fragments of DNA may persist for a longer time after cell death than larger sequences, designing primers to generate large amplicons may reduce the risks of positive results due to DNA from dead cells.²⁰⁹ Moreover,

assays directed toward the detection of RNA through RT-PCR can be more reliable for detection of living cells. RNAs are more labile and have a shorter half-life when compared to DNA, and they can be rapidly degraded after cell death.²⁰⁰

Primary Intraradicular Infections

Over 700 bacterial species can be found in the oral cavity, with any particular individual harboring 100 to 200 of these species.²¹⁰ However, only a limited assortment of species is consistently selected out of the oral microbiota for growth and survival in root canals with necrotic pulp tissue. Taken together, data from studies using culture-dependent or culture-independent identification approaches have suggested that a selected group of bacterial species can be considered as candidate endodontic pathogens based on both frequency of detection and potential pathogenicity.

Culture-dependent studies have consistently demonstrated the essential role of microorganisms in causation of the different forms of apical periodontitis.^{76,211,212} Also, several putative endodontic pathogens have been recognized. More recently, with the advent of culture-independent molecular biology tools, significant technical hurdles of culture methods have been deftly overcome.¹³⁵ Not only have molecular methods corroborated findings from most culture studies, but a great deal of new information has been added to the knowledge of candidate endodontic pathogens. Molecular biology technology has enabled the recognition of new putative pathogens, which had never been previously found in endodontic infections.¹¹¹ Moreover, many species that had already been considered as putative pathogens due to their frequencies as reported by culture-dependent methods have been found in even higher prevalence values by molecular biology approaches, strengthening their association with causation of apical periodontitis.

Endodontic infections have a polymicrobial nature, and obligate anaerobic bacteria conspicuously dominate the microbiota in primary infections. Furthermore, the endodontic microbiota presents a high inter-individual variation, that is, it can significantly vary in species diversity and abundance from individual to individual,^{110,213} indicating that apical periodontitis has a heterogeneous etiology and multiple bacterial combinations can play a role in disease causation.

The following is an overview of the major bacterial groups and species regarded as candidate endodontic pathogens.

Black-pigmented Gram-negative anaerobic rods include species formerly known as *Bacteroides melaninogenicus*. These bacteria have been reclassified into two genera: the saccharolytic species were transferred to the genus *Prevotella* and the asaccharolytic species to the genus *Porphyromonas*.^{214,215} Some bile-sensitive non-pigmented *Bacteroides* species were also transferred to the genus *Prevotella*.²¹⁶ *Prevotella* species frequently detected in primary endodontic infections include *P. intermedia*, *P. nigrescens*, *P. tanneriae*, *Prevotella multisaccharivorax*, *Prevotella baroniae*, and *Prevotella denticola*.^{79,89,101–103,217–225} Of the *Porphyromonas* spp, only *P. endodontalis* and *P. gingivalis* have been consistently found in endodontic infections, and they seem to play an important role in the etiology of different forms of apical periodontitis lesions, including acute apical abscesses.^{79,89,94,223,226–228}

Tannerella forsythia (previously called *Bacteroides forsythus* or *Tannerella forsythensis*) is a recognized periodontal pathogen that was first detected in endodontic infections by species-specific single PCR.²²⁹ Several studies using different culture-independent molecular biology techniques, such as species-specific single or nested PCR,^{230–233} checkerboard hybridization,^{227,234} and microarray,²³⁵ have confirmed that *T. forsythia* is a common member of the microbiota associated with different types of endodontic infections, including abscesses.

Dialister species are asaccharolytic obligately anaerobic Gram-negative coccobacilli that represent another example of bacteria that have been consistently detected in endodontic infections only after the advent of molecular biology techniques. *Dialister pneumosintes* and the recently described *Dialister invisus* are amongst the most frequently detected species in asymptomatic and symptomatic primary endodontic infections in several molecular studies.^{224,236–242}

Fusobacterium species are also common members of the endodontic microbiota in primary infections including abscesses, with *Fusobacterium nucleatum* being the most frequent representative of the genus.^{31,83,221,230,232,243,244} PCR-based microbial typing approaches have revealed that different clonal types of *F. nucleatum* can be isolated from the same infected canal.²⁴⁵ *Fusobacterium periodonticum* has been detected in acute abscesses of endodontic origin by checkerboard hybridization.²³⁴

Spirochetes are highly motile spiral-shaped Gram-negative bacteria with periplasmic flagella that originate at opposite poles of the cell and usually are long enough to overlap near the middle of the cell body. All oral spirochetes fall into the genus *Treponema*, which have been linked to several oral diseases.^{246–248}

For many years, spirochetes have been observed in samples from endodontic infections by microscopy, but they have never been reliably identified to the species level.^{249–251} Culture-independent molecular biology methods allowed speciation of spirochetes in endodontic infections and revealed that all of the hitherto named oral treponemes can be found in primary endodontic infections.^{235,252–262} The most prevalent treponemes in infections of endodontic origin are *Treponema denticola* and *Treponema socranskii*.^{252,253,257,260} The species *Treponema parvum*, *Treponema maltophilum*, and *Treponema lecithinolyticum* have been moderately prevalent.^{253,254,259,260}

Gram-positive anaerobic rods have also been found as common members of the microbiota associated with primary endodontic infections. Of these, *Pseudoramibacter alactolyticus* has been detected by culture-dependent and culture-independent studies in frequencies as high as the most prevalent Gram-negative species.^{83,263,264} *Filifactor alocis* is an obligately anaerobic rod that had been only occasionally isolated from root canal infections by culture,⁸³ but a recent species-specific nested PCR study detected this species in about one-half of the cases of primary endodontic infections.²⁶⁵ *Actinomyces* spp, *Propionibacterium propionicum*, *Olsenella* spp, *Slackia exigua*, *Mogibacterium timidum*, and *Eubacterium* spp have also been reported to occur in infected root canals in relatively high prevalence.^{83,232,236,266–272}

Some Gram-positive cocci are frequently present in primary endodontic infections. *Parvimonas micra* (previously called *Peptostreptococcus micros* or *Micromonas micros*) have been isolated from about one-third of the primarily infected canals, and their prevalence in symptomatic infections has also been relatively high.^{83,87,220,222,243,273} Members of the *Streptococcus anginosus* group have been reported to be the most prevalent streptococci, but *Streptococcus gordonii*, *Streptococcus mitisi*, and *Streptococcus sanguinis* can also be often recovered/detected.^{83,268} *E. faecalis*, which has been closely found in association with root-filled teeth, has not been so frequent in primary infections.^{268,274}

Campylobacter spp, including *Campylobacter rectus* and *Campylobacter gracilis*, are Gram-negative anaerobic rods that have been detected in primary endodontic infections, but in low to moderate prevalence values.^{83,227,275–277} *Catonella morbi*, a saccharolytic obligately anaerobic Gram-negative rod associated with marginal periodontitis, has been found in about one-fourth of the cases of primary endodontic infections by a nested PCR approach.²⁷⁸ Other bacteria detected more sporadically in primary infections include *Veillonella parvula*, *Eikenella corrodens*, *Granulicatella*

adiacens, *Neisseria mucosa*, *Centipeda periodontii*, *Gemella morbillorum*, *Capnocytophaga gingivalis*, *Corynebacterium matruchotii*, *Bifidobacterium dentium*, and anaerobic lactobacilli.^{83,227,234,278–280}

Studies using broad-range PCR associated with clone library analysis^{224,236} or T-RFLP²²⁴ have indicated that as-yet-uncultivated bacteria can participate in endodontic infections—more than 40 to 55% of the endodontic microbiota is composed of bacterial phylotypes, that is, species that are known only by a 16S rRNA gene sequence and that have yet to be cultivated and fully characterized. Several uncultivated phylotypes can be very prevalent, and there is no reason to believe that they are not important to disease causation. For instance, oral *Synergistes* clones BA121, E3_33, BH017, and W090 are hitherto uncultivated bacteria that can be commonly detected in samples from both asymptomatic and symptomatic endodontic infections.^{237,239,281} Moreover, several as-yet-uncultivated phylotypes related to the genera *Dialister*, *Megasphaera*, *Solobacterium*, *Olsenella*, *Eubacterium*, and *Cytophaga*, as well as phylotypes related to the family *Lachnospiraceae* have been identified in primary endodontic infections.^{224,236,242,282} A study using both 16S rRNA gene clone library and T-RFLP analyses²²⁴ found some uncultivated phylotypes among the most prevalent bacteria in primary intraradicular infections, including *Lachnospiraceae* oral clone 55A-34, *Megasphaera* oral clone CS025, and *Veillonella* oral clone BP1-85. Two phylotypes, *Bacteroidetes* oral clone X083 and *Dialister* oral clone BS016, were detected only in asymptomatic teeth, while *Prevotella* oral clone PUS9.180, *Eubacterium* oral clone BP1-89, and *Lachnospiraceae* oral clone MCE7_60 were exclusively detected in symptomatic samples.²²⁴ Detection of as-yet-uncultivated phylotypes in endodontic infections suggests that they can be previously unrecognized bacteria that play a role in the pathogenesis of different forms of apical periodontitis.

Figure 3 displays several cultivable and as-yet-uncultivated bacterial species found in endodontic infections by culture-dependent and culture-independent analyses. As the breadth of bacterial diversity in endodontic infections has been unraveled by molecular biology methods, the list of candidate endodontic pathogens has expanded to include several cultivable and as-yet-uncultivated species that had been underrated by culture-dependent methods. Endodontic bacteria are now recognized to belong to 8 of the 12 phyla that have oral representatives, namely *Firmicutes*, *Bacteroidetes*, *Spirochaetes*, *Fusobacteria*, *Actinobacteria*, *Proteobacteria*, *Synergistes*, and TM7. Members of the two latter phyla and several representatives of the other phyla still remain to be cultivated.

Other Microorganisms in Endodontic Infections

FUNGI

Although fungi are members of the oral microbiota, particularly *Candida* spp, they have been only occasionally found in primary root canal infections,^{212,244,283,284} even though a recent molecular study¹ has reported the occurrence of *Candida albicans* in 21% of the samples from primary root canal infections.

ARCHAEA

Archaea comprise a highly diverse group of prokaryotes, distinct from bacteria. Members of this domain have been traditionally recognized as extremophiles, but recently some of these microorganisms have also been found to thrive in non-extreme environments, including the human body. To date, no member of the *Archaea* domain has been described as a human pathogen. However, methanogenic archaea have been detected in samples from subgingival plaque associated with periodontal disease.²⁸⁵ Only two molecular studies surveyed endodontic samples for the presence of archaea, with conflicting results.^{286,287} While one study failed to detect these microorganisms in necrotic root canals,²⁸⁶ another study detected methanogenic archaea in 25% of the canals of teeth with chronic apical periodontitis.²⁸⁷ Archaeal diversity was limited to a *Methanobrevibacter oralis*-like phylotype.

VIRUS

Viruses are particles structurally composed of a nucleic acid molecule (DNA or RNA) and a protein coat. Because viruses require viable host cells to infect and use the cell's machinery to replicate the viral genome, they cannot survive in a root canal containing necrotic pulp tissue. The presence of viruses in the root canal has been reported only for non-inflamed vital pulps of patients infected with the human immunodeficiency virus.²⁸⁸ On the other hand, herpes viruses have been detected in apical periodontitis lesions, where living cells are found in abundance. Of the eight human herpes viruses currently identified, the human cytomegalovirus (HCMV) and the Epstein-Barr virus (EBV) have been linked to the pathogenesis of diverse forms of periodontal diseases.^{289–293} More recently, molecular biology studies using single PCR or RT-PCR have

Figure 3 Phylogenetic tree of the most prevalent cultivable and as-yet-uncultivated bacterial species found in endodontic infections. Note that endodontic pathogens fall into seven major phyla. Another phylum, TM7, have been identified, but it does not contain species that are frequently detected. Courtesy J. Siqueira.

detected herpes viruses in samples from apical periodontitis lesions, and a pathogenetic role has been suggested.^{5,6,294–296} HCMV and EBV transcripts have

been found in high frequencies in the presence of symptoms,^{5,295} in lesions exhibiting elevated occurrence of anaerobic bacteria,⁶ and in cases of large

periapical bone destruction.^{5,6} It has been hypothesized that HCMV and EBV may be implicated in the pathogenesis of apical periodontitis as a direct result of virus infection and replication or as a result of virally induced impairment of local host defenses, which might give rise to overgrowth of pathogenic bacteria in the very apical part of the root canal.²⁹⁶

Symptomatic Infections

Whereas microbial causation of apical periodontitis is well established, there is no strong evidence disclosing specific involvement of a single species with any particular form of endodontic disease. Some Gram-negative anaerobic bacteria have been suggested to be involved with symptomatic lesions,^{76,87,88,94,95,224,297} but it has been revealed that the same species can also be present in somewhat similar frequencies in asymptomatic cases.^{89,102,227,230,232,234} Therefore, factors other than the mere presence of a given putative pathogenic species may play a role in the etiology of symptomatic endodontic infections. Other factors that may be involved with symptomatic infections include differences in virulence ability among strains of the same species, bacterial interactions resulting in synergism or additive effects among species, number of bacterial cells (load), environmental cues regulating expression of virulence factors, host resistance, and concomitant herpesvirus infection.^{296,298,299}

Cross-sectional studies suggest that bacterial succession occurs before symptoms arise.¹¹⁰ The possibility exists that, at a given moment during the endodontic infectious process, the microbiota reaches a certain degree of pathogenicity that elicits acute inflammation at the periapical tissues, with consequent development of pain and sometimes swelling. Molecular studies using DGGE or T-RFLP analysis revealed that the structure of the endodontic bacterial communities in symptomatic teeth is significantly different from that of asymptomatic teeth.¹¹⁰ Differences are represented by different dominant species in the communities and larger number of species in symptomatic cases. Therefore, a shift in the structure of the microbial community is likely to occur before appearance of symptoms. Such

a shift is probably a result of the arrival of new pathogenic species or of variations and rearrangements in the number of members of the bacterial consortium. Differences in the type and load of dominant species and the resulting bacterial interactions may affect virulence of the whole bacterial consortium. These findings confirmed that there is no key pathogen involved with symptomatic infections but, along with the factors mentioned above, the occurrence of certain specific bacterial combinations in infected root canals may be a decisive factor in causing symptoms.

Microorganisms: One Visit versus Two Visits

Bacteria play a major role in persistence of apical periodontitis lesions after treatment.^{108,109,300–302} It has been revealed that the outcome of the endodontic treatment is significantly influenced by the presence of bacteria in the canals at the root canal-filling stage.^{303–307} This suggests that persisting bacteria can survive in treated canals and sustain periapical tissue inflammation, underpinning the concept that eradication of bacteria from the root canal system should be the main goal of the endodontic treatment of teeth with apical periodontitis.

It is important to understand some aspects related to the significance of bacteria found in post-treatment samples. In this discussion, one should be aware of the time “persisters” are found in treated canals. Studies of the bacteria occurring in the root canal after treatment approaches involve three basic conditions: post-instrumentation samples (collected immediately after completion of chemomechanical procedures), post-medication samples (collected immediately after removal of interappointment dressings), and post-obturation samples (collected from root canal-treated teeth with associated apical periodontitis lesion at a given time—months to years—following treatment). Studies investigating bacteria remaining in the canals after chemomechanical procedures or intracanal medication provide a prospective view, that is, bacteria found in these samples have the potential to influence the treatment outcome. On the other hand, studies dealing with the microbiota of root canal-treated teeth evincing apical periodontitis

offer a cross-sectional view, in which the bacteria found are arguably participating in the etiology of persistent disease.

Even when the endodontic treatment does not succeed in completely eradicating the infection, the huge majority of bacteria are eliminated and the environment is markedly disturbed. To survive and therefore be detected in post-treatment samples, bacteria have to resist or escape intracanal disinfection procedures and rapidly adapt to the drastically altered environment caused by treatment procedures. Bacteria detected in post-instrumentation samples are remainders of the initial infection that resisted the effects of instruments and irrigants or were introduced in the canal as a result of a breach in the aseptic chain. Whatever the source, these bacteria are temporary “persisters” but have not yet had enough time to adapt to the new environment, drastically changed by chemomechanical procedures. Their survival and involvement with the treatment outcome will be reliant on this adaptation ability. Bacteria detected in post-medication samples can be real persisters that survived both chemomechanical procedures and intracanal medication or gained entry into the canal via leakage through the temporary restoration. These bacteria have had more time for adaptation to the modified environment. Bacteria found in filled root canals in cases indicated for retreatment are conceivably adapted to the new environment and are remainders of a primary infection that resisted treatment procedures or penetrated in the canal after filling via coronal leakage (re-infection). In these cases, treatment failure is already established and the bacteria found in the canals are arguably the major culprits.

BACTERIA PERSISTING INTRACANAL DISINFECTION PROCEDURES

Diligent antimicrobial treatment can occasionally fail to promote total eradication of bacteria from root canals, with consequent selection of the most resistant segment of the microbiota. Gram-negative bacteria, which are common members of primary intraradicular infections, are usually eliminated following endodontic treatment procedures, though studies have reported that some Gram-negative anaerobic rods, such as *F. nucleatum*, *Prevotella* spp, and *C. rectus*, are amongst the most common species isolated from post-instrumentation samples.^{304,308–311} However, most studies on this subject have revealed an overall higher occurrence of Gram-positive bacteria in both post-instrumentation and post-medication samples.³¹² This gives support to the notion that Gram-positive bacteria can be more resistant to

antimicrobial treatment measures and have the ability to adapt to the harsh environmental conditions in instrumented and medicated canals. Root canal samples positive for bacterial growth after chemomechanical procedures followed or not by intracanal medication have been shown to harbor one to six bacterial species per case. Gram-positive bacteria predominating in these samples include streptococci (*S. mitis*, *S. gordonii*, *S. anginosus*, and *Streptococcus oralis*), lactobacilli (*Lactobacillus paracasei* and *Lactobacillus acidophilus*), staphylococci, *E. faecalis*, *Olsenella uli*, *P. micra*, *P. alactolyticus* and *Propionibacterium* spp.^{304,308–311,107,313–316} Other Gram-positive bacteria, including *Actinomyces* spp, *Bifidobacterium* spp, and *Eubacterium* spp, can also be found, but in lower frequencies^{304,315,317} (Table 6).

With the recent findings showing as-yet-uncultivated bacteria as constituents of a significant proportion of the endodontic microbiota,^{224,236} studies on the effects of intracanal antimicrobial procedures should also rely on the detection of these bacteria. A study using 16S rRNA gene clone library analysis of bacteria persisting after endodontic procedures revealed that 42% of the taxa found in post-treatment samples were as-yet-uncultivated bacteria.³¹¹ In some cases, they even constituted the most dominant taxa in the sample. These findings suggest that previously uncharacterized bacteria may also participate in persistent endodontic infections.

PERSISTING BACTERIA INFLUENCING THE OUTCOME

Overwhelming scientific evidence demonstrates that apical periodontitis lesions are diseases of infectious origin.^{72,76,318} Given the essential role played by microorganisms in causation of apical periodontitis, endodontic treatment should focus on both elimination of microbial cells colonizing the root canal system (through antiseptic means) and prevention of introduction of new microorganisms in the canal (through aseptic means). The success rate of the endodontic treatment will depend on how effective the clinician is in accomplishing these goals.^{75,319} Root canal treatment of teeth containing irreversibly inflamed pulps is essentially a prophylactic treatment, as the radicular vital pulp is usually free of infection and the rationale is to prevent further infection of the root canal system.³²⁰ On the other hand, in cases of infected necrotic pulps or in root-filled teeth associated with apical periodontitis, an intraradicular infection is established and, as a consequence, endodontic procedures should focus not only on prevention of the introduction of new microorganisms into

Table 6 Studies Showing Bacterial Persistence After Intracanal Disinfection Procedures

Study	Species Per Canal (Mean)	Irrigant	Intracanal Medication	Sample Taken After	Most Prevalent Species	Gram-Positive Bacteria

the root canal system, but also on the elimination of those located therein.^{321,322}

The major factor influencing the outcome of the endodontic treatment is the presence of microorganisms in the canal at the time of filling.^{303–307} Better put, there is an increased risk of adverse outcome of the endodontic treatment if bacteria are left behind in the canals after intracanal procedures. It has been demonstrated that the permanent root canal filling per se has limited effect on the outcome of the endodontic treatment, even when it has been technically well performed.³⁰³ When no bacteria are recovered from the canal at the filling stage, healing of

apical periodontitis occurs uneventfully and independently of the quality of the root canal filling.

Thus, no matter whether bacteria were thoroughly eliminated after chemomechanical procedures (instrumentation and irrigation) or only after one or more sessions of intracanal medication, the success of the endodontic therapy depends on how effective the procedures are in rendering the canal bacteria-free. Therefore, the discussion on the topic “One × Two × Multiple visits” should focus on how many visits are required for the canal to be predictably disinfected. Total eradication of bacteria (or at least of culturing-detectable bacteria) can be achieved in some cases after

chemomechanical procedures, and the outcome of these cases has been shown to be excellent.³⁰⁴ However, microorganisms can survive the effects of chemomechanical preparation using antimicrobial irrigants in approximately 40% to 60% of the cases.^{304,310,323} Studies have demonstrated that predictable disinfection of the root canal system is only achieved after proper antimicrobial medications are placed in the canals and left therein between appointments.^{98,324,325}

Extraradicular Infections

Apical periodontitis lesions are formed in response to intraradicular infection and by and large comprise an effective barrier against spread of the infection to the alveolar bone and other body sites. In most situations, apical periodontitis inflammatory lesions succeed in preventing microorganisms from gaining access to the periapical tissues. Nevertheless, in some specific circumstances, microorganisms can overcome this defense barrier and establish an extraradicular infection. The most common form of extraradicular infection is the acute apical abscess, characterized by purulent inflammation in the periapical tissues in response to a massive egress of virulent bacteria from the root canal. There is, however, another form of extraradicular infection which, unlike the acute abscess, is usually characterized by absence of overt symptoms. This condition encompasses the establishment of microorganisms in the periapical tissues, either by adherence to the apical external root surface in the form of biofilm structures^{326,327} or by formation of cohesive actinomycotic colonies within the body of the inflammatory lesion.³²⁸ These extraradicular microorganisms have been discussed as one of the etiologies of persistence of apical periodontitis lesions in spite of diligent root canal treatment.³²⁹

Conceivably, the extraradicular infection can be dependent on or independent of the intraradicular infection.³³⁰ For instance, the acute apical abscess is for the most part clearly dependent on the intraradicular infection—once the intraradicular infection is properly controlled by root canal treatment or tooth extraction and drainage of pus is achieved, the extraradicular infection is handled by the host defenses and usually subsides. Nonetheless, it should be appreciated that in some rare cases, bacteria that have participated in acute apical abscesses may persist in the periapical tissues following resolution of the acute response and establish a persistent extraradicular infection associated with a chronic periapical inflammation. This

would then characterize an example of extraradicular infection independent of the intraradicular infection.

Except for apical actinomycosis and cases evincing sinus tracts, it is still controversial whether chronic apical periodontitis lesions can harbor bacteria for very long beyond initial tissue invasion.³³¹ Studies using culture-dependent^{332–334} or culture-independent molecular methods, such as the checkerboard hybridization^{335,336} and FISH,³³⁷ have reported the extraradicular occurrence of a complex microbiota associated with apical periodontitis lesions that do not respond favorably to the root canal treatment. Anaerobic bacteria have been reported to be the dominant microorganisms in several of those lesions.^{333,335} Because these studies did not evaluate the bacteriological conditions of the apical part of the root canal, it is difficult to ascertain whether those extraradicular infections were dependent on or independent of an intraradicular infection.

Most oral microorganisms are opportunistic pathogens and only a few species have the ability to challenge and overcome host defense mechanisms, acquire nutrients and thrive in the inflamed periapical tissues, and, then, establish an extraradicular infection. Of the several species of putative oral pathogens that have been detected in recalcitrant apical periodontitis lesions, some may have an apparatus of virulence that theoretically can allow them to invade and to survive in a hostile environment, such as the inflamed periapical tissues. For instance, it is currently recognized that some *Actinomyces* species and *P. propionicum* have the ability to participate in extraradicular infections and cause a pathological entity called apical actinomycosis, which is successfully treated only by periapical surgery.^{91,330,338} Some other putative oral pathogens, such as *Treponema* spp, *P. endodontalis*, *P. gingivalis*, *T. forsythia*, *Prevotella* spp, and *F. nucleatum*, have also been detected in persistent chronic apical periodontitis lesions by culture, immunological, or molecular studies.^{332,335,336,339,340} Most of these species possess an array of virulence traits that may allow them to avoid or overcome the host defenses in the periapical tissues.^{341–344}

The incidence of independent extraradicular infections in untreated teeth is conceivably low,^{251,345} which is congruent with the high success rate of non-surgical root canal treatment.³¹⁹ Even in root canal-treated teeth with recalcitrant lesions, in which a higher incidence of extraradicular bacteria has been reported, a high rate of healing following retreatment³¹⁹ indicates that the major cause of post-treatment disease is located within the root canal system, characterizing a persistent or secondary intraradicular infection. This has been

confirmed by studies investigating the microbiological conditions of root canals associated with persistent apical periodontitis.^{109,108,300–302} Based on this, it is reasonable to assume that most of the extraradicular infections observed in root-filled teeth could have been fostered by an intraradicular infection.

There are some situations that permit intraradicular bacteria to reach the periapical tissues and establish an extraradicular infection.³⁴⁶ This may be (1) a result of direct advance of some bacterial species that overcome host defenses concentrated near the apical foramen or that manage to penetrate into the lumen of pocket (bay) cysts, which is in direct communication with the apical foramen; (2) due to bacterial persistence in the apical periodontitis lesion after remission of acute apical abscesses; (3) a sequel to apical extrusion of debris during root canal instrumentation (particularly after over-instrumentation). Bacteria embedded in dentinal chips can be physically protected from the host defense cells and therefore can persist in the periapical tissues and sustain periapical inflammation. The virulence and the quantity of the involved bacteria as well as the host ability to deal with infection will be decisive factors dictating whether an extraradicular infection will develop or not.

Interactions between Microorganisms and the Host

The human commensal microbiota populates the mucosal surfaces of the oral cavity, gastrointestinal tract, urogenital tract, and the surface of the skin. A balance exists between the commensal bacteria and epithelia that allow both bacterial survival and prevention of the induction of inflammation that can damage the host.³⁴⁷ The commensal microbiota, which has co-evolved with its host, has acquired the means of surviving and tolerating host defense mechanisms.³⁴⁸ However, when the host is compromised, or if invading microorganisms are sufficiently pathogenic, disease can develop. Pathogenicity refers to the ability of an organism to cause disease in another organism. When microorganisms break through host barriers and multiply within host tissues, infection is initiated. The host mounts an immune response by mobilizing defense systems in an effort to ward off the invading microorganisms,³⁴⁸ generally referred to as pathogens. Pathogens are capable of interfering with innate and adaptive immune responses, thereby escaping eradication by the host. They include bacteria, fungi, viruses, protozoa, and higher parasites.

Some pathogens can benefit from the inflammatory response while others are able to avoid recognition by the host,³⁴⁹ or dampen host immune responses via sophisticated pathogen–host interactions.^{348,349} In bacterial infections, the release of a range of bacterial components can give rise to the synthesis of local hormone-like molecules known as proinflammatory cytokines that can induce pathology.

Successful pathogens must be able to adhere, colonize, survive, propagate, and invade, while at the same time evading host defense mechanisms such as neutrophils, complement, and antibodies. In addition, pathogens can initiate tissue destruction either directly or indirectly.³⁵⁰ Direct tissue damage can be induced by enzymes (eg., collagenase, hyaluronidase, and acid phosphatase), exotoxins (eg., cytolytins), and metabolites (eg., polyamines, and short chain fatty acids). Indirect damage results from a host immune reaction capable of causing tissue destruction that is stimulated by various bacterial components that include LPS, peptidoglycan (PG), lipoteichoic acid (LTA), fimbriae, outer membrane proteins, capsular components, and extracellular vesicles.

Virulence is generally understood to refer to the degree of pathogenicity or disease-producing ability of a microorganism. However, some microorganisms commonly described as “pathogens” do not necessarily cause disease in all hosts.³⁵¹ In addition, infections can be initiated by otherwise commensal organisms in immunocompromised hosts, a concept that is at odds with previously held pathogen-centered views of microbial pathogenesis. Thus, virulence is now seen as multifactorial with the susceptibility of the host playing a critical role.^{348,351,352} Pathogens have generally been distinguished from nonpathogens by their expression of virulence factors, a diverse collection of proteins or molecules produced by microorganisms that facilitate adhesion, colonization, invasion, and tissue damage. Virulence factors enable a microorganism to establish itself on or within a host and enhance its potential to cause disease. For many bacterial species, cytokine induction is a major virulence mechanism related to stimulation by certain components associated with the bacterial cell wall, including LPS, proteins, lipoproteins, glycoproteins, carbohydrates, and lipids. In general, toxins that are potential virulence factors become available either directly via secretion from viable cells (exotoxins) or as a result of cell lysis (endotoxins). Toxins produced by bacteria include enterotoxins, neurotoxins, cytotoxins, and lysins.

HOST–MICROBE INTERACTIONS IN THE INFECTED ROOT CANAL SYSTEM

At the outset of carious activity, inflammatory lesions can develop in the pulp in response to dentin permeability to bacterial products and the activation of signals released from the dentinal fluids.³⁵³ The pulp has an inherent capacity to process foreign antigens released from bacteria. Pulpal antigen presenting cells provide the necessary signals to activate T lymphocytes to mount a local immune defense.³⁵⁴ Human dental pulps have immunocompetent cells in the form of helper/inducer T cells, cytotoxic/suppressor T cells, macrophages, and Class II antigen-expressing cells essential for the initiation of immunological responses.^{355,356} In shallow carious lesions, the induction of type 1 cytokines in pulp tissue and the preferential activation of CD8 (+) T cells suggest that *Streptococcus mutans* may have a major influence on both the initial pulpal lesion and subsequent pulpal pathology.³⁵⁷ Furthermore, in mononuclear cell cultures, *S. mutans* was the most potent and persistent interferon-gamma inducer; whereas *Lactobacillus casei* was the dominant species giving rise to interleukin-10 (IL-10).³⁵⁸ The destructive aspect of inflammation may be particularly significant in the pulp due to its unique hard-tissue encasement that may be responsible for further tissue damage.³⁵⁹ The repair of damaged pulp tissue may be compromised because of the limited access to appropriate repair-competent cells because of these anatomic constraints. Thus, carious pulpitis has been described as an infection where the host reaction has the capacity to produce more damage than that caused simply by the effects of the microorganisms.³⁵⁹ Regardless, the interplay between pulpal injury, defense and repair can result in tissue regeneration following caries.³⁶⁰

The relationship between the microbiota in advancing caries and the histopathology of pulpitis involves irreversible tissue damage, healing, and repair in association with both specific and non-specific inflammatory reactions.^{357–359,361,362} Quantitative real-time PCR has shown that the microbiota of carious dentin has significant numbers of Gram-negative bacteria that have been strongly implicated in endodontic infections subsequent to pulpitis.³⁶³ Studies on induction of cytokines by bacteria associated with caries have provided a clearer understanding of the processes involved. Inflammatory reactions in the dental pulp of monkeys were initiated when dentin was exposed to products of certain bacteria such as *Streptococcus sanguinis*, *V. parvula*, *Rothia dentocariosa*, *Propionibacterium acnes*, and *Dialister pneumosintes*.³⁶⁴ Within the pulp itself, an

advancing carious lesion induced both specific and non-specific inflammatory reactions, with resultant healing and repair but also with some irreversible tissue damage.³⁶²

The relationship between the microbiota and the histopathology of chronic pulpitis in symptomatic teeth is less well understood. Although lactobacilli dominate in deep caries,³⁶⁵ the numbers of lactobacilli and total Gram-positive rods in the carious lesions were negatively associated with the length of pain triggered by cold and heat stimulants.³⁶⁶ In contrast, the less numerous Gram-positive cocci and non-black-pigmented *Prevotella* (BPB) were positively associated with thermal sensitivities. In particular, the presence of BPB, *S. mutans*, and total anaerobic counts were positively related to heat sensitivity, while *F. nucleatum*, *Actinomyces viscosus*, and enteric bacteria were associated with cold sensitivity. Furthermore, the duration of pain with thermal test was longer in teeth with low, compared to high, numbers of lactobacilli recovered from the carious lesions.³⁶⁶

As well, several physicochemical factors in the root canal have the potential to influence the pathogenicity of bacteria and in themselves modulate the host defense mechanisms. These factors include the degree of anaerobiosis, pH level, the availability of exogenous and endogenous nutrients, as well as the surfaces available for adherence and their characteristics (i.e., dentin vs cells). In infected root-filled teeth, additional factors to be considered include any medication remnants and root filling materials.

VIRULENCE FACTORS

Many of the microorganisms found in endodontic infections have also been identified as commensals in the oral cavity that have gained entry into the pulp tissue of the root canal typically via the caries process. The transition from oral “commensal” to root canal “pathogen” may reflect an innate ability to switch on genes that encode “virulence” factors enabling survival and propagation in a different environment. Table 7 lists some virulence factors that pathogens utilize to facilitate this process. At this time, the identification and characteristics of specific virulence factors that might play a role in endodontic infections has not been widely studied. Those with known, or potential, relevance to endodontic infections will be discussed below.

Lipopolysaccharide (LPS)

One of the first virulence factors to be identified in endodontic infections is LPS, also known as endotoxin.³⁶⁷ Historically, the term “endotoxin” was used

Table 7 Some Virulence Factors Utilized by Pathogens and Their Effects

Factor	Effect
Lipopolysaccharides/endotoxin	Proinflammatory
Peptidoglycans	Proinflammatory
Lipoteichoic acids	Proinflammatory
Fimbriae	Adherence
Capsules	Protection against phagocytosis and desiccation
Extracellular vesicles	Secretory products
Exotoxins	Diverse
Extracellular proteins	Diverse
Short-chain fatty acids	Proinflammatory
Polyamines	Growth factors
Superoxide anions	Denatures proteins
Chondroitin sulfatase	Digests ground substance
Hyaluronidase	Digests ground substance
Fibrinolysin	Damages fibrin
Gelatinase	Proteolytic, digests gelatin
Protease	Proteolytic
Hemolysins	Destroys erythrocytes
Leukocidin	Destroys leukocytes
Coagulases	Activates fibrin clotting
Elastase	Destroys elastin
Acids	Denatures proteins
Alcohols	Denatures proteins

based on the understanding that portions of Gram-negative bacteria caused toxicity, as opposed to “exotoxins” that were produced by bacteria and secreted into their environment. In Gram-negative bacteria, the outer membrane is constructed of a lipid bilayer, separated from the inner cytoplasmic membrane by PG with the LPS molecule embedded in the outer membrane. The lipid A portion of the molecule serves to anchor LPS in the bacterial cell wall. LPS is an integral part of the cell wall of Gram-negative bacteria regardless of their pathogenicity. When released, LPS has numerous biologic effects, including the mobilization of immunosurveillance mechanisms in the pulp. In vitro studies showed that LPS from *P. endodontalis* strains isolated from root canals and radicular cyst fluids stimulated IL-1 β release from human dental pulp cells in a time- and dose-dependent manner.³⁶⁸ LPS rapidly induced the expression of IL-8 in post-natal human dental pulp stem cells.³⁶⁹ Both *E. coli* and *P. intermedia* LPS upregulated the expression of the pro-angiogenic vascular endothelial growth factor (VEGF) in odontoblast-like cells and macrophages³⁷⁰ that was mediated, in part, by Toll-like receptor 4 (TLR4) signaling.³⁷¹

In human clinical and animal studies, the presence of endotoxin has been associated with pulpal pain and periapical inflammation,^{367,372–377} activation of comple-

ment,^{372,373} and periapical bone destruction in monkeys³⁷⁸ and cats.³⁷³ Symptomatic teeth with apical rarefactions and the presence of exudate have a higher endotoxin content in root canals than do asymptomatic teeth.³⁷⁵ A positive correlation was reported between the presence of endodontic signs and symptoms and the concentration of endotoxin in the root canal.³⁷⁷

Peptidoglycan (PG)

PG is the major component of Gram-positive cell walls where it forms a layer which is considerably thicker than in Gram-negative bacteria. PG functions to counteract osmotic pressure of the cytoplasm and provides cell wall strength and shape. It is a cross-linked complex consisting of polysaccharides and peptides that form a homogeneous layer outside the plasma membrane. Specifically, it is composed of interlocking chains of identical PG monomers. Each monomer consists of two joined amino sugars, *N*-acetylglucosamine and *N*-acetylmuramic acid (NAM), with a pentapeptide attached to the NAM.³⁷⁹ Upon cell lysis, PG is released and can react with the innate immune system as well as induce upregulation of both proinflammatory and anti-inflammatory cytokines in T cells.³⁸⁰ In T cells and monocytes, PG from *Staphylococcus aureus* induced IL-6 and IL-10 mRNA accumulation, and in *L. casei* stimulated IL-6 production in human dental pulp cells in a time- and dose-dependent manner.³⁸¹ PG may also facilitate an adaptive immune response via macrophages.³⁷⁹ The potency of PG is strongly boosted in the presence of LPS.^{379,382} The latter may be of particular significance to endodontic infections which are known to be typically polymicrobial, involving both Gram-positive and Gram-negative species.

Lipoteichoic Acid (LTA)

LTA is a cell wall component of Gram-positive bacteria, composed of teichoic acid and lipid.³⁸³ LTA shares with LPS many of its pathogenic properties but is reported to be much less active, on a weight-for-weight basis.^{379,384} The lipid component of LTA may be involved in the binding of Gram-positive bacteria to fibronectin in cell membranes³⁸⁵ and to eukaryotic cells that include neutrophils^{385,386} and lymphocytes.³⁸⁵ LTA is released as a result of cell lysis and can bind to target cells either non-specifically to membrane phospholipids, or specifically to TLRs and to CD14.³⁸⁰ Once bound to the target cell, LTA is able to interact with circulating antibodies and activate the complement cascade. LTA can trigger the release from neutrophils and macrophages of many molecules that may act alone or together to amplify damage—

reactive oxygen and nitrogen species, acid hydrolases, highly cationic proteinases, bactericidal cationic peptides, growth factors, and cytotoxic cytokines.³⁸⁷ In animals, LTA has been shown to induce a diverse range of inflammatory diseases ranging from a localized inflammatory tissue response³⁸⁸ to arthritis, nephritis, meningeal inflammation, septic shock, and multiorgan failure.³⁸⁷ In cell culture studies, LTA can induce expression of the pro-angiogenic VEGF in macrophages and pulp cells.³⁸⁹

Fimbriae

Fimbriae are long, filamentous macromolecules found on the surface of many Gram-negative bacteria. The thin hair-like projections are made of protein subunits. They are distinct from flagella, which are longer and involved in cell motility. Fimbriae are involved in attachment to surfaces and interactions with other bacteria.³⁹⁰ Enteric pathogens, for example, *E. coli* and *Salmonella* spp, have a diverse array of fimbriae that are involved in bacterial adherence and invasion.³⁹¹ For example, type IV fimbriae, which can aggregate into bundles, have been detected on *E. corrodens*,³⁹² a periopathogen that has also been detected in root canal samples from teeth with acute periapical abscesses.^{243,291} Hemagglutination activity was shown to be induced by fimbriae associated with *P. intermedia*.^{393,394} Fimbriae have been identified on *Actinomyces israelii*, a species associated with failed endodontic treatment³⁹⁴ and *Actinomyces naeslundii*.³⁹¹

Capsules

An important element in the virulence of pathogenic microorganisms is their ability to evade or counteract host immune defenses. One strategy used by bacteria and fungi utilizes capsule formation to inhibit complement activation and resist ingestion by phagocytes. A capsule is a well-organized layer outside the cell wall of the bacteria generally composed of polysaccharides and other materials. Capsules serve to facilitate protection of the bacterial cell against desiccation, phagocytosis, bacterial viruses, and hydrophobic toxic materials such as detergents. The presence of capsules, for example, in Gram-negative black-pigmented bacteria, contributes to the persistence of the bacteria by facilitating the avoidance of, or survival after, phagocytosis.⁵¹ In addition, capsules were identified as crucial for maturation of *Streptococcus pyogenes* biofilm formation on abiotic surfaces.³⁹⁵

Extracellular Vesicles

Extracellular vesicles are produced by Gram-negative bacteria and allow the release of their products into the

Figure 4 Extracellular vesicles (arrow) are shown between *Prevotella intermedia* cells ($\times 20,000$ original magnification). Courtesy C. Baumgartner.

extracellular environment. They develop from evagination of the outer membrane and have a similar trilaminar structure as their parent cell (Figure 4). The contents of extracellular vesicles derive from the periplasm and include proteins and lipids that are involved in a diverse array of activities, including hemagglutination, hemolysis, bacterial adhesion, and proteolytic activities.³⁹⁶ With an average diameter of 50 to 250 nanometers,³⁹⁷ adhesive properties, toxic contents, and an ability to carry contents into host cells, extracellular vesicles are a means by which bacteria interact with both prokaryotic and eukaryotic cells.^{397,398} As well, extracellular vesicles can modulate interactions between neighboring bacteria. For example, vesicles from the outer membrane of *P. gingivalis* can induce aggregation of a wide range of species that include *Streptococcus* spp, *F. nucleatum*, *A. naeslundii*, and *A. viscosus*.³⁹⁹ In addition, specific coaggregation interactions between different species can be modulated in the presence of *P. gingivalis* vesicles—as was demonstrated by the coaggregation of *S. aureus* with the mycelium type, but not the yeast type, of *C. albicans*.³⁹⁹ *P. gingivalis* releases vesicles that may also bind chlorhexidine, thereby providing its own protection.⁴⁰⁰ Specific virulence factors associated with oral bacterial vesicles include leukotoxin produced by *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans*⁴⁰¹ and the proteases Arg- and Lys-gingipain produced by *P. gingivalis*.⁴⁰² Transmission electron microscopy of lesions associated with teeth with refractory apical periodontitis showed the presence of extracellular material and outer membrane vesicles, with outer membrane vesicles in close contact with the bacterial cell wall and between cells.³³³

Exotoxins

Exotoxins are toxins released by a living cell that can trigger, among other responses, excessive and aberrant activation of T cells.⁴⁰³ Some exotoxins are extremely potent, for example, the toxic shock syndrome toxin-1 produced by certain strains of *S. aureus* and the pyogenic exotoxins produced by some *S. pyogenes* strains producing toxic shock-like syndrome.^{403,404} Bacteria produce an array of toxins that differ in terms of structure, mode of action, and eukaryotic targets. Bacterial toxins can also target other microorganisms as bacteriocins, proteinaceous toxins produced by bacteria which are bacteriostatic or bacteriocidal to other bacteria.⁴⁰⁵ Bacterial cytotoxins act on eukaryotic cells by targeting the cell cytostructure, either directly by modifying actin or indirectly by targeting regulators, in particular Rho GTPase regulators.⁴⁰⁶ The Rho GTPases are essential for the functional integrity of the immune system, including transcriptional regulation of the expression of inflammatory mediators including cytokines and chemokines. A specific role for exotoxin-producing bacteria in endodontic infections has not been established.

Extracellular Proteins

Diverse arrays of extracellular proteins, many of them enzymes, are produced by bacteria. Some are enzymes released during bacterial cell lysis that can contribute to the spread of infection, including proteases that neutralize immunoglobulins and complement components.⁴⁰⁷⁻⁴¹⁰ In the "eight-strain collection" of bacteria with known pathogenicity isolated from an infected monkey root canal,⁷⁷ the enzymes hyaluronate lyase, chondroitin-sulphatase, beta-glucuronidase, DNase, and acid phosphatase contributed to tissue disintegration. Variations were observed in the ability of different strains to produce different histolytic enzymes.⁴¹¹ Species demonstrating evidence of enzymes that could play a role in the pathogenesis of endodontic infections include *S. gordonii*, *S. anginosus*, *S. oralis*,³¹⁴ *P. gingivalis*,⁴¹² and *E. faecalis*.^{413,414} Extracellular proteins produced by root canal isolates of *S. gordonii*, *S. anginosus*, and *S. oralis* may be of pathogenic significance in post-treatment apical periodontitis.³¹⁴ The presence of the collagenase gene was detected in endodontic isolates of *P. gingivalis*,⁴¹² and increased collagenase was shown to be associated with larger periapical lesions.⁴¹⁵ While *E. faecalis* cytolytins can enhance pathogenicity in animal models,⁴¹⁶ *E. faecalis*, as well as *P. acnes* showed evidence of proteolytic activity but were weak pathogens when tested in root canals or in

tissue cages in both mixed and single-strain infections.⁴¹¹ Serine protease, an enzyme that cleaves peptide bonds, was shown to contribute to the binding of *E. faecalis* to dentin,⁴¹⁴ while gelatinase production was observed in more than 70% of *E. faecalis* strains recovered from infected root canals.⁴¹³

Short-Chain Fatty Acids

Short-chain fatty acids are major by-products of a fermentation process performed by obligate anaerobes and include butyric acid and propionic acid. These can act as virulence factors by stimulating the inflammatory response and inflammatory cytokine release via upregulation of neutrophil gene transcription, translation, and protein expression.⁴¹⁷ Leakage of butyric acid from coronal to apical reservoirs occurred in canals of human root sections obturated with gutta-percha and AH26.⁴¹⁸ Leakage of these very small molecules from root canals into the apical area could contribute to the infection process. For example, in cell culture studies, butyric acid stimulated monocyte IL-1 β production, a cytokine associated with bone resorption.⁴¹⁹ The inhibition of cell growth induced by high levels of butyric acid resulted in inhibition of T-lymphocyte cell growth and an increase in apoptosis.⁴²⁰ Other in vitro investigations showed that butyric acid increased the expression of the intercellular adhesion molecule-1 and E-selectin in endothelial cells.⁴²¹ Salts of butyric and propionic acids inhibited proliferation of mouse L929 cells and human gingival fibroblasts.⁴²² Clinically, the presence of the obligate anaerobe *F. nucleatum* has been associated with the most severe forms of interappointment endodontic flare-ups.⁴²³ It is feasible that the butyric acid produced by these microorganisms might be a contributory virulence factor to endodontic flare-ups.

Polyamines

Polyamines are small, polycationic molecules that have two or more primary amino groups. They include putrescine, cadaverine, spermidine, and spermine. These molecules are essential growth factors for both eukaryotic and prokaryotic cells and act by modulating a variety of ion channels.⁴²⁴ Leakage of polyamines from the infected root canal into the apical area might contribute to clinical symptoms. This hypothesis is based on an analysis of the amounts of polyamines in root canals of teeth with various clinical symptoms compared to symptom-free teeth.⁴²⁵ In infected root canals of teeth with spontaneous pain and percussion pain, the levels of putrescine were significantly higher than in pain-free teeth. In the presence of a sinus tract,

the levels of cadaverine from teeth with sinus tract were greater.⁴²⁵

Superoxide Anions

Superoxide anions are biologically toxic and highly reactive free radicals. Production is widespread among cells of the immune system. A few bacterial species can also produce extracellular superoxide. Blood isolates of *E. faecalis* were shown to produce large amounts of extracellular superoxide,⁴²⁶ with production by an enterococcal blood isolate causing lysis of erythrocytes.⁴²⁷ Superoxide production may also be involved in interspecies interactions. In a mouse model, it was shown that extracellular superoxide production by *E. faecalis* enhanced its in vivo survival in a mixed infection with *Bacteroides fragilis*.⁴²⁸

From the above, it is apparent that diverse arrays of virulence factors are potentially available in the root canal microbiota to modulate the participation of microorganisms in host–microbe interactions. However, the role of these virulence factors at this time is still mostly speculative. An absolute cause and effect relationship has not been proven between the presence of identified virulence factors and clinical signs and symptoms in root canal infections. There are additional mechanisms presently under investigation by which microorganisms might modulate the infection process. These include the ability of some intracellular bacteria to inactivate the killing mechanisms of phagocytic cells and therefore avoid being killed by macrophages and neutrophils.⁴²⁹ Of potential relevance concerning commensal microorganisms is the development of host cell tolerance as a result of previous exposure that may influence the ability to counteract subsequent bacterial challenge.³⁵² In addition, some bacteria can genetically vary their surface antigens, making it difficult for the immune system to target these organisms.³⁴⁹ Future research in these areas may clarify the role of virulence factors in endodontic infections and ultimately help identify therapeutic targets.

Interactions between Microorganisms

GENE TRANSFER SYSTEMS

The bacterial virulence factors previously described are encoded by genes usually located on chromosomal DNA, but also on extra-chromosomal DNA, for example, plasmids. The predominant means by which

chromosomal genes are inherited is via replication, segregation, and cell division, also sometimes termed vertical inheritance.⁴³⁰ Mechanisms of genetic variability between generations can include point mutations and genetic rearrangements.

The dissemination of genes can also occur via horizontal gene transfer (HGT, also called lateral gene transfer), whereby genetic material moves between bacterial cells. There is growing recognition of the importance of HGT for pathogenicity because genes transferred horizontally have the potential to propagate extremely rapidly across species barriers.⁴³⁰ HGT provides pathogens with the means to adapt rapidly, for example, by the acquisition of genes for antibiotic resistance. Overall, these processes benefit pathogens by enabling their continual adaptation to their hosts.³⁵⁰

Virulence genes can also be transferred via pathogenicity islands, or horizontally transferable genomic islands that are located on the bacterial chromosome or may be a part of a plasmid. Pathogenicity islands have been identified in both Gram-negative and Gram-positive species including *P. gingivalis*,⁴³¹ *E. faecalis*,⁴³² *S. mutans*,⁴³³ and *S. aureus*.⁴³⁴ They can be associated with a particular microbial adaptation, such as antibiotic and metal resistance. For example, in *S. aureus*, a mobile pathogenicity island carries the gene for toxic shock toxin.⁴³⁴

EXTRA-CHROMOSOMAL DNA: THE HORIZONTAL GENE POOL

The accessory genetic elements, collectively described as the horizontal gene pool include plasmids (Figure 5), bacteriophages, transposons, and insertion sequences. These elements can profoundly influence genome plasticity and evolution by allowing movement of genetic information both within and between species. HGT of DNA in bacteria occurs by three basic methods: transformation, transduction, and conjugation. “Recipient” cells receive the DNA, while “donor” cells are the source of the DNA.

Transformation of bacteria involves the active uptake by a cell of free (extracellular) DNA and its subsequent incorporation into the recipient genome, giving rise to “transformants” (i.e., the recipient cell becomes “transformed”). Lysed donor cells release genomic DNA. Usually only fragments of donor genomic DNA are taken up by the recipient. This process depends on the function of specific genes located on the recipient’s chromosome.⁴³⁵ The DNA

Figure 5 DNA in bacterial cells. Bacterial virulence factors are encoded by genes located usually on chromosomal DNA, but also on extra-chromosomal DNA, for example, plasmids. The dissemination of such genes can occur via vertical or inherited means and by horizontal gene transfer of extra-chromosomal DNA. Reproduced with permission from Sedgley CM and Clewell DB.⁴⁴⁷

acquired can include fragments of DNA that recombine with homologous regions of the recipient genome, or intact plasmids that can replicate autonomously in the recipient. Not all bacteria are capable of natural transformation. Natural transformation has been observed in the oral Gram-positive bacteria *S. mutans* in biofilms,⁴³⁶ *S. gordonii*,⁴³⁷ and *Streptococcus pneumoniae*.⁴³⁸

Transduction involves gene transfer whereby bacterial viruses (also termed phages or bacteriophages) carry genetic material to recipient cells that become “transductants.”⁴³⁹ Bacteriophages have been isolated from *A. actinomycetemcomitans*⁴⁴⁰ and *Actinomyces* spp⁴⁴¹ in dental plaque and from *E. faecalis* in saliva samples.⁴⁴²

Conjugation is the most efficient gene transfer phenomenon in bacteria. The requirement for cell–cell contact distinguishes conjugation from transduction and transformation. DNA is transferred between cells that are in physical contact allowing unidirectional transfer of genetic information from donor to recipient (which then becomes a “transconjugant”). Conjugation can involve the crossing of species barriers and can also occur between bacteria and eukaryotic cells.⁴⁴³ Chromosomal DNA segments, plasmids, and conjugative transposons can be transferred by conjugation.

Plasmids are extrachromosomal, autonomously replicating elements important for bacterial adaptability and survival by the provision of functions that might not be encoded by the chromosome. Bacterial plasmids are ubiquitous and can encode a variety of different traits including, in many cases, genes that specifically enable them to transfer copies of themselves to recipient bacteria. Plasmids are found in Gram-negative and Gram-positive bacteria as well as in archaea⁴⁴⁴ and yeasts.⁴⁴⁵ In addition, the double-stranded circular plasmids encoding the EBV, Kaposi’s sarcoma-associated herpesvirus, and papillomavirus have been shown to exist “naturally” in mammalian cells.⁴⁴⁶ From a clinical perspective, plasmids are particularly important because they are involved in the dissemination of antibiotic resistance.

In terms of structure, plasmids are typically covalently closed circular, double-stranded, supercoiled DNA molecules that replicate independently of chromosomal DNA, and range in size from approximately 1 to greater than 200 kilo base pairs (kb).⁴⁴⁷ In contrast, the size of chromosomal DNA is much larger, for example, 3,218 kb, as reported for the clinical isolate *E. faecalis* V583.⁴⁴⁸ The copy number of plasmids in the bacterial cell is typically characteristic for the particular plasmid and can range from greater than 30 copies per chromosome for a small plasmid (eg., <10 kb) to one to two copies for a larger plasmids (eg., >25 kb).⁴⁴⁷ Plasmids rely on their host cell to provide essential ingredients for DNA replication. More than one type of plasmid can occur stably in a given cell provided they are compatible. Incompatibility relates to a close relationship between plasmids whereby there is competition for replication machinery, the necessary consequence being the need for a plasmid to maintain a certain copy number in the cell. Whichever plasmid is able to replicate faster, or has some other advantage, will eventually remain at the expense of its competitor. Some plasmids exhibit a broad host range and are able to propagate in many different species of bacteria. It is not always clear what genes are encoded on wild-type (or “naturally occurring”) plasmids. If no known function or gene expression is associated with a plasmid, it is referred to as “cryptic.” In contrast, some plasmids have had their DNA sequenced and specific genes have been identified. Figure 6 shows a simplified “map” of pAD1, a conjugative plasmid originally isolated from a clinical isolate of *E. faecalis*. Clinical strains of *E. faecalis* can carry as many as five or more co-resident plasmids with different sizes and copy numbers. While not necessarily essential to the

Figure 6 Simplified map of the conjugative plasmid pAD1 originally isolated from *Enterococcus faecalis* ds16. Segments are described according to the functions coded by genes contained within (1) replication and maintenance; (2) regulation of pheromone response; (3) structural genes relating to conjugation; (4) unknown; (5) cytolysin biosynthesis; (6) unknown; (7) resistance to UV light; oriV, origin of replication; oriT, origin of transfer. Reproduced with permission from Sedgley CM and Clewell DB.⁴⁴⁷

bacterial host, plasmids can confer traits facilitating survival under atypical conditions such as in the presence of antibiotics and heavy metals. For example, hospital-acquired bacterial infections are often associated with the rapid spread of antibiotic resistance, traits that are often encoded on plasmids.

Transposons, sometimes also called “jumping genes,” are segments of DNA that can move (“jump”) from one DNA molecule to another—for example, from the chromosome to a resident plasmid. Transposons frequently accumulate on plasmids and encode functions necessary for their own transposition as well as other functions such as antibiotic resistance.⁴⁴⁹ Insertion sequences are short DNA sequences that usually encode the ability to transpose but do not carry accessory genes like transposons do. Insertion sequences sometimes represent components of a transposon.⁴⁵⁰

Conjugative plasmids and conjugative transposons are transferred between cells that are in physical contact. They are ubiquitous in Gram-negative bacteria as well as in the Gram-positive *Enterococcus*, *Streptococcus*, *Staphylococcus*, *Lactococcus*, *Listeria*, *Bacillus*, *Clostridium*, *Streptomyces*, and *Rhodococcus*.⁴⁵¹ The conjugative transfer process in Gram-negative bacteria typically involves a single strand of DNA being transferred from the donor cell to the recipient cell after which a complementary strand is

Figure 7 Conjugative transfer of plasmids in Gram-negative bacteria. Cell–cell contact is facilitated by a plasmid-encoded pilus. A single strand of DNA is then transferred from the donor to the recipient. A complementary strand is synthesized in the recipient and the resulting double-stranded DNA is circularized. Reproduced with permission from Sedgley CM and Clewell DB.⁴⁴⁷

synthesized in the recipient, and the resulting double-stranded DNA is circularized (Figure 7). The size of conjugative plasmids can range from as small as 10 kb to well over 100 kb.^{451,452} Perhaps due in part to the inherent differences in structures of the cell envelope, conjugative systems differ somewhat between Gram-negative and Gram-positive bacteria. For example, Gram-positive hosts generally do not make use of a pilus structure to achieve a close cell–cell contact.⁴⁵³ The transfer of conjugative plasmids can also occur from the prokaryote *E. coli* to the eukaryote yeast, *Saccharomyces cerevisiae*,⁴⁵⁴ as well as to higher eukaryotes such as Chinese hamster ovary cells (CHO K1).⁴⁴³ A broad range of genes can be transported as a result of conjugation. Furthermore, otherwise non-transferable elements such as non-conjugative co-resident plasmids and even chromosomal genes can be mobilized by conjugative plasmids. Conjugative transposons are also widespread, being found for example in enteric *Bacteroides* spp.^{455,456} Sometimes referred to as integrative conjugative elements, they cannot replicate autonomously, but can excise from the chromosome generating a circular intermediate that can then conjugate in a manner similar to a plasmid. Once taken up by a recipient, the transposon is believed to circularize prior to inserting itself into the chromosomal DNA. Conjugative transposons are important in the

dissemination of antibiotic resistance.^{451,457} Four of fifteen tetracycline-resistant bacteria isolated from root canals were shown to possess elements similar to the conjugative transposon Tn916.⁴⁵⁸

PHEROMONE-INITIATED CONJUGATIVE TRANSFER OF PLASMIDS

Some plasmids conjugatively transfer copies of themselves from one bacterial cell to another using small peptides called pheromones as essential signals in the process. Conjugative plasmids that make use of pheromones were first observed in an oral *E. faecalis* strain recovered from a patient with acute periodontitis.^{459,460} The pheromones are secreted by a potential “recipient” cell which “activates” the transfer system of a potential “donor” cell. Pheromone-responding plasmids in *E. faecalis* can carry genes relating to antibiotic resistance as well as virulence traits. A single *E. faecalis* strain may secrete multiple pheromones, each one being specific for inducing transfer of different “families” of plasmids. The pheromones provide the signals essential to the conjugation process that results in transfer of the plasmid DNA to a plasmid-free cell (Figure 8). Specifically, conjugation functions are activated, including a dramatic “clumping response” mediated by the appearance of a surface adhesin (“aggregation substance” or “AS”) that facilitates the attachment of the donor cells

Figure 8 Pheromone-initiated conjugative plasmid transfer. The pheromone induces the appearance of a surface adhesin (aggregation substance) that facilitates the attachment of the donor and recipient cells. Aggregates give rise to conjugal channels through which the plasmid is transferred from the donor to the recipient cell. Reproduced with permission from Sedgley CM and Clewell DB.⁴⁷⁷

to enterococcal binding substance which is present on the surface of recipients as well as donors.⁴⁶⁰ The plasmid is then transferred from the donor to the recipient cell. Once the recipient cell has acquired the plasmid, it assumes a phenotype of the original donor and shuts down the production of endogenous pheromone. However, the transconjugants continue to produce pheromones specific for donors harboring different classes of plasmids. Presently, the use of pheromone initiated transfer of conjugative plasmids within species other than *E. faecalis* has thus far not been observed. However, a peptide similar to the *E. faecalis* pheromone cAM373 has been detected in culture supernatants of *S. aureus* and *S. gordonii*.⁴⁶¹

ANTIBIOTIC RESISTANCE AND VIRULENCE ASSOCIATED WITH PLASMIDS

In return for “lodging,” plasmids can provide important survival properties to their host, in particular by conferring resistance to an antibiotic. In hospitals where patients are frequently being administered antibiotics, the selective pressure on bacteria containing plasmids bearing resistance genes has been responsible for once useful antibiotics losing their effectiveness. In addition to antibiotic resistance, a diverse range of products that may potentially contribute towards “virulence” such as cytotoxins, adhesions, and certain metabolic enzymes are also often encoded by plasmids.⁴⁶² Genes for protecting a cell against deleterious substances like mercury, copper, or silver have been found on plasmids.^{463,464} Plasmids can therefore carry genes that enhance the bacterial host cell’s ability to cause a disease, for example, the 92 kb plasmid (pO157) encoding a toxin that is associated with the strain *E. coli* O157:H7 resulting in febrile hemorrhagic colitis with potentially life-threatening complications.⁴⁶⁵ Virulence plasmids in *S. aureus* can encode extracellular toxins that have been linked to systemic shock, for example, toxic shock syndrome,⁴⁶⁶ and enterotoxins associated with food poisoning.⁴⁶⁷ Genes on plasmids that encode cytolytins are found in *E. faecalis*, often in association with clinical isolates.^{468,469} Cytolytins can lyse erythrocytes and other eukaryotic cells as well as kill certain Gram-positive bacteria.⁵⁹

PLASMIDS IN THE ORAL AND ENDODONTIC MICROBIOTA

Data on plasmids associated with the oral and endodontic microbiota are limited.⁴⁴⁷ In the oral microbiota, studies have focused on the identification⁴⁷⁰⁻⁴⁷² and epidemiology of plasmids in streptococci,⁴⁷³⁻⁴⁷⁵

black-pigmented anaerobic bacteria,⁴⁷⁶ *P. nigrescens*,⁴⁷⁷ *F. nucleatum*,⁴⁷⁸ oral spirochetes,⁴⁷⁹ and *E. faecalis*.^{480–482} Plasmids were found in 26.7% of *F. nucleatum* strains from periodontal patients but not in any strains from healthy subjects.⁴⁷⁸ In contrast, no association was found between the disease status of periodontal sampling sites and the presence of a plasmid in *P. nigrescens* strains.⁴⁷⁷ Plasmids were isolated from 7 of 11 oral *E. faecalis* strains recovered from endodontic patients.⁴⁸¹ The ability of plasmids in oral streptococci to transfer between species has been demonstrated.^{472,483,484} Recently, it was shown that gene transfer can occur from *T. denticola* to *S. gordonii* in experimental biofilms.⁴³⁷

Information relating to plasmids associated with endodontic microbiology appears to be limited to those associated with *Enterococcus* sp. Plasmid DNA was isolated from 25 of 33 endodontic enterococcal isolates (31 *E. faecalis* and 2 *E. faecium* strains) recovered from patients in Sweden, with up to four plasmids per strain.⁴¹³ Several strains which appeared to be clones based on pulsed field gel electrophoresis analyses of total DNA were shown to have distinct plasmid types. (Figure 9). Phenotypic studies showed that 16 of the plasmid-positive strains exhibited a “clumping response” (characteristic of a response to pheromone) when exposed to a culture filtrate of a plasmid-free strain, suggesting the potential for conjugative transfer of genetic elements in these endodontic isolates. It is conceivable that if endodontic strains contain conjugative plasmids with genes that could enhance survival during or after endodontic treatment, such properties might be transferred to other strains.

COOPERATIVE AND ANTAGONISTIC INTERACTIONS BETWEEN MICROORGANISMS

Bacteria can communicate, cooperate, and alter their behavior according to changes in their communal environment. Interactions between different species, or even between different strains of the same species, can modulate the infectious process by communication processes. Some bacteria communicate and coordinate behavior via signaling molecules using a process called quorum sensing.⁴⁸⁵ Here, cells express particular characteristics only when present as a population whose density is above a certain minimum (“quorum”). When a high density population reaches a certain threshold, the concentration of normally low levels of certain “signal molecules” becomes high enough to act as an autoinducer (AI) resulting in the increased expression of specific operons that enhance survival or are important in bringing about the next stage

Figure 9 Total DNA and plasmid DNA analysis of endodontic *Enterococcus faecalis*. **A**, Pulsed field gel electrophoresis (PFGE) of *Sma*I-digested genomic DNA from endodontic *E. faecalis* strains GS3–GS7, GS12, GS13, GS21, GS22. Note similarities between GS3–GS7, GS12, and GS21. Reference standard: lambda phage DNA. **B**, Plasmid analysis of the same *E. faecalis* isolates. Lane M, molecular size marker (1 Kb plus DNA Ladder, Invitrogen); –, undigested; H, digested with *Hind*III. Strain designations are shown above the lane designations. Isolates classified based on PFGE pattern as clonal, GS3, GS12, and GS21 are similar in plasmid content. GS4 and GS5 appear to be alike in plasmid content. GS6 and GS7 each contain two similar small plasmids, however GS6 has two additional plasmids. Reproduced with permission from Sedgley CM and Clewell DB.⁴⁴⁷

of a colonization or virulence process. *N*-acyl homoserine lactone-based signaling is used by Gram-negative bacteria, while small peptides are often involved in Gram-positive bacteria. AI-2 signal is used by both Gram-negative and Gram-positive bacteria and can play a role in communication between different bacterial species. As a result of quorum sensing, the expression of key proteins can be regulated. This coordinated regulation of behavior is of particular relevance in biofilms.⁴⁸⁶ For example, AI-2 produced by the oropharyngeal microbiota in cystic fibrosis patients modulates gene expression of *Pseudomonas aeruginosa* which enhances its pathogenicity.⁴⁸⁷ However, while quorum sensing provides an opportunity for cooperation, it also has the potential to result in competition and conflict both within and between species, although this is not well understood.⁴⁸⁵

Certain microbial interactions can have beneficial or antagonistic outcomes. Examples of beneficial interactions include enzyme complementation and food chains. For example, in early dental plaque, *Veillonella atypica* requires *S. gordonii* to be present to colonize dental surfaces because *S. gordonii* ferments sugars and releases lactic acid, which is the preferred carbon source for *V. atypica*.⁴⁸⁸ Other beneficial relationships may involve coaggregation interactions, or the recognition and adhesion between genetically distinct bacteria,⁴⁸⁹ as distinct from “autoaggregation”, or the adherence of bacteria belonging to the same strain.⁴⁹⁰ In plaque, coaggregation commonly occurs between “early” and “late” colonizers and involves specific adhesins and complementary receptor molecules. Cell–cell adhesion occurs when cells of one microbial species adhere more or less specifically to those of a different species.⁴⁹¹ Coaggregation interactions have been shown to be involved in the establishment and maintenance of biofilms,⁴⁹¹ which may play an important role in endodontic infections.^{492,493} Interactions between pairs of bacteria are highly specific. For example, recognition of the antigen I/II polypeptide facilitates coinvasion of dentinal tubules by *P. gingivalis* with *S. gordonii*, but not with *S. mutans*.^{494,495} A protein adhesin and a carbohydrate receptor, often a polysaccharide,⁴⁹⁶ mediates coaggregation. Coaggregation interactions provide an ideal environment for HGT,⁴⁹⁷ perhaps by facilitating plasmid transfer.⁴⁴⁷ Individual bacteria might gain a survival advantage by coaggregating with other bacteria within biofilms. By forming ordered assemblies of bacteria with species-specific molecular interactions, the bacteria are better able to adapt to fluctuating environmental conditions.⁴⁹⁸ Recent observations suggest a potential role for specific combinations of species in endodontic infections. Using confocal microscopy, both autoaggregation and coaggregation interactions were

observed, particularly in association with *Prevotella*, *Streptococcus*, and *Fusobacterium* species isolated from acute endodontic infections.⁴⁹⁹ Coaggregation interactions were also observed between oral and endodontic isolates of *E. faecalis* and *F. nucleatum* and between *F. nucleatum* and *S. anginosus*, *Peptostreptococcus anaerobius* and *Prevotella oralis*.⁵⁰⁰ *F. nucleatum* may provide a specific link or connection for other coaggregating microorganisms. Fusobacteria have been shown to have a wide array of coaggregation partners^{501–503} and their interactions with Gram-positive and Gram-negative bacteria being distinct.⁵⁰¹ *F. nucleatum* and many streptococci form “corn cob” coaggregation arrangements⁵⁰⁴ and in doing so may act as a “bridge” between early and late colonizers.⁵⁰¹

Antagonistic interactions between microorganisms can occur as a consequence of pH changes and nutrient competition and subsequent to the release of hydrogen peroxide, organic acids (eg., lactic), and bacteriocins. Bacteriocins are protein or peptide “antibiotics” produced by some strains of Gram-positive and Gram-negative bacteria. Genes for bacteriocins are commonly carried on plasmids. They are bacteriostatic or bactericidal to other, often closely related, bacterial strains. The production of bacteriocins may provide the producer strain with a selective advantage over other strains, especially those closely related to the bacteriocin-producing strain.⁴⁰⁵ Bacteriocins are diverse in terms of size and structure, ranging from short peptides to multi-component systems with induction and regulation factors. Their mechanism of action is usually characteristic for each bacteriocin. There are few data available about bacteriocins in association with endodontic infections. Fourteen of thirty-three *Enterococcus* species recovered from infected root canals, and six of 12 oral rinse strains,⁴⁸¹ produced bacteriocin activity, using indicator strains *E. faecalis* FA2-2, *E. faecalis* DS16, and *E. faecium* 409, but not *S. aureus* ATCC 6538, *E. coli* DH5 α , and *E. coli* ATCC 29417.⁴¹³ The use of a bacteriocin as an antimicrobial agent for use in endodontics has been explored. Nisin was as effective as calcium hydroxide in the eradication of *E. faecalis* and *S. gordonii* from root canals of extracted teeth.⁵⁰⁵

SPECIES-SPECIFIC INTERACTIONS BETWEEN MICROORGANISMS IN ROOT CANAL INFECTIONS

Several papers have been published reporting observations of positive and negative associations of bacteria or pairs of bacteria with various clinical signs and symptoms (Table 8). For example, positive

associations were found between *F. nucleatum* and *P. micra*, *P. endodontalis*, *Selenomonas sputigena*, and *Campylobacter rectus* in teeth with apical periodonti-

tis.⁸³ In contradistinction, species of streptococci, *P. propionicum*, *Capnocytophaga ochracea*, and *V. parvula* showed no or negative associations with the other

bacteria.⁸³ In monkeys, indigenous oral bacteria were able to induce apical periodontitis, with certain combinations of bacteria more potent than were single strains.⁷⁸ Combinations of bacteria obtained

from teeth with purulent apical inflammation that induced transmissible infections in guinea pigs always contained strains of black-pigmented anaerobic bacteria.⁵⁰⁶

Microbes and Unsuccessful Endodontic Treatment

The presence of microorganisms in the dental pulp is directly associated with the development of periapical disease.^{72,77,78,318} Following biomechanical preparation of the infected root canal using antimicrobial agents, followed by optimal obturation and coronal restoration procedures, a favorable long-term outcome can be expected. However, failure of root canal treatment can sometimes occur, particularly in the presence of persistent or secondary intraradicular infection.^{507,508,322} A statistically significant association between the presence of microorganisms in the root canal and persistence of infection at five years recall was shown in a clinical study of 55 root canals by Sjogren et al.³²² Complete periapical healing occurred in 94% of 33 cases that had yielded a negative culture prior to root canal obturation compared to 68% of 22 cases when samples were positive prior to root filling.

It is generally understood that the microbiota associated with failed endodontic treatment differs from that associated with primary root canal infections. Culture studies have shown that primary root canal infections are polymicrobial and dominated by anaerobes,^{509,510} while secondary root canal infections are composed of fewer species which are dominated by facultatively anaerobic Gram-positive bacteria, principally *Enterococcus* sp.^{301,302,508} More recently, PCR-based analyses of 16S rDNA sequences in root canal samples have indicated that the microbiota associated with failed root canal infections is more diverse than previously considered, although *E. faecalis* still is frequently present.^{109,111} These findings are not unexpected, considering that less than 1% of environmental microbial species are considered culturable.^{118,511} In fact, numerous studies have shown that culture methods used to analyze samples from previously treated root canals are significantly far less sensitive than molecular methods in the detection of microorganisms in root canal samples.^{482,512–515} However, research evaluating the contribution of unculturable organisms to the pathogenesis of endodontic infections, and their interactions, if any, with other species is still at an early stage. In the future, studies examining gene expression may be able to provide information on the viability and virulence of these putative pathogens⁵¹³ and their role in unsuccessful endodontic treatment.

Microorganisms found in failed endodontically treated teeth have either remained in the root canal from previous treatment or have entered since treat-

ment via leakage. Regardless of methodology used for processing clinical samples, it is not possible to differentiate between viable cells or DNA remaining from primary infections and new microorganisms contributing to the secondary infection. Those remaining from the original microbiota would need to have maintained viability throughout treatment procedures, including exposure to disinfectants, and thereafter adapted to a root canal environment in which the availability of a variety of nutrients is more limited because of lack of pulp tissue. This might occur as a result of an inability of chemomechanical instrumentation procedures to completely debride the root canal system in a single visit and because of the inaccessible locations of bacteria in isthmuses, accessory canals, and apical regions of canals.⁴⁹³ While it is considered that many such remaining bacteria will be unable to cause harm once entombed by the obturation material, there is little evidence for this.⁵¹⁶

It is clear that studies of endodontic treatment outcomes in humans are limited by the heterogeneity of patients and the difficulty in maintaining sufficiently standardized clinical and observational conditions. Furthermore, ethical considerations prevent systematic studies of cause and effect using histopathological analyses on human material concurrent with microbiological sampling, as was possible in classic monkey studies.^{72,78} Obtaining representative root canal samples from previously root-filled teeth can present considerable practical difficulties, particularly if the previous restoration and root filling are difficult to remove. For this reason, strict criteria need to be applied for inclusion and exclusion of teeth in clinical studies. For example, inclusion of previously root-filled teeth with coronal leakage introduces the potential for inclusion of oral microbiota contaminants that may have played no role in the presenting symptoms. In a recent study, the predominant cultivable species recovered from root-filled teeth with persistent periapical lesions and coronal leakage was *Staphylococcus*,⁵¹⁷ which differs from the findings of those studies which have sampled intact teeth.^{108,301,509} Sampling guidelines using strictly aseptic conditions and appropriate controls were developed by Möller.²¹⁴ Even when these are observed, the recovery of microorganisms from root canals is usually performed using absorbent paper points. Although paper point sampling is clinically convenient, it is limited in that the paper points will only hold what is displaced from the canal into the paper and do not provide information on what remains in the root canal. Whether the

microorganisms that are absorbed into the paper point are representative of those involved in the infectious process is not always, if ever, clear.

Despite the above limitations, several independent studies have shown that certain microorganisms have been repeatedly recovered from infected previously root-filled teeth. In addition to enterococci, these are chiefly *Actinomyces*, propionibacteria, yeasts, and streptococci, with occasional reports of other types. These will be discussed below.

ENTEROCOCCUS

Description

Enterococcus is a genus of Gram-positive facultatively anaerobic coccoid bacteria that until 1984 were classified as Group D streptococci.⁵¹⁸ Enterococcal cells are ovoid and occur singly or in pairs or short chains and can grow at temperatures ranging from 10 to 45 °C. *E. faecalis* and *E. faecium* are the most common enterococcal species found in humans. After coagulase-negative staphylococci, *E. faecalis* is the most common bloodstream nosocomial pathogen in the United States and can also cause urinary tract infections, abdominal-pelvic infections, infective endocarditis, and prosthetic joint infections, among other infections.^{519,520} Multiple antibiotic resistance by *E. faecalis* is a major factor in its prominence in nosocomial infections. *E. faecalis* exhibits an intrinsic resistance to many antibiotics, for example, β -lactams antibiotics, most aminoglycosides, and clindamycin,⁵²¹ and can commonly harbor multiple antibiotic resistance determinants carried on transferable plasmids.⁴⁴⁷

The oral cavity is a potential reservoir of *E. faecalis* for entry to root canals. Enterococci were detected in samples from multiple oral sites in 75% of eight endodontic patients,⁵²² but subgingival enterococci were recovered from only 1% of 100 early-onset periodontitis patients and 5.1% of 545 adult periodontitis patients.⁵²³ *E. faecalis* was cultured from oral rinse samples in 11% of 100 patients receiving endodontic treatment and 1% of 100 dental students with no history of endodontic treatment ($p = 0.0027$).⁴⁸¹ Real-time quantitative PCR reported a higher incidence of *E. faecalis* in 30 oral rinse samples (17%) than did culture techniques (5%) and showed that *E. faecalis* accounted for up to 0.005% of the total bacterial load in oral rinse samples.⁵¹⁵ Oral prevalence of *E. faecalis* may vary according to the sampling site and periodontal condition; *E. faecalis* was detected more in tongue than in gingival sulcus, oral rinse, and root

canal samples (43, 14, 10, and 10% of patients, respectively; $p = 0.0148$) and in proportionally greater numbers from patients with gingivitis/periodontitis compared to those with healthy periodontium (73% vs 20%; $p = 0.03$).⁴⁸²

Prevalence of *Enterococci* in Previously Root-Filled Teeth

Both culture and molecular-based studies have demonstrated that *E. faecalis* could also be recovered from root canals with primary infections.^{98,279,514} *E. faecalis* has been repeatedly identified as the species most commonly recovered from root canals of teeth with failed root canal treatment and persistent root canal infections.^{98,108,109,285,524–526} Strains have been recovered from approximately one-third of root canals of failed endodontically treated teeth in culture studies^{108,214,527} and over 70% using PCR-based methods of detection.^{109,514} However, the prevalence rates of *E. faecalis* in root canal infections reported in different studies varies widely (Table 9), and in one study, enterococci were never recovered from endodontically treated teeth with asymptomatic periapical lesions.⁵²⁸

The different prevalence rates of enterococci in infected root canals might be a consequence of geographical location.²²⁹ They could also be due to differences in methods of clinical sampling and sample analysis, particularly since the introduction of molecular methods to analyze root canal samples. For example, using sampling and culture techniques based on the “gold standard” method of Möller,²¹⁴ *E. faecalis* was recovered from root canal samples in 30% of culture-positive cases in Sweden¹⁰⁸ and the United States.¹⁰⁴ In contrast, investigations using 16S rDNA-based endpoint PCR reported that *E. faecalis* was detected in 77% of samples from 22 failed endodontically treated teeth undergoing retreatment¹⁰⁹ and in 67% of 30 cases of persistent endodontic infections associated with root-filled teeth²⁸⁵ in Brazil. In an analysis of the same root canal samples using parallel culture and molecular techniques performed by investigators blinded to the analysis results of the other sample, *E. faecalis* was detected in 10.2% and 79.5% of 88 samples by culture and qPCR, respectively ($p < 0.0001$), and in more failed root filled teeth than primary infection samples (89.6% vs 67.5%; $p = 0.01$). In samples where *E. faecalis* was detected using qPCR, it accounted for up to 100% of total bacterial counts ranging from approximately 10^3 to 10^6 cells per sample.⁵¹⁴ *E. faecalis* was up to three times more prevalent in refractory than primary root canal infections sampled upon access,

*In culture studies refers to prevalence in culture positive sample.

post-instrumentation/irrigation and post-calcium hydroxide treatment.⁵¹³

Information about the prevalence of enterococci in root-filled teeth without signs of apical periodontitis but receiving endodontic retreatment for technical purposes may help elucidate its importance in persistent infection. Molander et al.³⁰¹ cultured enterococci from only 1 of 20 teeth without signs of apical periodontitis undergoing root canal retreatment. Growth was described as sparse. Recent 16S rDNA-based studies comparing the prevalence of *E. faecalis*

in teeth with and without periapical lesions have suggested that *E. faecalis*, although present, does not play a significant role in post-obturation infections.^{512,529} In one study, *E. faecalis* 16S rDNA was detected in 81.5% of 27 root-filled teeth without periapical lesions and 78% of 23 root-filled teeth with periapical lesions.⁵¹² In a study where the overall prevalence of *Enterococcus* spp was low (12.1%), Kaufman et al.⁵²⁹ observed a trend that the presence of enterococcal 16S rDNA was not associated with a periapical lesion.

POTENTIAL ROLE OF *ENTEROCOCCI* IN UNSUCCESSFUL ROOT CANAL TREATMENT

The pathogenicity of enterococci in endocarditis and peritonitis has long been established in animal models.^{530–532} In contrast, despite their frequent recovery, whether *E. faecalis* plays a significant role in the pathogenesis of human root canal infections remains unclear. In studies concerning the survival of selected bacterial strains inoculated into monkey root canals, after 8–12 months *E. faecalis* was the only species to be re-isolated from all 24 root canals as well as produce radiographic evidence of apical periodontitis in all cases.⁵³³ However, *E. faecalis* as a single species in the monkey model caused only low-grade periapical reactions. Only in the presence of other species within an “eight-strain collection” was lesion size larger.⁷⁸ It has been hypothesized that in periapical infections that involve *E. faecalis*, tissue damage may be predominantly caused by the host response to the bacteria

rather than direct damage from bacterial products.⁵³⁴ Thus, the repeated recovery of enterococci from root canal samples may instead represent an ability to survive in the root canal.

The mechanisms by which *E. faecalis* enters and survives in the root canal system for extended periods despite endodontic treatment are not well understood. However, it is well established that *E. faecalis* has the capacity to survive under various stressful environmental conditions, including intracellular survival in macrophages.⁵³⁵ *E. faecalis* was capable of surviving more than 90 days on commonly used hospital fabrics and plastics⁵³⁶ and for up to 4 months in water.⁵³⁷ In an ex vivo model, *E. faecalis* survived in human root-filled teeth for 12 months (Figure 10). In addition, *E. faecalis* is capable of entering and recovering from the viable but non-culturable (VBNC) state, a survival strategy adopted by bacteria when exposed to environmental stress.^{538,539} VBNC *E. faecalis* was detected by RT-PCR in four root canal samples that were negative by cultivation.⁵¹³ VBNC *E. faecalis* displayed cell wall alterations that might

Figure 10 Infection of dentinal tubules by *Enterococcus faecalis* OG1-S after 48-hour incubation (**A** and inset in **B**), and after root canal filling and 12-month incubation (**C** and inset in **D**). Brown and Brenn stain. Reproduced with permission from Sedgley et al. *Int Endod J* 2005;38:735–42.

provide protection under unfavorable environmental conditions⁵⁴⁰ and maintained adhesive properties to cultured human cells.⁵⁴¹ *E. faecalis* produce a variety of stress proteins when exposed to adverse environmental factors such as sodium hypochlorite,⁵⁴² salt, bile salts, acid and heat,⁵⁴³ alkaline stress⁵⁴⁴ glucose starvation,^{545–547} elevated temperatures,⁵⁴⁸ and starvation in tap water.⁵⁴⁸

It has been suggested that enterococci may be selected in root canals undergoing standard endodontic treatment because of low sensitivity to antimicrobial agents,^{549,550} including the ability to resist the high pH of antimicrobial agents commonly used, such as calcium hydroxide paste [Ca(OH)₂] (pH > 11.5).^{323,551,552} For example, *E. faecalis* transcripts of *ftsZ*, a gene involved in cell division, was observed to increase by 37-fold after 5 days incubation at pH 10 at 37 °C.⁵⁵² Love⁵⁵³ postulated that the proficiency with which *E. faecalis* can invade dentinal tubules facilitates protection from chemomechanical root canal preparation and intracanal dressing techniques. In the presence of human serum, *E. faecalis* bound better to collagen than did *S. gordonii* or *S. mutans*.⁵⁵⁴ Another mechanism by which *E. faecalis* colonization of treated root canals with *E. faecalis* might occur is by the formation of coaggregates with other species, for example, *F. nucleatum*.⁵⁰⁰ Coaggregation interactions occurring in biofilms may provide an effective means by which *E. faecalis* remain in the root canal. Using pure cultures of *E. faecalis* in root canals of extracted teeth, experimental biofilms have been grown⁴¹⁴ that appear to vary in terms of ultrastructure and physicochemical properties under different growth conditions.⁵⁵⁵ Furthermore, as *E. faecalis* biofilms on root dentin mature, they exhibit the ability to calcify⁵⁵⁶ which may facilitate their stability.

Virulence factors with the potential to promote adaptation and survival in different environments have been identified in enterococci recovered from infected root canals⁴¹³ as well as other sources.^{414,557–559} These include enterococcus surface protein (Esp), collagen-binding protein (Ace), and AS, as well as factors that enable secretion of proteases (eg gelatinase) and toxins (eg., cytolysin).⁴¹³ Production of serine protease and Ace by *E. faecalis* have been shown to contribute to the ability to bind to dentin,^{414,557} and AS can promote resistance to killing by human neutrophils.⁵⁵⁸ Of 31 *E. faecalis* strains from infected root canals, potential virulence traits expressed included production of gelatinase by 23 strains and production of AS by 16 strains in response to pheromones in *E. faecalis* culture filtrate.⁴¹³ The latter has potential clinical significance as genes relating to antibiotic resistance, as well as viru-

lence traits, can be found on plasmids that respond to pheromones.⁴⁴⁷ Pheromones from *E. faecalis* were chemotactic for human neutrophils and triggered superoxide production,⁵⁵⁹ as well as being potent chemotactic agents for rat neutrophils and inducing lysosomal granule enzyme secretion.⁵⁶⁰ Overall, possession of the above “virulence traits” might provide a selective advantage over other species in the infected root canal that enables survival in teeth.

STREPTOCOCCUS

Description

Streptococcus is a genus of Gram-positive, asporogenous, facultatively anaerobic, catalase-negative cocci or coccoid bacteria. 16S rDNA gene sequencing has shown at least 50 species within the *Streptococcus* genus.⁵⁶¹ They are non-motile and typically approximately 1 μm in diameter, occurring in pairs or chains. Several species can form capsules. *Streptococcus* forms part of the normal commensal microbiota of the mouth, skin, intestine, and upper respiratory tract of humans.

Traditional classification of *Streptococcus* species relied on their phenotypic properties, with four species groups designated A, B, C, and D. Many group D streptococci have been reclassified as *Enterococcus*. Individual species of streptococci were further classified in terms of their hemolytic properties, or ability to lyse red blood cells, as one measure of potential virulence. “Alpha” hemolysis reduces iron in hemoglobin, resulting in a greenish color on blood agar. Alpha hemolytic streptococci are commonly referred to as “viridans” streptococci and are among the major causative microorganisms of infective endocarditis.⁵⁶² *S. mutans*, an important species in dental caries, is an example of alpha hemolytic oral streptococci. “Beta” hemolysis results in complete rupture of red blood cells and gives distinct, clear areas around bacterial colonies on blood agar. Beta hemolytic streptococci, for example, *S. pyogenes*, have been implicated in bacteremia and a range of streptococcal infections, including pharyngitis, rheumatic fever, and acute glomerulonephritis. Another important oral streptococcal species is *S. gordonii* (formerly *S. sanguis*), a normal inhabitant of the oral cavity and an early colonizer in the formation of dental plaque. *S. gordonii* is a causative agent for infective endocarditis, potentially due in part to its ability to avoid polymorphonuclear leukocyte (PMN) killing,⁵⁶³ the presence of a sialic acid-binding adhesion,⁵⁶⁴ and an ability of some strains to aggregate platelets.⁵⁶⁵

Prevalence of *Streptococci* in Previously Root-Filled Teeth

Streptococci were recovered from root canal samples in 6 of 24 culture-positive asymptomatic previously root-filled cases with radiographic evidence of apical periodontitis in Sweden.¹⁰⁸ Culture studies have shown that in teeth with clinical and radiographical signs of apical periodontitis, streptococci (and lactobacilli) appear to survive following root canal treatment although less frequently than enterococci.^{108,301,316,528} In teeth with apical periodontitis receiving endodontic treatment, the most frequently isolated streptococci were *S. gordonii*, *S. anginosus*, and *S. oralis*.³¹⁴ In more than half of the culture positive samples, *S. gordonii* and *S. oralis* still predominated in subsequent samples. *Streptococcus intermedius*, *S. anginosus*, *S. oralis*, and *S. gordonii* recovered from root canals were strong producers of extracellular proteins suggesting that these species may play a significant role in post-treatment apical periodontitis.³¹⁴ Typically, streptococci recovered from periapical lesions are only rarely resistant to antibiotics commonly used for the treatment of endodontic infections.^{566,567}

Potential Role of *Streptococci* in Unsuccessful Root Canal Treatment

In root-filled teeth with persisting periapical lesions, significant positive associations were observed between the presence of a sinus tract and *Streptococcus* spp and between coronally unsealed teeth and *Streptococcus* spp.³⁰² In endodontically treated teeth associated with asymptomatic periapical lesions in patients in Hong Kong, streptococci, as well as coagulase-negative staphylococci and *P. aeruginosa* were most frequently isolated.⁵²⁸ The effect of streptococci on periapical tissue in humans is not well understood. Using FISH colonies with *Streptococcus* spp were seen in some periapical lesions of asymptomatic root-filled teeth,³³⁷ suggesting a positive association. However, in monkeys, 8–12 months after being introduced into root canals, 85% of teeth from which *Streptococcus milleri* was recovered had radiographic evidence of apical periodontitis, although the contribution of anaerobic bacteria to the infection could not be eliminated.⁵³³

Genetic recombination and transfer of genes encoding adhesins, antibiotic resistance determinants, and virulence factors are known to occur in oral streptococci.⁵⁶⁸ Of the oral streptococci, *S. mutans* has been the most widely studied. Horizontal transfer has led to widespread distribution of properties such

as adhesion, acid tolerance, and acidogenicity properties.⁴³³ The virulence factors of *S. mutans* are diverse and are often proteins associated with the cell wall.⁵⁶⁹ More specifically, glucan-binding proteins participate in plaque cohesion and can play a role in the modulation of virulence.⁵⁷⁰

The cell walls of Gram-positive bacteria contain PG and LTA that are released upon lysis of the cell. PG and LTA can bind to cell surface receptors and induce the release of proinflammatory cytokines.⁷⁵ LTAs are present on the cell surface of most oral streptococci³⁸³ and are important virulence factors, sharing many pathogenic properties with the LPS of Gram-negative bacteria.³⁸⁷ Lysis of the bacterial cell induced by lysozyme, cationic peptides from leukocytes, or beta-lactam antibiotics results in release of LTA.

Streptococci also have a large range of cell surface adhesins that facilitate binding to various substrates including other bacterial cells, epithelial cells, and dentin.⁵⁷¹ *S. gordonii* amylase-binding protein A functions as an adhesin to amylase-coated HAP and in human saliva-supported biofilm formation.⁵⁷² Furthermore, streptococci may recognize components present within dentinal tubules, such as collagen type I. This stimulates bacterial adhesion and intra-tubular growth. *S. gordonii* has been shown to invade cervical and midroot dentin up to 200 microns into dentinal tubules, compared to 60 microns at apical dentin.⁵⁷³ In addition, specific interactions between other bacteria and streptococci may facilitate the invasion of dentin by selected bacterial groupings. For example, recognition of the streptococcal antigen I/II polypeptide facilitates coinvasion of dentinal tubules by *P. gingivalis* and *S. gordonii* but not with *S. mutans*.^{494,495} It has been suggested that the potential exists for infective endocarditis to result from bacteria originating in root canals under certain circumstances. For example, if the bacteria possess genes encoding functional binding regions of streptococcal fibronectin-binding protein and staphylococcal fibrinogen-binding protein, bacterial colonization of the endocardium is feasible.⁵⁷⁴

ACTINOMYCES

Description

Actinomyces species are non-spore-forming Gram-positive bacteria occurring as rods, branched rods or filaments, or as rudimentary mycelia. All species can grow anaerobically. Many *Actinomyces* species are commensals in the oral cavity but can become opportunistic pathogens in humans and other

mammals.^{575,576} Occasionally, they cause actinomycosis, a disease characterized by the formation of abscesses in the mouth, lungs, or the gastrointestinal tract. Happonen et al.⁵⁷⁷ reported that *A. israelii* was involved in osteoradionecrosis of the jaws in 1983. Recently, *Actinomyces* has been described as an important pathogen in infected osteoradionecrosis following radiation therapy for head and neck cancer.⁵⁷⁸

Actinomyces species have been implicated in root caries.⁵⁷⁹ Species recovered from active root caries include *A. israelii*, *A. naeslundii*, *Actinomyces gerencseriae*, *Actinomyces odontolyticus*, and *Actinomyces georgiae* with more than one species isolated from individual lesions.⁵⁷⁹ In germ-free rats, *A. israelii* was shown to cause root surface caries and invasion of pulp tissue.⁵⁸⁰ In patients with periodontally affected non-vital teeth, the periodontal pocket may provide a source of *Actinomyces*.⁶⁴

Prevalence of *Actinomyces* in Previously Root-Filled Teeth

In primary root canal infections, reports of recovery of *Actinomyces* are not uncommon.^{279,581} *Actinomyces* was predominant in the apical 5 mm of root canals of extracted teeth with carious pulpal exposures and periapical lesions contiguous with the root apex in culture studies.⁸⁰ *Actinomyces* species also have been implicated in secondary root canal infections non-responsive to conventional treatment.^{315,581} However, most information is limited to that based on case reports following recovery of *Actinomyces* species from persistent lesions following root canal filling,^{582,583} sometimes several years after completion of treatment.^{104,322} The presence of *Actinomyces* in a periapical cyst has also been reported.⁵⁸⁴ Strains of the species *Actinomyces radidentis* were first found in the root canal and periapical abscesses from two patients with persisting infections following endodontic treatment.⁵⁸⁵ Since then, there have been reports of recovery of *A. radidentis* from previously filled root canals in endodontic patients who had persistent signs and symptoms after conventional root canal treatment^{586,282} and also in two primary infection cases.²⁸²

Potential Role of *Actinomyces* in Unsuccessful Root Canal Treatment

Actinomyces species can be fimbriated or non-fimbriated. Fimbriae on the surface of the *A. israelii* cell wall can be detected using electron microscopy.³⁹⁴ These structures may be involved in coaggregation interactions with other bacteria,^{587,588} and it has been

speculated that they contribute to the pathogenicity of *A. israelii*.³⁹⁴ The higher cell surface interactive forces associated with fimbriated compared to non-fimbriated *Actinomyces* may contribute to modulation of their adhesion and coaggregation properties.³⁹⁰ In mice, intraperitoneal injections of *A. israelii* and *A. naeslundii* produced suppurative lesions.⁵⁸⁹ In other studies using guinea pigs, it was concluded that the pathogenicity of *A. israelii* was due to the ability of the branching filamentous organisms to evade elimination by host phagocytic cells.⁵⁹⁰

PROPIONIBACTERIUM

Description

Propionibacterium species are slow-growing, non-sporulating, Gram-positive anaerobic rods with propionic acid, an end product of fermentation. While *Propionibacterium* species are normal inhabitants of the skin and usually nonpathogenic,⁵⁹¹ they are also common contaminants of blood and body fluid cultures. The human cutaneous propionibacteria include *P. acnes*, *Propionibacterium avidum*, *Propionibacterium granulosum*, *Propionibacterium innocuum*, and *P. propionicum* (also called *Propionibacterium propionicus*, and formerly *Arachnia propionica*). They can be opportunistic pathogens, causing a diverse collection of infections that includes acnes vulgaris,⁵⁹² brain abscesses,⁵⁹³ central nervous system infections,⁵⁹⁴ and infective endocarditis.⁵⁹⁵ *P. propionicum* is frequently associated with infections of the lacrimal apparatus⁵⁹⁶ and has been implicated as a less common causative agent of a disease process similar to actinomycosis.⁵⁹⁷ *P. propionicum* has been cultured from shallow and deep coronal caries⁵⁹⁸ and deep layers of infected root canal dentin.⁵⁹⁹

Prevalence of *Propionibacteria* in Previously Root-Filled Teeth

P. propionicum was detected in 52% of failed endodontic cases using PCR¹⁰⁹; using a nested PCR method, the same group reported that *P. propionicum* 16S rDNA was detected in samples from 7/12 (58%) root-filled teeth with chronic periapical lesions compared to 6/21 (29%) previously untreated teeth with chronic periapical lesions.²⁸² In teeth with apical periodontitis undergoing root canal treatment, the most frequent Gram-positive rod species cultured was *P. propionicum*, in addition to *O. uli* and *L. paracasei*.³¹⁵ *Propionibacterium* species were detected in refractory endodontic

cases²⁸² and survived in the periapical tissues of a tooth that did not respond to conventional endodontic therapy.⁶⁰⁰ *P. acnes* was identified in the root canal and blood of the same patient using molecular methods.⁶⁰¹

Potential Role of *Propionibacteria* in Unsuccessful Root Canal Treatment

Although a *P. propionicum* isolate from a failed root-filled tooth did not survive in connective tissue in guinea pigs,⁵⁹⁰ there is some evidence that the species possesses characteristics that might facilitate its survival in conditions found in the treated root canal, including an ability to penetrate into dentinal tubules.⁶⁰² The surface fibrillar layer that forms part of a complex cell wall structure contributes toward resistance to phagocytosis. In addition, *Propionibacterium* can survive and persist intracellularly in macrophages.⁶⁰³ *P. acnes* was shown to survive for 8 months under anaerobic conditions without subculture in vitro, suggesting that it could also survive in human tissues at low oxidation potentials.⁶⁰⁴

Propionibacterium species produce proinflammatory mediators, including lipases, neuraminidases, phosphatases, and proteases.⁶⁰⁵ Their virulence is thought to be associated with an ability to cause direct damage to the host by means of bioactive extracellular products and metabolites.⁶⁰⁵ In particular, *P. acnes* can induce the production of cytokines IL-1 α , IL-1 β , IL-8, and tumor necrosis factor (TNF)- α by monocytes⁵⁹² and is a potent adjuvant in terms of the ability of its products to modulate the immune response to unrelated antigens.⁶⁰⁶ Thus far, there appear to be no reports of multiply-antibiotic-resistant root canal isolates. *P. acnes* isolates from necrotic pulps were sensitive to amoxicillin, amoxicillin combined with clavulanate, and tetracycline.²⁸⁷

YEASTS

Description

Yeasts are unicellular fungi. The most clinically relevant yeasts belong to the large heterogeneous genus *Candida*, with members forming part of the commensal microbiota in many parts of the human body. *Candida* species can also be opportunistic pathogens as they have the ability to colonize and infect nearly all human tissues.⁶⁰⁷ They make up 12% of bacteremias in intensive care units,⁵¹⁹ and are a leading cause of infections in immunocompromised hosts, causing systemic candidiasis in severely immunocompromised patients. *C. albicans* is the most common oral yeast, with other

relevant species being *Candida glabrata*, *Candida krusei*, and *Candida tropicalis*.⁶⁰⁷ Non-*C. albicans* yeast infections may occur in patients who have received azole-based antifungal therapy.⁶⁰⁸ *C. albicans* cells are significantly larger than bacteria and can switch between several different phenotypes in a manner that is heritable and reversible.⁶⁰⁹ *Candida* spp reproduce by means of multilateral budding and can form biofilms and tolerate a range of pH conditions. The cell walls are rigid and contain mannan, glucan, and chitin. Cell surface hydrophobicity and pH influence the adherence of *Candida* to host cells.⁶⁰⁷

Prevalence of Yeasts in Previously Root-Filled Teeth

While yeasts are occasionally recovered from primary root canal infections,²⁸³ they may be more frequently recovered from root canals of obturated teeth in which treatment has failed.⁶¹⁰ Yeasts may gain access to the root canal during treatment via contamination.⁵²⁷ The presence of yeasts in root canals was significantly associated with their presence in saliva²⁸³ and with coronally unsealed teeth.³⁰² On the other hand, it has been suggested that the incidence of yeasts in root canals may be under-detected in some studies because selective media was not used.⁶¹¹

While there appears to be sufficient data to consider yeasts as potential non-bacterial causes of endodontic failures,⁶¹² it is not clear if the prevalence of *Candida* is different in teeth with primary compared to secondary root canal infections. Culture studies showed that 10% of primary cases involved the presence of *Candida* spp,²⁸³ compared to 15% and 3% of root-filled teeth with chronic periodontitis in Lithuania¹⁰⁷ and Sweden,³⁰¹ respectively, and 7% of culture positive samples in 967 samples from persistent endodontic infections in Finland.⁶¹³ Using PCR, *C. albicans* was detected in 21% of infected root canals¹ and 9% of cases of failed endodontic therapy.¹⁰⁹ Along with other species, yeasts were cultured from samples taken from periapical tissues of teeth with refractory apical periodontitis,³³³ but were not detected in aspirates from cellulitis/abscesses of endodontic origin using PCR.¹ Yeasts were recovered from 2 of 18 endodontically treated teeth with asymptomatic periapical lesions.⁵²⁸ Evidence for the presence of *Candida* species in refractory periapical lesions was not found using PCR methods,⁶¹⁴ but was found in two of 36 cases (6%) using culture methods.³¹⁶

Potential Role of Yeasts in Unsuccessful Root Canal Treatment

In 4 of 10 extracted teeth with necrotic pulps and periapical lesions, heavy infection with yeasts was observed under scanning electron microscopy (SEM),⁷ and subsequent SEM studies showed hyphae and budding yeast cells (blastospores) penetrating into dentinal tubules suggesting that *C. albicans* had an affinity to dentinal structures.⁸ Penetration into dentinal tubules by *C. albicans* was less than *E. faecalis* in vitro.⁶¹⁵ Thick biofilm formation was associated with the presence of the smear layer, suggesting it provided a suitable substrate for attachment and growth of *C. albicans*.⁸ This was supported by the observation that, following dentin treatment with ethylene diamine tetraacetic acid (EDTA) and NaOCl to remove smear layer, biofilm formation by *C. albicans* was hindered.⁶¹⁶

Clinical strains of *C. albicans* recovered from infected root canals in samples in Finland revealed genotypic and phenotypic diversity,⁶¹⁷ but were similar to strains from other oral and non-oral sites, suggesting that *C. albicans* strains from infected root canals do not require unique characteristics to exist in the root canal environment.⁶¹⁸ Yeasts may play an important role in cases of persisting apical periodontitis, although the mechanisms are not clear. Nair et al.¹¹² studied therapy-resistant root canal infections and found yeast-like organisms in two of six specimens with microorganisms.

Streptococcus species were the most frequent facultative bacteria accompanying yeasts in root canal samples associated with persistent endodontic infections.⁶¹³ *C. albicans* has been observed to coaggregate with some oral streptococci,^{503,619} a phenomenon that is enhanced when the yeast is in a starvation stage.⁶²⁰ Coaggregates also form between *C. albicans* and oral *Fusobacterium*,⁶²¹ and *Actinomyces*⁶²² species. Characteristics of *C. albicans* that might contribute to apical periodontitis were reviewed by Waltimo et al.⁶¹⁸ Possible factors include the ability to adhere to dental tissues, the utilization of hyphae to penetrate into dentinal tubules, and a form of contact sensing that allows hyphae to identify breaks on surfaces or between cells through which hyphae can penetrate (“thigmotropism”). Secretion of proteases that allow degradation of human proteins may also be a contributory factor. Secreted aspartyl proteinases (Sap proteins) at tissue lesion sites have been shown to directly contribute to *C. albicans* pathogenicity.⁶²³ The Sap proteins digest molecules for nutritional purposes, disrupt host cell membranes for adhesion and invasion, and also target immune cells

for digestion or to avoid killing, for example, by acting as cytolysins in macrophages after *Candida* has been phagocytosed.⁶²⁴ The ability to switch between phenotypes to allow adaptation to different ecological conditions and between the yeast form and hyphae form may also contribute to pathogenicity although the mechanisms are not clear.⁶¹⁸

OTHER SPECIES

Species from the family *Enterobacteriaceae* and the genera *Lactobacillus*, *Peptostreptococcus*, and *Fusobacterium* have also been occasionally cultured from previously root-filled teeth in studies from Sweden, Hong Kong, and the United States.^{104,108,301,302,528} Positive associations were observed between lactobacilli and Gram-positive cocci in teeth with apical periodontitis undergoing root canal treatment.³¹⁵ *Lactobacillus* is a genus of Gram-positive asporogenous bacteria that are anaerobic, microaerophilic, or facultatively aerobic and are generally considered non-pathogens,⁶²⁵ apart from their association with dental caries.⁶²⁶ In culture-based studies, the obligate anaerobes, peptostreptococci, have been occasionally recovered.^{104,108,301,302,528} The recovery of peptostreptococci from root-filled teeth with persisting periapical lesions was significantly associated with the presence of clinical symptoms³⁰² and when root canal therapy had been completed more than 3 years earlier.¹⁰⁴

Using PCR-based methods, several other species have been identified as putative pathogens in samples from root-filled teeth requiring endodontic retreatment.¹¹¹ These include *P. alactolyticus* (52%), *D. pneumosintes* (48%), and *F. alocis* (48%) in 22 root-filled teeth with persistent periapical lesions selected for re-treatment.¹⁰⁹ In PCR assays, *T. forsythia* (previously called *B. forsythus*) was detected in 14% of samples from 14 previously root-filled teeth from a South Korean population.⁶²⁷ *D. invisus*, *Synergistes* oral clone BA121, and *O. uli* were detected in canals of previously treated teeth with persistent infections.²⁴⁸ The viability, pathogenicity, and relative proportion of these species in root canal infections has not been established.

In contrast, in 50 teeth with unsuccessful endodontic treatment, 16S rDNA sequences from the black-pigmented bacteria *P. gingivalis*, *P. endodontalis*, *P. intermedia*, and *P. nigrescens* were identified less frequently in teeth with failing endodontic treatment (36%) compared to teeth with necrotic pulp (64%),²²³ suggesting that these species may not play an important role in infections associated with unsuccessful endodontic treatment.

From the above, it is apparent that the pathogenicity of specific bacterial species, or combinations of species identified in secondary root canal infections in humans, has yet to be unequivocally established in controlled studies. In addition, a better understanding of the role of specific virulence traits associated with microorganisms in root canal infections may help understand the process and ultimately identify therapeutic targets.

Microorganisms and Endodontic Flare-Ups

ENDODONTIC FLARE-UPS

An endodontic flare-up is defined by the American Association of Endodontists (AAE) as “an acute exacerbation of an asymptomatic pulpal and/or periapical pathosis after the initiation or continuation of root canal treatment.”⁶²⁸ Flare-ups are unpredictable events with reported prevalence rates varying from 1.4% to 19% (see Chapter 21). Presenting symptoms include pain with or without swelling^{629–631} that is of sufficient severity for the patient to seek emergency treatment.⁶³²

Flare-ups can be distressing and disruptive events for both patients and clinicians. Consequently, several investigations have focused on associations between the flare-up event and corresponding pre-treatment clinical factors. The definition of a flare-up has varied among studies. However, in accordance with the current AAE definition,⁶²⁸ the most likely predisposing clinical condition for its occurrence appears to be asymptomatic necrotic pulp with periapical lesion.^{629,631,633} Where symptomatic pre-treatment patients have been included in the study cohort, predisposing conditions include acute apical abscess, acute apical periodontitis,^{629,631,634} preoperative pain,⁶³⁵ and swelling.⁶³⁰

It is well established that the presence of microorganisms in the dental pulp is directly associated with the development of periapical disease.^{72,77,78,318,509} In contrast, the specific means by which microbes contribute to endodontic flare-ups is less clear. The flare-up etiology is likely multifactorial, and dependent on the interactions between the host immunological response, infection, and physical damage,⁶³⁰ with the major causative factor described as microbial in origin.^{632,636,637} While there is sound circumstantial evidence for the latter assumption, direct proof is lacking. Indirect support is found in studies showing that the lowest incidence of flare-ups occurred in patients with-

out periapical pathosis^{629,631,638} and when a sinus tract is present^{629,634,639} the latter presumable permitting some form of drainage.

Interestingly, other factors that might be expected to contribute to a predominantly microbiological etiology have been reported to have no association with the occurrence of flare-ups. These include incomplete root canal debridement,^{629,640,641} under-filled canals,⁶⁴² over-instrumentation beyond the apex⁶³⁴ where extrusion of infected debris might be expected to occur, and the use of antimicrobial intracanal medicaments.^{634,643} Perhaps most unexpectedly if residual viable bacteria are the major cause of flare-ups, prophylactic antibiotics are ineffective in their prevention. This has been established in a series of prospective, randomized, double-blind, placebo-controlled clinical trials that found prophylactic antibiotics (penicillin or amoxicillin) to be ineffective in preventing post-treatment flare-ups in cases of pulpal necrosis and periapical lesions in asymptomatic^{644,645} and symptomatic⁶⁴⁶ teeth as well as in untreated teeth with irreversible pulpitis.⁶⁴⁷ Other reports indicate that the prevention of flare-ups was better managed with intracanal medicaments containing steroids^{648,649} and anti-inflammatory agents.⁶⁵⁰

The above suggests that viable microorganisms remaining after treatment procedures may not be as critical to the development of a flare-up like the interactions between immunological factors, microbial breakdown products, and the collateral damage resulting from treatment procedures. Occasionally, environmental changes in the infected root canal and associated periodontium of a clinically asymptomatic tooth following root canal treatment procedures can trigger a severe host response. It has been hypothesized that the “immunological status of the periapical tissue may predispose patients to develop a post endodontic flare-up.”⁶³⁰ Fortunately, the occurrence of an endodontic flare-up does not appear to influence the long-term prognosis of the tooth. Sjögren et al.³⁴⁰ reported that the occurrence of flare-ups had no significant influence on the outcome of endodontic treatment when reviewed 8 to 10 years later.

ASSOCIATIONS BETWEEN SPECIFIC BACTERIA AND ENDODONTIC FLARE-UPS

Very few studies have investigated the microbiological aspects of flare-ups, and there are no case controlled studies. The low incidence of flare-ups makes conducting prospective clinical studies with appropriate controls for microbiological analyses particularly difficult, in part because of the need for sufficiently large

numbers of samples to allow statistical analyses. In addition, baseline data about the preoperative flare-up microbiota, including yeasts and viruses, should ideally be available. Future studies utilizing microarray technology that will allow rapid detection of multiple bacterial species in a single sample have the potential to make this task less arduous. In view of the importance of the role of the host, such studies could apply multiple qualifiers to account for the status of the host as well as the potential pathogens.⁶⁵¹

An early study found no difference between the microbiota of asymptomatic teeth and those presenting with flare-ups; however, strict anaerobic methods were not used.⁶⁵² More recently, Chavez de Paz⁴²³ examined the root canal microbiota of 28 patients who had originally received treatment for non-painful teeth with necrotic pulp and periapical lesions and subsequently developed symptoms necessitating emergency treatment. Correlations were made between the severity of pain and the culturable root canal microbiota. The recovery of *F. nucleatum* was associated with the most severe flare-up pain and swelling. Similarly, Peciuliene et al.¹⁰⁷ reported that *F. nucleatum* was isolated (along with *E. faecalis* and *A. israelii*) from an asymptomatic root-filled tooth with chronic apical periodontitis undergoing retreatment that had a flare-up after the first appointment.

Other isolates identified in the root canal microbiota of teeth with flare-ups were Gram-negative obligate anaerobic rods belonging to the genera *Prevotella* and *Porphyromonas*.⁴²³ Chavez de Paz suggested that the combination of *F. nucleatum*, *Prevotella* species, and *Porphyromonas* species may provide a risk factor for endodontic flare-ups by acting in synergy to increase the intensity of the periapical inflammatory reaction.⁴²³ This hypothesis is supported by an animal study demonstrating that root canal isolates of *F. nucleatum* combined with either *P. gingivalis* or *P. intermedia* induced more severe pathologic subcutaneous lesions in mice in mixed compared to pure cultures.⁶⁵³

Fusobacterium, *Prevotella*, and *Porphyromonas* are non-motile Gram-negative anaerobic rods belonging to the *Bacteroidaceae* family that are found in the human mouth and intestine. Because of their frequent recovery from asymptomatic cases¹¹¹ in addition to flare-up cases, further information is required to understand their role, if any, in endodontic flare-ups. However, it is possible that alterations in the root canal environment and surrounding periodontium as a result of treatment procedures might modulate interspecies interactions and in doing so facilitate virulence. For example, the pathogenic potential of *F. nucleatum*

might be enhanced as a result of synergistic associations with *P. micra*,³⁶⁶ another species frequently recovered from root canal infections.¹¹¹

Virulence factors released by fusobacteria can engender numerous biologic effects. For example, *F. nucleatum* LPS applied to pulp tissue in rats induced a rapid immune response⁶⁵⁴ and produced a large array of biological effects in macrophage-like cells (U937 cells) by directly upregulating several proinflammatory cytokines (IL-1, IL-6, TNF- α , and IL-8).⁶⁵⁵ In addition, production of butyric acid by *F. nucleatum* can stimulate inflammatory cytokine release in neutrophils.⁴¹⁷

Prevotella and *Porphyromonas* species have been isolated from numerous anatomic sites,⁶⁵⁶ and are frequently detected in root canal samples from asymptomatic and symptomatic root canal infections, and aspirates from acute periapical abscesses.^{89,111} They are sometimes generically identified as “BPB” based on the fact that some species form brown or black pigments when cultured on blood-containing media. Various virulence factors have been associated with these species. In vitro studies using human dental pulp cells have shown that LPS from *P. endodontalis* stimulated IL-1 β release³⁶⁸ and IL-8 expression.³⁶⁹ The expression of the pro-angiogenic VEGF in odontoblast-like cells and macrophages was upregulated by *P. intermedia* LPS.³⁷⁰ Fimbriae associated with *P. intermedia* induced hemagglutination activity.^{393,394}

ASSOCIATIONS BETWEEN SPECIFIC BACTERIA AND ENDODONTIC SYMPTOMS IN GENERAL

In contrast to the paucity of data on microbiological aspects of flare-ups, there are several cohort studies that have looked for associations between specific species, or groups of species, and various clinical symptoms. Direct extrapolation of these data to the etiology of flare-ups has yet to be proven. However, it is reasonable to expect that similar virulence mechanisms are involved. In general, the release of various bacterial components (eg., LPS, LTAs, and PGs) can give rise to the synthesis of proinflammatory cytokines. For example, LPS enhances bone resorption,^{367,374} inflammation,⁶⁵⁷ and pain.^{375,377,658}

Several studies have obtained microbiological samples from cohorts of patients with and without symptoms. For example, BPB species in 35 symptomatic and 27 asymptomatic root canal infections, *P. gingivalis* and *P. endodontalis*, were present only in symptomatic infections, while *P. intermedia nigrescens* was found both in symptomatic and in asymptomatic infections, and *P. denticola* occurred mostly in asymptomatic infections.⁸⁹ At 1-week review, BPB species

were isolated in 9 of the 11 teeth that remained symptomatic compared to less than half of the 51 teeth that were symptom-free. This suggests that the presence of BPB at the start of treatment could be associated with the continuation of symptoms.

In single-cohort studies, the occurrence of symptoms has been associated with BPB^{88,92,102,415,659,660} and *Streptococcus* species²³² in root canals. A positive correlation was noted between BPB and purulent drainage, but no other clinical signs, in samples from root canals of intact teeth with necrotic pulps and apical periodontitis.¹⁰² Specifically, the presence of black-pigmented anaerobic bacteria and other *Bacteroides* species in infected root canals was associated with foul odor, pain, and sinus tracts in cariously and traumatically exposed non-vital teeth.⁸⁸ Gomes et al.⁶⁵⁹ reported that both *Prevotella* and *Peptostreptococcus* species were isolated from significantly more painful than painless teeth. *P. micra* previously *Peptostreptococcus micros* has been associated with endodontic abscesses in children.⁶⁶¹

Environmental changes in the infected root canal favor the development of an increasingly anaerobic environment over time.⁷⁷ The root canals of symptomatic teeth harbor more obligate anaerobes than do asymptomatic teeth.⁶⁶⁰ Certain combinations of obligate anaerobes might be associated with certain symptoms.⁶⁶² For example, there were significant associations between (1) pain and the combination of *Peptostreptococcus* species and *Prevotella* species; (2) swelling and the combination of *P. micra* and *Prevotella* species; and (3) wet canals and the combinations of *Eubacterium* species with either *Prevotella* species or *Peptostreptococcus* species.⁶⁶² Synergistic interactions between species might enhance virulence. For example, *P. micra* from necrotic infected root canals enhanced the pathogenicity of other bacteria black-pigmented anaerobic bacteria in mixed experimental infections in guinea pigs.⁵⁰⁶

Significant relationships were reported concerning percussion pain and the bacteria, *Peptostreptococcus*, *Eubacterium*, and *Porphyromonas* and concerning odor and *Porphyromonas* and *Prevotella* in the infected root canals of a cohort of 25 patients.⁹² Phenotypic analyses of the recovered strains showed that subacute clinical symptoms with percussion pain were associated with bacteria producing collagenase or chondroitinase and hyaluronidase. Recovery of collagenase-producing bacteria in root canal samples was associated with periapical radiolucencies larger than 5 mm in diameter.⁴¹⁵

In contrast to the above, other studies have reported no association between specific clinical symptoms and BPB,²³² *P. micra*,²⁸⁴ and the combination of *T. denticola*,

P. gingivalis, and *T. Forsythia*.²⁴⁰ The recovery of *Fusobacterium* species, *P. micra*, and *P. gingivalis* did not differ in cohorts of symptomatic and asymptomatic patients.²³⁰ Associations have been made between apical periodontitis and the cytomegalovirus and EBV in the pathogenesis of symptomatic periapical lesions associated with permanent^{5,6,294,296,663} and deciduous⁶⁶⁴ teeth. Obtaining adequate controls from the same patient to control for the virus existing in latent form presents unique challenges in these studies.

Information on specific virulence factors associated with specific strains recovered from root canal infections is limited. Because different strains of a species recovered from infected root canals can express different virulence factors,⁴¹³ this suggests a capacity to modulate virulence under varying environmental conditions.⁶³² This may help explain the apparent disparity of the same species being recovered from both symptomatic and asymptomatic cases.^{89,102,111} In addition, the importance of the host cannot be overstated and can help explain why only small numbers of virulent microorganisms may be sufficient to cause disease in an immunocompromised host.³⁵¹

Overview of Bacterial Biofilms

Biofilm is a mode of microbial growth where dynamic communities of interacting sessile cells are irreversibly attached to a solid substratum, as well as each other, and are embedded in a self-made matrix of extracellular polymeric substances (EPS).⁶⁶⁵ A microbial biofilm is considered a community that meets the following four basic criteria: The microorganisms living in the community (1) must possess the abilities to self-organize (*autopoiesis*); (2) resist environmental perturbations (*homeostasis*); (3) must be more effective in association than in isolation (*synergy*); and (4) respond to environmental changes as a unit rather than single individuals (*communality*).⁶⁶⁶ Dental plaque is the typical example of a biofilm.

In the past, bacteriological studies were conducted on free-floating bacterial cells (*planktonic state*), ignoring the importance of the sessile bacterial cells (*biofilm state*).⁶⁶⁷ Ironically, in nature, pure cultures of free-floating bacteria rarely exist. Biofilms can be formed wherever there is a flow of fluid, microorganisms, and a solid surface. It is one of the basic survival strategies employed by bacteria in all natural and industrial ecosystems in response to starvation. The sessile bacterial cells in a biofilm state differ greatly from their planktonic counterparts. Inside a biofilm, the bacterial cells exhibit altered phenotypic properties and are

protected from antimicrobials, environmental stresses, bacteriophages, and phagocytic amoebae. Biofilms are responsible for most of the chronic infections and almost all recalcitrant infections in human beings, as bacteria in a biofilm are resistant to both antibiotic therapy and host defense mechanisms.⁶⁶⁸ However, common biofilms found in the oral cavity and gastrointestinal tract are protective in nature. These biofilms featuring a large number and diverse array of commensal bacteria hinders the adherence of pathogenic microorganisms.⁶⁶⁹

ULTRASTRUCTURE OF BIOFILM

A fully developed biofilm is described as a heterogeneous arrangement of microbial cells on a solid surface. The basic structural unit of a biofilm is the microcolonies or cell clusters formed by the surface adherent bacterial cells. Microcolonies are discrete units of densely packed bacterial cell (single or multispecies) aggregates. There is a spatial distribution of bacterial cells (microcolony) of different physiological and metabolic states within a biofilm. A glycocalyx matrix made up of EPS surrounds the microcolonies and anchors the bacterial cell to the substrate.⁶⁷⁰ Eighty-five percent by volume of the biofilm structure is made up of matrix material, while 15% is made up of cells. A fresh biofilm matrix is made of biopolymers such as polysaccharides, proteins, nucleic acids, and salts.^{671,672} The structure and composition of a matured biofilm is known to modify according to the environmental conditions (growth conditions, nutritional availability, nature of fluid movements, physicochemical properties of the substrate, etc). Figure 11 represents the structure of a

mature biofilm. Typically, a viable, fully hydrated biofilm appears as “tower-” or “mushroom”-shaped structures adherent to a substrate. The overall shape of a biofilm structure is determined by the shear forces generated by the flushing of fluid media. Biofilms formed in high-shear environments have shown that the microcolonies are deformed by these forces to produce tadpole-shaped oscillation in the bulk fluid. Advanced microscopy of living biofilms have revealed that single-species biofilms growing in the laboratories to complex multispecies biofilms growing in the natural ecosystems have similar basic community structure, with some subtle variations.⁶⁷³

The water channels, which are regarded as a primitive circulatory system in a biofilm, intersect the structure of biofilm to establish connections between the microcolonies. Presence of water channels facilitates efficient exchange of materials between bacterial cells and bulk fluid, which in turn helps to coordinate functions in a biofilm community.⁶⁶⁵ The structural feature of a biofilm that has the highest impact in chronic bacterial infection is the tendency of microcolonies to detach from the biofilm community. During the process of detachment, the biofilm transfer particulate constituents (cells, polymers, and precipitates) from the biofilm to the fluid bathing the biofilm.⁶⁷⁴ There are two main types of detachment process: erosion (the continual detachment of single cells and small portions of the biofilm) and sloughing (the rapid, massive loss of biofilm). Detachment has been understood to play an important role in shaping the morphological characteristics and structure of mature biofilm. It is also considered as an active dispersive mechanism (*seeding dispersal*). These detached cells, which have acquired the resistance traits from the

Figure 11 Schematic representation of the structure of a mature biofilm. Courtesy A. Kishen.

parent biofilm community, can be source for persistent infection.⁶⁷⁵

Bacterial colonization and biofilm formation can alter the physicochemical properties of many substrates. The EPS and the metabolic activities of bacteria within a biofilm determine the physicochemical characteristics of the substrate. Bacterial cell surfaces are typically anionic due to the presence of carboxylate or phosphate moieties in capsular or cell wall polymers. Therefore, a colonized substrate will acquire an anionic character, regardless of its original physicochemical properties. Under a favorable environment, metal ions including Ca^{2+} , Mg^{2+} , and Fe^{3+} will readily bind to and precipitate within anionic biofilms, inducing biofilm-mediated mineralization.⁶⁷⁶

CHARACTERISTICS OF BIOFILM

Bacteria in a biofilm state show distinct capacity to survive tough growth and environmental conditions. This unique capacity of bacteria in a biofilm state is due to the following features: (1) biofilm structure protects the residing bacteria from environmental threats; (2) structure of biofilm permits trapping of nutrients and metabolic cooperativity between resident cells of same species and/or different species; (3) biofilm structures display organized internal compartmentalization, which allows bacterial species with different growth requirements to survive in each compartment; (4) bacterial cells in a biofilm community may communicate and exchange genetic materials to acquire new traits.

PROTECTION OF BIOFILM BACTERIA FROM ENVIRONMENTAL THREATS

Bacteria residing in a biofilm community experience certain degree of protection and homeostasis. Many bacteria are capable of producing polysaccharides, either as cell surface structures (eg., capsule) or as extracellular excretions (eg., EPS). EPS covers biofilm communities and creates a microniche favorable for the long-term survival and functioning of the bacterial communities.⁶⁷⁷ EPS protects the biofilm bacteria from a variety of environmental stresses, such as UV radiation, pH shifts, osmotic shock, and desiccation.^{678–680} EPS can sequester metals, cations, and toxins.^{681,682} Metallic cations such as magnesium and calcium minimize electrostatic repulsion between negatively charged biopolymers, increasing the cohesiveness of the EPS matrix.⁶⁸³ Diffusion is the predominant transport process within cell aggregates. The diffusion distance in a planktonic cell is on the order of magnitude of the dimension of an individual cell, while the diffusion

distance in a biofilm is on the order of the dimension of the multicellular aggregate. A biofilm that is 10 cells thick will exhibit a diffusion time 100 times longer than that of a single cell.⁶⁸⁴ Furthermore, diffusion of compounds into the biofilm depends upon the nature of both the compound and the EPS matrix. EPS can physically prevent the permeability of certain compounds into the biofilm by acting as an ion exchanger.^{677,678,680}

NUTRIENT TRAPPING AND ESTABLISHMENT OF METABOLIC COOPERATIVITY IN A BIOFILM

An important characteristic of biofilms growing in a nutrient-deprived ecosystem is its ability to concentrate trace elements and nutrients by physical trapping or by electrostatic interaction.⁶⁷⁷ Besides, the highly permeable and interconnected water channels in the biofilm provide an excellent means for material exchange. The water channel connects the outer fluid medium with the interior of the biofilm, ensuring nutrient availability to microbial communities deep inside the biofilm structure.

The complex architecture of a biofilm provides the opportunity for metabolic cooperation, and niches are formed within these spatially well-organized systems. Bacterial microcolonies in a biofilm structure are exposed to distinct environmental signals. For example, cells located near the center of a microcolony are more likely to experience low oxygen tensions compared to cells located near the surface. Moreover, due to the juxtapositioning of different microorganisms, cross-feeding and metabolic cooperativity between different species of microorganisms are seen in a biofilm.^{685,686} Studies have reported the production of essential growth factors such as hemin by *W. recta* to support the growth of fastidious organisms such as *P. gingivalis* in a biofilm.⁶⁸⁶ In addition, each bacterial species residing in a biofilm possess different array of lytic enzymes, and a biofilm as a unit is equipped with a wide spectrum of enzymes that can degrade complex organic materials. For instance, bacterial species possessing proteolytic enzymes make nutrients available to all other bacteria in a protein-rich environment.⁶⁸⁷

ORGANIZED INTERNAL COMPARTMENTALIZATION IN BIOFILM

Environmental niches that support the physiological requirements of different bacterial species are available in a biofilm. A mature biofilm structure displays gradients in the distribution of nutrients, pH, oxygen,

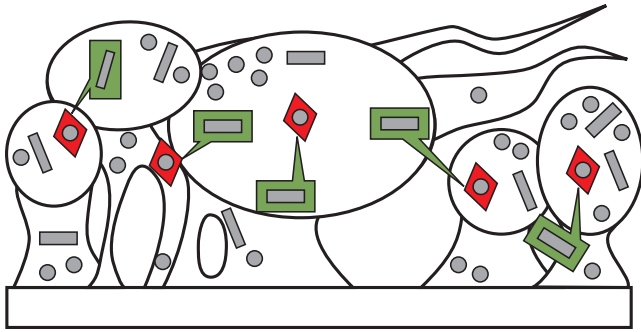

Figure 12 Schematic diagram representing cell–cell communication in a biofilm. Some bacteria can produce chemical signals (green) and other bacteria from the same species or from different species or strain can respond to them (red). Reproduced with permission from Al Cunningham et al.⁶⁸⁴

metabolic products, and signaling molecules within the biofilm (Figure 12). This would create different micro-niche that can accommodate diverse bacterial species within a biofilm. The gradients in nutrients, chemicals, and gases, observed in a biofilm structure, are influenced by the type of nutrients and the physiological requirements of the residing microorganisms.⁶⁸⁸ In a multispecies biofilm involving aerobic and anaerobic bacteria, oxygen is consumed by the aerobic and facultative anaerobic species, making the environment rich in carbon dioxide and other gases. When the aerobic bacteria residing on the surface of the biofilm consumes all available oxygen, the interior of the biofilm can be absolutely anaerobic that it can even support the growth of obligatory anaerobes. Despite the fact that oral cavity is abundant in oxygen, anaerobic microbes are found to dominate oral biofilms because of the possible redox gradient formed within the biofilm structure.⁵¹⁹

BACTERIAL CELLS RESIDING IN A BIOFILM COMMUNICATE, EXCHANGE GENETIC MATERIALS, AND ACQUIRE NEW TRAITS

Bacterial biofilm provides a setting for the residing bacterial cells to communicate with each other. Some of these signals, produced by cells, may be interpreted not just by members of the same species, but by other microbial species too. Communications between bacterial cells residing in a biofilm is attained through signaling molecules, by a process called *quorum sensing*. Quorum sensing is mediated by low molecular weight molecules, which in sufficient concentration can alter the metabolic activity of neighboring cells, and coordinate the functions of resident

Figure 13 Schematic diagram showing quorum sensing in biofilm bacteria. Reproduced with permission from Al Cunningham et al.⁶⁸⁴

bacterial cells within a biofilm.^{689,690} The process of cell–cell communication and quorum sensing is illustrated in Figures 12 and 13, respectively. Exchange of genetic materials between bacterial species residing in a biofilm will result in the evolution of microbial communities with different traits. Close proximity of microbial cells in a biofilm facilitates genetic exchange between bacteria of genetically distant genera.⁶⁹¹ Even the possibility of gene transfer between a commensal organism (*Bacillus subtilis*) and oral biofilm bacteria (*Streptococcus* species) has been demonstrated.⁶⁹² The horizontal gene transfer is of importance in human diseases caused by bacterial biofilm as it can result in the generation of antibiotic-resistant bacterial population. Gene transfer between bacteria residing in a biofilm is thought to be mediated by bacterial conjugation. The presence of diverse bacterial species in a biofilm presents a pool of genetic codes for nutrient breakdown, antibiotic resistance, and xenobiotic metabolism. Cell–cell communication can result in the coordinated behavior of microbial population residing in a biofilm.

DEVELOPMENT OF BIOFILM

Bacteria can form biofilms on any surface that is bathed in a nutrient-containing fluid. The three major components involved in biofilm formation are bacterial cells, a solid surface, and a fluid medium. Development of biofilm is influenced by the physicochemical properties of the components involved in the biofilm and is

shown in Figure 14.^{689,693–695} Figure 15 shows the step-by-step manner of biofilm formation. The first step involved in the development of biofilm is the adsorption of inorganic and organic molecules to the solid surface creating what is termed a conditioning layer (stage 1). During dental plaque formation, the tooth surface is conditioned by the saliva pellicle. Once the conditioning layer is formed, the next step in biofilm formation is the adhesion of microbial cells to this layer (stage 2). Amongst the pioneer organisms, the oralis group of streptococci is the major population to form a bacterial monolayer on the salivary pellicle coated tooth surface.

There are many factors that affect bacterial attachment to a solid substrate. These factors include pH, temperature, surface energy of the substrate, flow rate of the fluid passing over the surface, nutrient availability, length of time the bacteria is in contact with the surface, bacterial growth stage, bacterial cell surface charge, and surface hydrophobicity. Physicochemical properties such as surface energy and charge density determine the nature of initial bacteria-substrate interaction (Phase 1: transport of microbe to substrate surface). In addition, the microbial adherence to a substrate is also mediated by bacterial surface structures such as fimbriae, pili, flagella, and EPS (glycocalyx). The bacterial surface structures form bridges between the bacteria and the conditioning film.⁶⁸⁷ Molecular-specific interactions between bacterial surface structures and substrate become active in this phase (Phase 2: initial non-specific microbial-substrate adherence phase). These bridges are a combination of electrostatic attraction, covalent and hydrogen bonding, dipole interaction, and hydrophobic interaction. *P. gingivalis*, *S. mitis*, *Streptococcus salivarius*, *P. intermedia*, *P. nigrescens*, *S. mutans*, and *A. naeslundii*

are some of the oral bacteria possessing surface structures.^{696,697} Initially, the bonds between the bacteria and the substrate may not be strong. However, with time these bonds gain in strength, making the bacteria-substrate attachment irreversible. Finally, a specific bacterial adhesion with a substrate is produced via polysaccharide adhesin or ligand formation (Phase 3: specific microbial-substrate adherence phase). In this phase, adhesin or ligand on the bacterial cell surface will bind to receptors on the substrate. Specific bacterial adhesion is less affected by many environmental factors such as electrolyte, pH, or temperature.^{698,699} The adhesive potential of microorganisms is considered to be a vital ecologic and pathogenic determinant in the development of biofilms.

Next step in the development of biofilm is the bacterial growth and biofilm expansion (stage 3). During this stage, the monolayer of microbes attracts secondary colonizers forming microcolony, and the collection of microcolonies gives rise to the final structure of biofilm.^{668,700} The lateral and vertical growth of indwellers gives rise to microcolonies similar to towers. A mature biofilm will be a metabolically active community of microorganisms where individuals share duties and benefits.⁷⁰¹ For instance, some microorganisms help in adhering to the solid support, while some others create bridges between different species, which otherwise would not have happened. The bacterial cells in a matured biofilm will exhibit considerable variation in its genetic and biochemical constitutions compared to its planktonic counterparts. Two types of microbial interactions occur at the cellular level during the formation of biofilm. One is the process of recognition between a suspended cell and a cell already attached to substratum. This type of interaction is termed

Figure 14 Schematic diagram showing different factors influencing initial bacteria-substrate interaction. Courtesy A. Kishen.

Figure 15 Stages in the development of biofilm. Courtesy A. Kishen.

co-adhesion. In the second type of interaction, genetically distinct cells in suspension recognize each other and clump together. This type of interaction is called coaggregation.^{702,703} Schematic representation of the co-adhesion and coaggregation process between bacterial cells is shown in Figure 16. These associations are highly specific and occur between co-aggregating partners only. Interestingly, most of the oral bacteria recognize each other as co-aggregating partners. *F. nucleatum*, a Gram-negative filamentous anaerobe can coaggregate with all oral bacteria tested and can act as a bridging bacterium that bind together even non-aggregating bacteria.^{704,705} The association of long-filamentous bacteria and surface-adsorbed spherical-shaped cocci produce the

Figure 16 Schematic diagram showing co-aggregation and co-adhesion between different bacterial cells forming biofilm. Reproduced with permission from Busscher HJ and van der Mei HC.⁷⁰²

characteristic corncob structure of oral biofilms.⁷⁰⁶ The attachment of cocci to filamentous bacteria is said to be mediated via fimbriae of the oral streptococci.⁷⁰⁷ Although genetic makeup of bacteria is the main determinant of coaggregation, the physicochemical characteristics of the environment also play a crucial role.⁷⁰⁸

Resistance of Microbes in Biofilm to Antimicrobials

The nature of biofilm structure and physiological characteristics of the resident microorganisms offer an inherent resistance to antimicrobial agents, such as antibiotics, disinfectants, or germicides. The resistance to antimicrobial agents has been found to amplify more than thousand times for microbes in biofilm, when compared to planktonic cells.⁷⁰⁹ Figure 17 shows the scanning electron micrographs of (see Figure 17A) an untreated biofilm of *Staphylococcus epidermidis* and (see Figure 17B) an identical biofilm exposed to vancomycin and rifampin for 72 hours at concentrations exceeding the minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) for the microorganism. In spite of the obvious changes in the treated biofilm, viable organisms were recovered for which the MIC and MBC of both antimicrobial agents

Figure 17 Scanning electron microscopy of **A**, an untreated biofilm of *Staphylococcus epidermidis* and **B**, an identical biofilm exposed to vancomycin and rifampin for 72 hours at concentrations exceeding the minimum inhibitory concentration and minimum bactericidal concentration for the organism. Reproduced with permission from Dunne WM et al.⁷¹⁰

were unaltered. The observed resistance to vancomycin and rifampin was attributed to the biofilm microenvironment, altered bacterial metabolism, and EPS barrier protection.⁷¹⁰ The mechanisms responsible for the resistance to antimicrobial agents may include the following: (1) resistance associated with the extracellular polymeric matrix; (2) resistance associated with growth rate and nutrient availability; and (3) resistance associated with the adoption of resistance phenotype. Factors responsible

for antimicrobial resistance in biofilm bacteria are shown in Figure 18. Although there are evidences to support each of these mechanisms, no single mechanism may account for the general resistance to antimicrobials. It is apparent that these mechanisms act in concert within the biofilm and amplify the effect of small variations in susceptible phenotypes.⁷¹⁰ Schematic diagrams of the hypothesized mechanisms of antimicrobial resistance in biofilm bacteria are shown in Figure 19.

RESISTANCE ASSOCIATED WITH THE EXTRACELLULAR POLYMERIC MATRIX

Inactivation of antimicrobials by the EPS is said to be an important cause for the observed antimicrobial resistance in biofilm bacteria. EPS, which forms the biofilm matrix, has the potential to modify the response of the biofilm bacteria to antimicrobial treatments through its action as a diffusion barrier and reaction sink (neutralizer). The latter function is enhanced by the retention of extracellular products and enzymes. It has been suggested that regulation of EPS under the control of signal substances such as *N*-acyl homoserine lactone (HSL) is responsible for the early transcriptional events associated with biofilm formation. Such regulators are responsive to increase in cell density beyond critical threshold values and may be general regulators of biofilm specific physiology. In biofilms, signal substances such as HSL would become concentrated within the microcolonies, thereby increasing the production of EPS. EPS with its highly charged and interwoven structure deters penetration of antimicrobials by ionic or electrostatic interactions. This is because the antimicrobial agents are usually positively charged and the EPS contains negatively charged or neutral polysaccharides.^{680,684,711,712} Antibiotics such as aminoglycosides, which are hydrophilic and positively charged molecules, are retarded by the biofilm matrix for the above reason.⁷¹³

The constituents of biofilm matrix polymer may react chemically and directly neutralize antimicrobial agents such as iodine, iodine–polyvinylpyrrolidone complexes, chlorine, and peroxygens.⁷¹⁴ Inactivation of antibiotics by the modified enzymes produced by the bacteria in a biofilm state has also been reported. High concentration of enzymes released by bacteria, for example, extracellular enzymes such as β -lactamase, can inactivate lactam antibiotics. In addition, the biofilm may also retain drug-inactivating enzymes within the glycocalyx, which in turn will amplify its barrier properties. The sequestration of β -lactamase enzymes^{711,715} or formaldehyde lyase and dehydrogenase would cause the degradation of β -lactam antibiotics and formaldehyde, respectively. Thus, the β -lactam resistance of *P. aeruginosa* biofilms has been associated to β -lactamase retention in the biofilm matrix.⁷¹⁶ It is suggested that the synergy between bacterial species may also hinder the action of antimicrobials. For instance, *E. faecalis* can inactivate metronidazole, thereby protecting *B. fragilis* found in a multispecies biofilm.⁷¹⁷ In another example, *Klebsiella aerogenes*, which produce only limited EPS matrix, are protected from antimicrobial agents

by other members of the polymicrobial biofilm community that are capable of producing EPS.⁶⁷⁸

RESISTANCE ASSOCIATED WITH GROWTH RATE AND NUTRIENT AVAILABILITY

Mature biofilm is composed of multiple layers of bacteria embedded in EPS matrix. The localized high cell density within a biofilm exposes the deep-lying cells to less nutrients and redox potential that are substantially altered from those experienced by the cells on the surface or grown as planktonic cells. It is established that susceptibility toward most antimicrobial agents varies as a direct function of growth rate, and much of the resistance associated with biofilm bacteria might be associated with slow growing, starved community members. It is also observed that the resistance to antimicrobial agents increases in thicker biofilms due to limited oxygen. Because nutrient and gaseous gradients will increase in extent as biofilm thickens and matures, growth rate effect on antimicrobial resistance is particularly marked in aged biofilm.⁶⁸⁴

RESISTANCE ASSOCIATED WITH THE ADOPTION OF RESISTANCE PHENOTYPE

Long-term survival of biofilm communities results in the adoption or clonal expansion of a more resistant phenotype. Bacteria can sense the proximity of a surface, up-regulate production of EPS, and rapidly alter their susceptibility toward antibiotics and biocides after binding (attachment-specific resistance phenotype). Nutrient limitation results in diminished bacterial growth rate, increased expression of stress response genes, shock proteins, and activation of multi-drug efflux pump. The above factors can enhance the antibiotic resistance of bacteria in a biofilm.⁷¹² Also, sub-lethal concentration of antibiotics and biocides may act as inducers/transcriptional activators of more tolerant phenotypes such as those expressing multi-drug resistance operon and efflux pumps. It has been suggested that certain bacterial cells living in a biofilm community, when exposed to unfavorable stress or low-level antimicrobials formed specialized survivor cells called persistent cells or persistors.⁶⁷⁹ The persistors are phenotypic variants that can regenerate the original population. Following removal of unfavorable stresses, the persistor cells would grow rapidly in the presence of nutrients released from the lysed community partners. Biofilm population are enriched in persistor cells; these cells would

survive treatment procedures and proliferate in the post-treatment phase. Figure 19 shows how different regions in the structure of a matured biofilm contributed differently to its antimicrobial resistance.⁶⁸⁴

Biofilms in Dentistry

Oral bacteria have the capacity to form biofilms on distinct surfaces ranging from hard to soft tissues. The characteristics of the biofilm formed depend upon the residing bacterial species, the surface or substratum composition, and the conditioning layer coating the surfaces on which they are formed. Oral biofilms are formed in three basic steps, namely, pellicle formation, bacterial colonization, and biofilm maturation. These stages do not occur randomly but involves series of complex interactions.^{519,718} Water constitutes 80% of the oral biofilm, while the organic and inorganic (solid) fractions form approximately 20% of the biofilm structure. Microorganisms, which makeup at least 70% to 80% of the solid fraction of the biofilm, are higher in the subgingival biofilm than in the supragingival biofilm. The chemical composition of biofilm differs among individuals, between tooth surfaces, in an individual and with age. The organic substance surrounds the microorganisms of the biofilm and contains primarily carbohydrates, proteins, and lipids. Carbohydrates are produced by many bacteria, and they include glucans, fructans, or levans. They contribute to the adherence of microorganisms to each other and are the stored form of energy in biofilm bacteria. The proteins found in the supragingival biofilm are derived from saliva, while the proteins in the subgingival biofilm are derived from gingival sulcular fluid. The lipid content may include endotoxins (LPS) from Gram-negative bacteria. The inorganic elements found in a biofilm are calcium, phosphorus, magnesium, and fluoride. The concentrations of these inorganic elements are higher in biofilm than in saliva.⁷¹⁹ The typical structure and development of biofilms have been discussed earlier in this chapter.

Human saliva contains proline-rich proteins that aggregate together to form micelle like globules called salivary micelle-like globules (SMGs). SMGs from saliva get adsorbed to the clean tooth surface to form acquired enamel pellicle, which acts as a “foundation” for the future multilayered biofilm.^{718,720} The globular micelles of acquired enamel pellicles are characterized by a negatively charged (calcium binding) surface and hydrophobic interior.⁷²⁰ Presence of calcium facilitates the formation of larger globules by bridging the

negative charges on the subunits.⁷²¹ The initial attachment of bacteria to the pellicle is by selective adherence of specific bacteria from oral environment. Innate characteristics of the bacteria and the pellicle determine the adhesive interactions that cause a specific organism to adhere to the pellicle. Dental biofilm consists of a complex mixture of microorganisms that occur primarily as microcolonies. The population density is very high and increases as biofilm ages. The prospect of developing dental caries or gingivitis increases as the number of microorganisms increases.

The acquired pellicle attracts Gram-positive cocci such as *S. mutans* and *S. sanguis*, which are the pioneer organisms in the plaque formation. Subsequently, filamentous bacterium such as *F. nucleatum* and slender rods adheres to primary colonizers. Gradually, the filamentous form grows into the cocci layer and replaces many of the cocci. Vibrios and spirochetes appear as the biofilm thickens. More and more Gram-negative and anaerobic organisms emerge as the biofilm matures. Interestingly, it is not only the surface of tooth that can be attached by bacterial cells.⁵¹⁹ The surface of some bacteria (bacilli and spirochetes) also can serve as attachment sites for certain smaller coccoids. This coaggregation of *F. nucleatum* with coccoid bacteria gives rise to “corn-cob” structure, which is unique in plaque biofilms.⁷²² The presence of these bacteria makes it possible for other non-aggregating bacteria to coexist in the biofilm, by acting as coaggregating bridges. The existence of anaerobic bacteria in an aerobic environment is made possible by the coexistence of aerobic and anaerobic bacteria.⁷²³

Calcified dental biofilm is termed as calculus. It is formed by the precipitation of calcium phosphates within the organic plaque matrix. Factors that regulate the deposition of minerals on dental biofilms are physicochemical factors such as plaque pH, local saturation of Ca, P, and availability of fluoride ions and biological factors such as presence of crystallization nucleators/inhibitors from either bacteria or oral fluids.^{724,725} The localized supersaturation of calcium and phosphate ions provides the driving force for mineralization. The inorganic or mineral fraction consists of calcium phosphates, magnesium, fluoride, and carbonate,⁷²⁶ and they make up 70% to 80% weight of dental calculus. Various mineral phases namely, HAP, whitlockite, octacalcium phosphate, and brushite have been reported in calculus.⁷²⁷

While much emphasis is placed on the adverse effects of biofilms and the difficulty in treating biofilm-mediated diseases, it must be understood that the biofilm formed by commensals are protective in nature. The commensal bacterial biofilms inhibits

Figure 20 The ecological plaque hypothesis showing the postulated dynamic relationship between environmental factors and ecological shifts with dental caries. Reproduced with permission from Marsh PD, et al.⁷²⁸

colonization by exogenous pathogenic microorganisms by a phenomenon termed colonization resistance. For instance, dental biofilm (plaque) formed on the tooth surface is harmless under normal conditions. Nevertheless, a shift in microenvironment due to repeated use of “habit forming” substances, diet, and host immune response can lead to biofilm-mediated infections or diseases in the oral cavity. According to the “ecological plaque hypothesis,” any environmental change that favors increasing colonization by potential pathogenic bacteria would cause disease.^{519,718,725,728,729} A decline in the host defense mechanisms caused by disease or immuno-suppressive medicaments may also render generally “harmless commensals” to become “opportunistic pathogens.” Type of nutrients, availability of nutrients, and oxygen tension could determine the nature of bacteria associated with a biofilm at any particular location in the oral cavity. Subsequently, the nature and activity of bacteria associated with site-specific biofilms manifest as various dental infections. Some studies have emphasized the importance of an individual’s threshold value of tolerance to these bacteria as the crucial factor in the shift from health to disease.^{730,731} Dental caries, gingivitis, periodontitis, peri-implantitis, and periapical (apical) periodontitis are examples of diseases caused by biofilm community (biofilm-mediated disease) rather than any single organism (Koch’s postulate).^{728,729} Figure 20 illustrates the ecological plaque hypothesis showing the postu-

lated dynamic relationship between environmental factors and ecological shifts in a dental biofilm with dental caries.

ENDODONTIC BIOFILMS

Endodontic microbiota is established to be less diverse compared to the oral microbiota. This transition in the microbial population is more conspicuous with the progression of infection.⁵²⁰ Progression of infection alters the nutritional and environmental status within the root canal. The root canal environment apparently becomes more anaerobic and the nutritional level will be depleted. These changes will offer a tough ecological niche for the surviving microorganisms.^{112,732} Furthermore, clinical investigations have shown that the complete disinfection of root canal is very difficult to achieve. Microbes are found to persist in the anatomical complexities such as isthmuses and deltas and in the apical portion of root canal system. Often, bacterial activities may not be confined to intracanal spaces, but also access regions beyond the apical foramen.^{732,594} These anatomical and geometrical complexities in the root canal systems shelter the adhering bacteria from cleaning and shaping procedures.⁵⁹⁴ Because biofilm is the manner of bacterial growth to survive unfavorable environmental and nutritional conditions, the root canal environment in both primary and post-treatment infections will favor biofilm formation. Additionally, biofilm mode of bacterial growth offers other advantages such as (1) resistance to

antimicrobial agents, (2) increase in the local concentration of nutrients, (3) opportunity for genetic material exchange, (4) ability to communicate between bacterial populations of same and/or different species, and (5) produce growth factors across species boundaries. Endodontic bacterial biofilms can be categorized as (1) intracanal biofilms, (2) extra radicular biofilms, (3) periapical biofilms, and (4) biomaterial centered infections.

INTRACANAL MICROBIAL BIOFILMS

Intracanal microbial biofilms are microbial biofilms formed on the root canal dentine of an endodontically

infected tooth. A detailed description on the intracanal bacterial biofilm was documented by Nair in 1987.⁷³³ Ultra-microscopic structure of the intracanal biofilm formed on uninstrumented portion of the root canal are shown in Figure 21. It was suggested that the intracanal microbiota in an endodontically infected teeth existed as both loose collection and biofilm structures, made up of cocci, rods, and filamentous bacteria. Monolayer and/or multi-layered bacterial biofilms were found to adhere to the dentinal wall of the root canal. The extracellular matrix material of bacterial origin was also found interspersed with the cell aggregates in the biofilm.

Green cells on the root canal wall indicate viable cells in the biofilm. Courtesy A. Kishen unpublished.

Different morphologically distinct types of bacteria were observed in these biofilms. Bacterial microcolonies formed by the coaggregation of single morphological type and/or several morphological types of bacteria were noticed. In a multispecies biofilm, the proportion and number of different bacterial species varied according to the stage of maturation. Intracanal biofilms displayed characteristic bacteria–dentine wall relationship and distinct patterns in the organization of microbes in the biofilm. The characteristic features in cell–cell and microbe–substrate interactions were explained based on the phenomena of microbial adherence.^{262,733}

Studies have established the ability of *E. faecalis* to resist starvation and develop biofilms under different environmental and nutrient conditions (aerobic, anaerobic, nutrient-rich, and nutrient-deprived conditions). However, the physicochemical properties of *E. faecalis* biofilms were noted to modify according to the prevailing environmental and nutrient conditions.

E. faecalis under nutrient-rich environment (aerobic and anaerobic) produced typical biofilm structures with characteristic surface aggregates of bacterial cells and water channels. Viable bacterial cells were present on the surface of the biofilm. Under nutrient-deprived environment (aerobic and anaerobic), irregular growth of adherent cell clumps were observed. The ultrastructure of *E. faecalis* biofilms formed on root dentine under different environmental and nutritional conditions is shown in Figure 22.⁵⁹³ Laser scanning confocal microscopy displayed many dead bacterial cells and pockets of viable bacterial cells in this biofilm structure. In vitro experiments have revealed distinct stages in the development of *E. faecalis* biofilm on root canal dentine. In stage 1, *E. faecalis* cells adhered and formed microcolonies on the root canal dentine surface. In stage 2, they induced bacterial-mediated dissolution of the mineral fraction from the dentine substrate. This localized increase in the calcium and phosphate ions will promote mineralization (or calcification) of the

E. faecalis biofilm in stage 3. The mature biofilm structure formed after 6 weeks of incubation showed signs of mineralization and subtle but distinct compositional difference (Figure 23A–D). The mineralized *E. faecalis* biofilm showed carbonated-apatite structure as compared to natural dentine which had carbonated-fluor-apatite structure.⁵⁹⁴ There were obvious signs of dentine surface degradation under nutrient-deprived environment (see Figure 23(A–C)). This degradation of dentine substrate was understood to be a consequence of the interaction of bacteria and their metabolic products on dentine.⁵⁹⁴ A recent investigation has highlighted the

ability of *E. faecalis* clinical isolate to coaggregate with *F. nucleatum*. The coaggregation interactions between *E. faecalis* and *F. nucleatum* suggested the ability of these microorganisms to coexist in a microbial community and contribute to endodontic infection.⁵²⁷ The inherent capacity of *E. faecalis* to resist the bactericidal action of many antimicrobial agents,⁷³⁴ along with its ability to form distinct biofilm under tough environmental and nutrient conditions, may contribute to its persistence in endodontically treated teeth.

Interestingly, the calcification of bacterial biofilms and bacterial-mediated dentine degradation observed

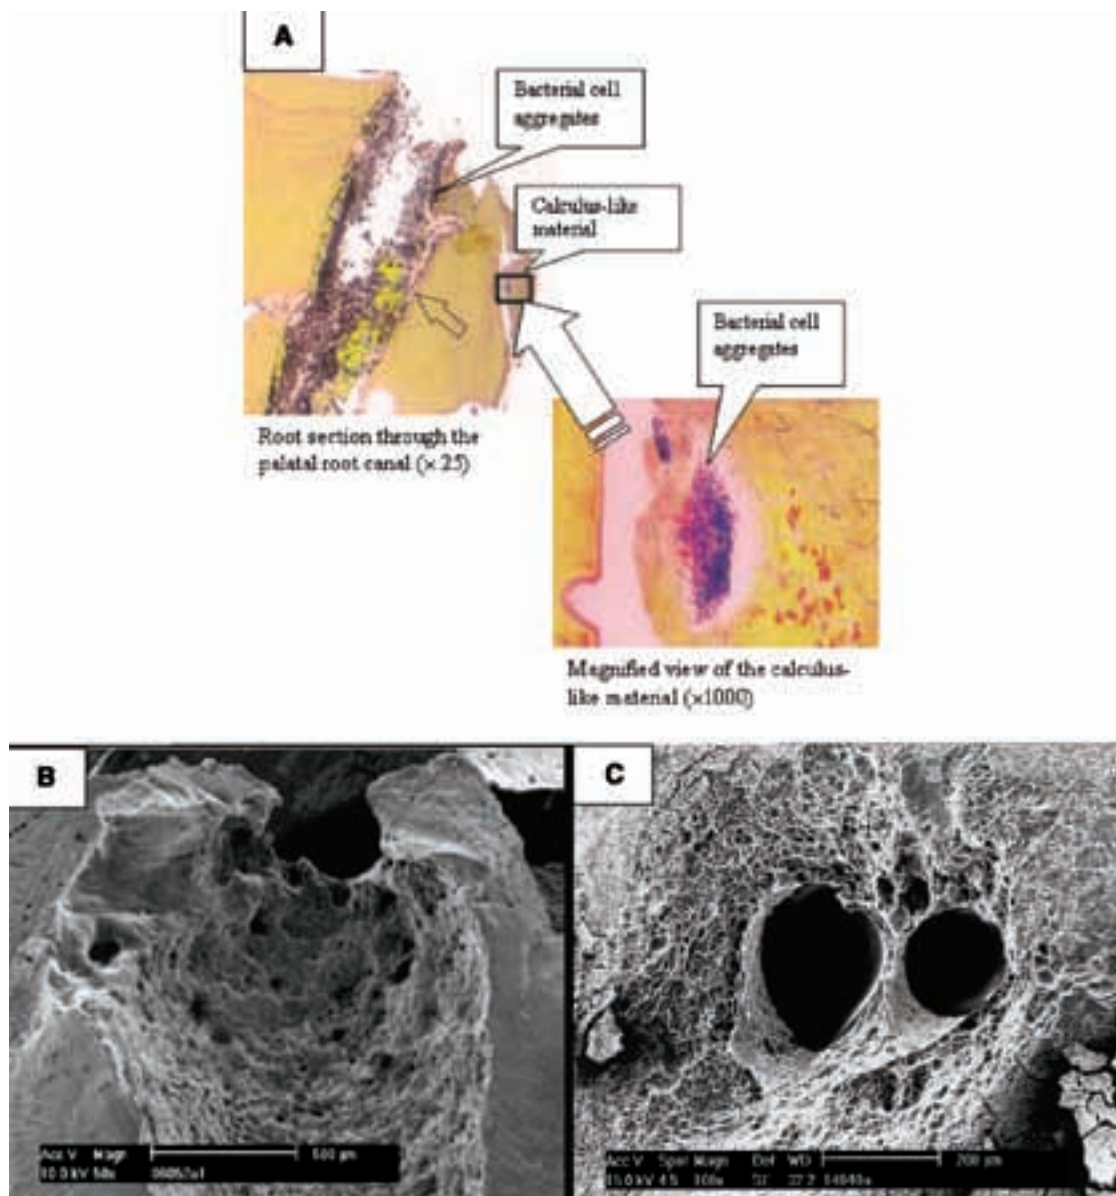

Figure 24 A calculus-like material on the external root surface in a clinical sample **A**, Magnified view showed bacterial aggregates in the deeper aspect of the amorphous material, Ricucci D, et al.⁷³⁵ Scanning electron microscopy images showing apical portion of root canal with extensive internal apical resorption of the root canal, Vier FV and Figueiredo JA,⁷³⁵ **B**, and root apex with extensive perforaminal and foraminal resorption exposing dentinal tubules **C**, Reproduced with permission from Vier FV and Figueiredo JA.⁷³⁷

in vitro were supported by clinical evidences. Two clinical cases were reported with mineralized calculus-like deposit on the root surface of teeth with post-treatment periapical periodontitis⁷³⁵ (Figure 24A). While internal resorption of root canal dentine was reported in 74.7% of teeth associated with periapical lesions.⁷³⁶ These resorptive lesions were mostly observed in the apical portion of the root canal (see

Figure 24B). In another study, perforaminal resorption was reported in 87.3% and foraminal resorption in 83.2% of roots from 104 root apices extracted from teeth with periapical lesions⁷³⁷ (see Figure 24C). Bearing in mind the complexities in the apical root canal anatomy, and the length and lateral limits of cleaning and shaping apical root canal, incomplete elimination of bacteria from the apical region of the root canal is

very likely.⁷³⁶ Investigations have also demonstrated biting force-induced retrograde fluid movement into the apical portion of the root canal (apical retrograde fluid movement).⁷³⁸ Cyclic influx of ion-rich tissue fluid into the apical portion of the root canal can promote persistence of bacteria as biofilms and their mineralization, while the observed internal resorption can be a consequence of bacterial-mediated substrate dissolution.

EXTRARADICULAR MICROBIAL BIOFILMS

Extraradicular microbial biofilms also termed root surface biofilms are microbial biofilms formed on the root (cementum) surface adjacent to the root apex of endodontically infected teeth.³⁴⁹ Extraradicular biofilms were reported in teeth with asymptomatic periapical periodontitis and teeth with chronic apical abscesses associated with sinus tracts. In this study, Tronstad et al. examined 10 root tips removed during surgical treatment of root-filled teeth with post-treatment disease (five teeth with the diagnosis of asymptomatic apical periodontitis and five teeth with the diagnosis of apical periodontitis with fistula). Mature bacterial biofilms were found in many areas of the apical root surfaces in all clinical specimens examined in this study.

They observed bacterial biofilms in the areas of the root surfaces between fibers and cells and in crypts and holes. The biofilm contained varying degrees of extracellular matrix materials (glycocalyx). The root surface biofilms were mostly multi-species in nature.³⁴⁸

The extraradicular biofilm structures were dominated by cocci and short rods, with cocci attached to the tooth substrate. Filamentous and fibrillar forms were also observed in the biofilm. Ultrastructure of extraradicular biofilms formed on the root surface adjacent to the apical foramen is shown in Figure 25. A smooth, structureless biofilm structure consisting of extracellular matrix material with embedded bacterial cells was noticed to coat the apex of the root tip adjacent to the apical foramen. There was no obvious difference in the biofilm structures formed on the apical root surface of teeth with and without sinus tracts.³⁴⁸ Clinical evidence of calcified biofilms on the extraradicular region was also reported. Ricucci et al.⁷³⁵ has reported the presence of calculus-like deposit on the root apex of teeth extracted due to post-treatment periapical periodontitis. While Harn et al. noticed calculus-like deposits on apical root surface of tooth presented with lesion refractory to conventional root canal treatment. These calcified biofilms were

Figure 25 Extraradicular microbial biofilm formed on the root surface. It is **A**, multispecies or **B**, smooth and structureless in nature Courtesy A. Kishen unpublished.

associated with periapical inflammation and delayed periapical healing in spite of adequate orthograde root canal treatment.⁷³⁹

PERIAPICAL MICROBIAL BIOFILMS

Periapical microbial biofilms are isolated biofilms found in the periapical region of an endodontically infected teeth. Periapical biofilms may or may not be dependent on the root canal. The microbiota in the majority of teeth associated with apical periodontitis is restricted to the root canal, as most of the microbial species that infect the root canal are opportunistic pathogens that do not have the ability to survive host defense mechanism in the periapical tissues.³¹⁵ Rarely microbial species or even strains within a species may possess strategies to survive and thus infect periapical tissues.³⁵² Members of the genus *Actinomyces* and the species *P. propionicum* have been demonstrated in asymptomatic periapical lesions refractory to endodontic treatment. These microorganisms have the ability to overcome host defense mechanisms, thrive in the inflamed periapical tissue, and subsequently induce a periapical infection.^{641,740,741} A clinical

investigation detected *Actinomyces* in 72 of 129 (55.8%) clinical samples. Of those, 41 of 51 (80.4%) were from infected root canals, 22 of 48 (45.8%) were from abscesses, and 9 of 30 (30%) were associated with cellulites.¹

Actinomyces species in tissues grow in microscopic or macroscopic aggregates, which may reach diameter of up to 3 to 4mm.⁷⁴² They are commonly referred to as “sulfur granules,” because of the yellow granular appearance.³⁵⁵ Microscopically, the granules give the appearance of rays projecting out from a central mass of filaments, which gave origin to the name “ray fungus” or *Actinomyces*. This granular biofilm structure consists of a central mass of intertwined branching bacterial filaments, held together by an extracellular matrix with the peripheral radiating clubs. The aggregation of *Actinomyces* cells were influenced by pH, ionic strength, and cell concentration.⁷⁴³ Aggregation of cells might facilitate accumulation of cells to form a biofilm structure that differentiate, communicate, cooperate, and deploy collective defense against biological antimicrobials. It is important to note that the periapical region is “patrolled” by PMNs and macrophages, which phagocytose incoming planktonic bacteria easily.

Figure 26 Endodontic periapical microbial biofilm. SEM image of the sectioned surfaces of sulfur granules showing rod-like bacteria, spiral-form bacteria, and an amorphous material between the cells. Large amounts of partly calcified extracellular material are present. Reproduced with permission from Sunde PT et al.³³³

However, the phagocytes are unable to engulf bacteria in matrix-enclosed biofilm structure.

Sunde et al. reported the incidence of “sulfur granules” in nine refractory periapical lesions and found bacteria in seven. *A. israelii*, *A. viscosus*, *A. naeslundii*, and *Actinomyces meyeri* were identified in five granules. Other bacterial species, both Gram-positive and Gram-negative, were detected in the granules as well. Two sulfur granules did not contain *Actinomyces*. SEM demonstrated rod- and spirochete-like cells in the granules, and transmission electron microscopy revealed organisms with abundant extracellular material. Many of the “sulfur granules” were calcified and the source for mineralization may have been the inflammatory exudate and/or the activity of the periapical bacteria. Although “sulfur granules” have been considered as suggestive of actinomycosis, it was confirmed that other species can form aggregates that are similar to those formed by *Actinomyces* species and *P. propionicum* (see Figure 26).^{740,743} Granular biofilm structures, resembling sulfur granules, were also observed in vitro by the clumping and calcification of *E. faecalis* cells on the dentine surface. It has been shown that the lysis of adherent bacterial cells in a biofilm would induce cell calcification.⁷⁴⁴ The calcium–phospholipid–phosphate complexes and calcifiable proteolipid, which are membrane constituents of calcified bacteria, can support biomineralization.⁷⁴⁵

BIOMATERIAL-CENTERED INFECTION

Biomaterial-centred infection (BCI) is caused when bacteria adheres to an artificial biomaterial surface and forms biofilm structures.⁷⁴⁶ Presence of biomaterials in close proximity to the host immune system can increase the susceptibility to BCI. BCI is one of the major complications associated with prosthesis and/or implant-related infections. Chronic bacterial infections occur when the pathogenic bacterial population reaches a critical size and overcomes the host defense mechanisms. Both specific and non-specific interactions play important roles in the ability of the bacteria to adhere to the biomaterial surface. The comparative contribution of specific and non-specific mechanisms depends on the surface properties of the biomaterial as well as the fluid flow conditions and the nature of liquid conditioning layer. Because biofilms are extremely resistant to host defense mechanisms and antibiotic treatments, BCI are rarely resolved, and often the only solution to an infected biomaterial such as implant is its surgical removal.⁷⁴⁷

BCI usually reveals opportunistic invasion by nosocomial organisms. Coagulase-negative *Staphylococcus*, *S. aureus*, enterococci, streptococci, *P. aeruginosa*, and

fungi are commonly isolated from infected biomaterial surfaces. Bacterial adherence to a biomaterial surface is also described in three phases—(1) phase 1: transport of bacteria to biomaterial surface, (2) phase 2: initial, non-specific adhesion phase, and (3) phase 3: specific adhesion phase. Details about bacteria–substrate interaction have been discussed in “Development of Biofilm.” Concentration of electrolytes and pH value of the environment influence bacterial adherence to biomaterial surface by changing the surface characteristics of both bacteria and biomaterial.⁷⁴⁸ Bacterial strains that do not produce EPS are less adherent and less pathogenic. Bacteria that do not adhere quickly to the surfaces are rapidly destroyed by the immune system. These features highlight the need to prevent bacterial adherence and biofilm formation to prevent BCI.

In endodontics, biomaterial-centered biofilms would form on root canal obturating materials. These biofilms can be intraradicular or extraradicular depending upon whether the obturating material is within the root canal space or has it extruded beyond the root apex. A study investigated the initial biofilm-forming ability of root canal isolates such as *E. faecalis*, *S. sanguinis*, *S. intermedius*, *S. pyogenes*, *S. aureus*, *F. nucleatum*, *P. acnes*, *P. gingivalis*, and *P. intermedia* on gutta-percha points in vitro. It was shown that *E. faecalis*, *S. sanguinis*, *S. intermedius*, *S. pyogenes*, and *S. aureus* developed biofilms on the surfaces of gutta-percha incubated in culture medium supplemented with 45% or 90% (vol/vol) serum. The *E. faecalis* and *S. sanguinis* biofilms were significantly thicker than those of *S. intermedius*, *S. pyogenes*, and *S. aureus*. *F. nucleatum*, *P. acnes*, *P. gingivalis*, and *P. intermedia* did not form biofilms on gutta-percha. The findings from this study suggested that Gram-positive facultative anaerobes have the ability to colonize and form extracellular matrices on gutta-percha points, while serum plays a crucial role in biofilm formation.⁷⁴⁹ In a clinical investigation, six teeth and five extruded gutta-percha points associated with refractory periapical disease were investigated. Nine out of eleven samples examined showed bacterial biofilms in the extraradicular region. The gutta-percha surface was covered with glycocalyx-like structures. Filaments, long rods, and spirochete-shaped bacteria were predominant in the biofilm formed on gutta-percha.³⁴⁹ Figure 27 shows the ultrastructure of (see Figure 27A) a microbial biofilm formed on extruded gutta-percha point in vivo and (see Figure 27B) *E. faecalis* biofilm formed on gutta-percha point in vitro. This study suggested that the extraradicular microbial biofilms formed on tissue or biomaterial surface were related to refractory periapical disease.³⁴⁸

Figure 27 Scanning electron microscopy image of **A**, microbial biofilm formed on extruded gutta-percha point from a clinical sample and **B**, *E. faecalis* biofilm formed on gutta-percha in vitro. Courtesy A. Kishen.

CHAPTER 8

NON-MICROBIAL ENDODONTIC DISEASE

P.N.R. NAIR

*“In microscopy, as in nature, one recognizes only what one already knows.”*¹

Apical periodontitis is an inflammatory disorder of periradicular tissues caused by irritants of endodontic origin, mostly of persistent microbes living in the root canal system of the affected tooth.^{2,3} It is primarily a disease of infection. But unlike classical infectious diseases of single, specific etiologic agents, apical periodontitis is caused by a consortium of microbial species living in the root canal in an ecologically balanced community form of living⁴ referred to as biofilms.⁵ The microbial etiology of the disease has been discussed in Chapter 7, “Microbiology of Endodontic Disease.” The purpose of this chapter is to provide a comprehensive overview of the nonmicrobial aspects of the disease, which are generally associated with asymptomatic persistent periapical radiolucencies, also referred to as endodontic failures.

Cystic Apical Periodontitis

By definition, a cyst is a closed pathologic cavity, lined by epithelium that contains a liquid or semisolid material.⁶ The term *cyst* is derived from the Greek word *Kystis* meaning sac or bladder. There are several varieties of cystic lesions in the body that are commonly referred to as congenital, neoplastic, parasitic, retention, implantation, and inflammatory types. A *periapical cyst is an inflammatory jaw cyst of the periodontium of a tooth with infected and necrotic pulp and has been extensively reviewed.*^{1,7,8}

INCIDENCE OF PERIAPICAL CYSTS

The epidemiology and global distribution of the disease are not yet known. Anatomically, periapical cysts are the most common of all jaw cysts and comprise about 52%⁷ to 68%⁹ of all the cysts affecting the human jaws. The prevalence of periapical cysts is

highest among patients in their third decade of life^{7,10,11} and higher among males than females.^{7,10} Periapical cysts occur in all tooth-bearing sites of the jaws but are more frequent in maxillary than mandibular teeth. In the maxilla, the anterior region appears to be more affected with cysts whereas in the mandible the radicular cysts occur more frequently in the premolar region.¹²

DIAGNOSIS OF PERIAPICAL CYSTS

The clinical diagnosis of periapical cysts from other forms of apical periodontitis has been extensively debated.¹³ Several radiographic features have been proposed to support a diagnosis, including size of the lesion and the presence of a radioopaque rim¹⁴ demarcating the lesion. Although the statistical probability of cyst occurrence may be higher among larger lesions,¹⁵ a conclusive relationship between the size of the lesion and cystic condition has not yet been substantiated by histologic data. Albeit the claim,¹⁶ periapical lesions cannot be differentially diagnosed into cystic and non-cystic lesions based on radiographic features.^{10,17–21} In a recent histologic investigation, it has been conclusively shown that no correlation existed between the presence of a radioopaque rim and the histologic diagnosis of the cysts.²² Assuming that cystic cavities may have a lower density than other apical periodontitis lesions, computer tomography²³ and densitometry¹⁶ have been used to differentiate these conditions, but without success. Echography, ultrasonic imaging technique, has been recently introduced as a periapical diagnostic method.^{24,25} The technique can detect fluid, soft tissue, and the real-time blood flow. In spite of the safety of ultrasound and the relative ease of use, the sonic waves do not pass through bone but are reflected back to the sensor, thereby enabling only detection of lesions that are not enclosed in bone. Currently, therefore, histologic serial sectioning of the lesions in toto remains to be the only reliable diagnostic method of

periapical cysts.^{1,8,26} This has been conclusively shown in a recent histologic investigation.²² Histologic diagnosis, however, can only be applied after surgical removal of the root tip with the attached periapical lesion, thus making it a post hoc diagnosis.

ORIGIN OF THE CYST EPITHELIUM

The lesions of apical periodontitis often contain epithelial cells²⁷⁻³⁸ that are generally believed to be derived from the cell rests of Malassez.²⁷ The cells proliferate in some lesions and serve as the *major source* of the stratified squamous epithelium^{7,8} that lines the lumen of lesions that develop into cysts. In rare instances, apical cysts have also been found to be lined by ciliated columnar or muco-secretory cells of respiratory origin.³⁸⁻⁴⁶ In one investigation,⁴⁶ 3 of the 256 apical periodontitis lesions examined were cysts lined with ciliated columnar epithelium (Figures 1 and 2). However, the origin of ciliated epithelium in radicular cysts has not yet been satisfactorily clarified. Currently, there are three explanations⁴³ for the presence of ciliated cells in radicular cysts: (1) migration of epithelial cells from the maxillary sinus or the nasal cavity; (2) metaplasia of the stratified squamous epithelium; and (3) differentiation of pluripotent cells within the jaw. Most of the reported ciliated cell-lined cysts were affecting maxillary teeth. The anatomic proximity of the periapical inflammatory lesion to the maxillary sinus may result in rarefaction of the sinus floor, perforation into the sinus cavity,^{38,40} and maxillary sinusitis.⁴⁷⁻⁴⁹ The lumen of such a periapical cyst can communicate with the sinus cavity, as has been convincingly demonstrated in photomicrographs by Kronfeld.⁴⁰ Once direct communication is established, a developing apical cyst can be lined with ciliary epithelium of sinus origin.

PREVALENCE OF CYSTS AMONG PERIAPICAL LESIONS

There have been many studies on the prevalence of periapical cysts among apical periodontitis lesions (Table 1). In this literature, the prevalence of cysts varies from 6% to 55%. However, accurate histopathologic diagnosis of radicular cysts is possible only through serial sectioning or step-serial sectioning of the lesions removed in toto.⁵⁰ There are only three studies^{31,50,51} in which either one of those essential techniques was used, whereas most of the others (Table 1) analyzed specimens obtained from wide sources for routine histopathologic reports. The statistically impressive 2,308 lesions in Bhaskar's study¹⁰ had been obtained from 314 contributors and the 800 biopsies of Lalonde and Luebke²¹ originated from 134 sources. Such histopathologic diagnostic specimens, often derived through apical curettage, do not represent lesions in toto. In random sections from fragmented and epithelialized lesions, part of the specimens can give the appearance of epithelium-lined cavities that do not exist in reality. Indeed, another author⁵² defined a typical radicular cyst as one in which "a real or imagined lumen was lined with stratified squamous epithelium."

It should be pointed out that the photomicrographic illustrations (Figure 3) in several studies^{10,21} represent only magnified views of selected small segments of epithelialized lesions. They are not supported by overview pictures of lesser magnifications of sequential sections derived from different axial planes of the lesions in question. The wide variation in the reported incidence of periapical cysts is most probably due to the difference in the histopathologic interpretation of the sections. When the histopathologic diagnosis is based on random or limited number of serial sections, most of epithelialized periapical

Figure 1 A photomicrograph **A**, of a cystic apical periodontitis (AP) of the left maxillary second premolar of a 34-year-old male patient. lesions would be wrongly categorized as radicular cysts. This view is substantiated by the results of a study⁵⁰ in which an overall 52% of the lesions ($n = 256$) were found to be epithelialized but only 15% were actually periapical cysts.

HISTOPATHOLOGY OF PERIAPICAL CYSTS

The structure of a periapical cyst in relation to the root canal of the affected teeth has not been taken into account in routine histopathologic diagnosis. The major reason for this has been the nature of the biopsy itself. Apical specimens removed by curettage do not contain the root tips of the diseased teeth making structural reference to the root canals of the affected teeth impossible. In 1980 Simon⁵¹ has pointed out that there are two distinct categories of radicular cysts namely, those containing cavities *completely enclosed in epithelial lining* and those containing epithelium-lined cavities *that are open to the root*

Figure 4 Root apices in cavities lined by epithelium (E in top). Original illustrations reprinted from Simon.⁵¹ Note the severe damage of the microanatomic relationship between the root apices and the cyst epithelia that might have influenced critics to wonder whether the “bay cysts”⁵¹ are histologic artifacts. Original magnification $\times 25$. Reproduced with permission from Williams & Wilkins©.

canals. The latter was designated as “bay cysts”⁵¹ and later renamed as “pocket cysts.”⁵⁰ It seems that Simon⁵¹ has observed only the large type of such lesions with voluminous cavities, into which the root apices of the affected teeth appeared to protrude. The photomicrographs in the publication reveal severe damage of the microanatomic relationship between the root apices and the cyst epithelia (Figure 4). This might have influenced critics to wonder whether the “bay cysts”⁵¹ are histologic artifacts. We⁵⁰ analyzed 256 periapical lesions obtained in toto with extracted

teeth. The specimens were processed by a modern plastic-embedding technique, and meticulous serial or step-serial sections were prepared and evaluated based on predefined histopathologic criteria. Of the 256 specimens, 35% were found to be periapical abscesses, 50% were periapical granulomas, and only 15% were periapical cysts. Equally significant was the finding that two distinct classes of radicular cysts—the *apical true cysts*, with cavities completely enclosed in epithelial linings (Figure 5), and the *apical pocket cysts*, with cyst lumina open to the root canals (Figure 6)—could be observed at the periapex when the lesions were analyzed in relation to the root canals. An overall 9% of the 256 lesions were apical true cysts and 6% were periapical pocket cysts.

GENESIS OF TRUE CYSTS

The periapical true cyst may be defined as a chronic inflammatory lesion at the periapex that contains an epithelium lined, *closed pathological cavity* (Figure 5). The pathogenesis of true cysts has been described by various authors.^{8,28,50,53–59} An apical cyst is a direct sequel to apical granuloma, although a granuloma need not always develop into a cyst. Owing to still unknown reasons, only a small fraction ($<10\%$) of the periapical lesions change into true radicular cysts.^{10,21} The pathogenesis of the true cyst has been described in three phases.⁷ During the *first phase*, the dormant cell-rests of Malassez begin to proliferate as a direct effect of inflammation,^{57,60} probably under the influence of bacterial antigens,⁶¹ epidermal growth factors,^{62–64} cell mediators, and metabolites that are released by various cells residing in the periapical lesion. During the *second phase*, an epithelium lined cavity comes into existence. There are two main theories regarding the formation of the cyst cavity: (1) the “nutritional deficiency theory” and (2) the “abscess theory.” The “nutritional deficiency theory” is based on the assumption that the central cells of the epithelial strands become removed from their source of nutrition and undergo necrosis and liquefactive degeneration.^{57,65–67} The accumulating products in turn attract neutrophilic granulocytes into the necrotic area. Such microcavities containing degenerating epithelial cells, infiltrating mobile cells, and tissue fluid coalesce to form the cyst cavity lined by stratified epithelium. The “abscess theory” postulates that the

Figure 5 Periapical true cyst. Photomicrograph **A**, of an axial section passing through the apical foramen (AF). The lower half of the lesion and the epithelium (EP in **B**) are magnified in **B**, and **C**, respectively. Note the cystic lumen (LU) with cholesterol clefts (CC) completely enclosed in EP having no communication to the root canal. Original magnifications: **A** $\times 15$, **B** $\times 30$, **C** $\times 180$. Reproduced with permission from Nair.¹

Figure 6 Periapical pocket cyst. Axial sections passing peripheral to the root canal **A, B**, give the false impression of the presence of a cyst lumen (LU) completely enclosed in epithelium. Sequential section **C**, passing through axial plane of the root canal clearly reveals the continuity of the LU with the root canal (RC in **D**). The apical foramen with the LU of the section **C**, are magnified in **D**. Note the pouch-like LU of the pocket cyst with the epithelium (EP) forming a collar at the root apex. Original magnifications: **A, B, C** $\times 15$; **D** $\times 50$. D = dentine. Reproduced with permission from Nair.¹

proliferating epithelium lines an abscess cavity formed by tissue necrosis and lysis because of the innate nature of the epithelial cells to cover exposed connective tissue surfaces.^{29,33} During the *third phase* the cyst grows, by which exact mechanism is still unknown. It is generally believed to be by osmosis. The presence of necrotic tissue in the cyst lumen attracts neutrophilic granulocytes, which extravasate and transmigrate through the epithelial lining (Figures 7 and 8) into the cyst cavity where they perish. The lytic products of the dying cells in the cyst lumen release a greater number of molecules. As a result, the osmotic pressure of the cyst fluid rises to a level higher than that of the tissue fluid.⁶⁸ The latter diffuses into the cyst cavity so as to raise the intraluminal hydrostatic pressure well above the capillary pressure. The increased intracyst pressure may lead to bone resorption and expansion of the cyst. However, *the fact that an apical pocket cyst with lumen open to the necrotic root canal can become larger*^{50,59} suggests against osmotic pressure as a potential factor in the development of radicular cysts. Furthermore, there is increasing evidence in support of a molecular mechanism for cyst expansion.⁵⁹ The T-lymphocytes⁶⁹ and macrophages in the cyst wall may provide a continuous source of bone resorptive metabolites⁷⁰ and cytokines. The presence of effector molecules such as matrix metalloproteinases 1 and 2 have also been reported in the cyst walls.⁷¹

GENESIS OF POCKET CYSTS

The periapical pocket cyst contains an epithelium-lined pathologic cavity that is open to the root canal of the affected tooth (Figure 6). As mentioned previously, such lesions were originally described as “bay cysts.”⁵¹ It has been postulated that biologically, a pocket cyst constitutes an extension of the infected root canal space into the periapex. The microluminal space becomes enclosed in a stratified squamous epithelium that grows and forms an epithelial collar (Figure 9) around the root tip. The epithelial collar forms an “epithelial attachment”³⁷ to the root surface that seals off the infected root canal and the micro-cystic lumen from the periapical milieu and the rest of the body (Figure 9C and D). The presence of microorganisms at the apical foramen (Figure 10) attracts neutrophilic granulocytes by chemotaxis into the microlumen. However, the pouch-like lumen—biologically outside the body milieu—acts as a “death trap” to the externalized neutrophils. As the necrotic tissue and microbial products accumulate, the sac-like lumen enlarges to accommodate the debris, forming a voluminous diverticulum of the root canal

Figure 7 Composite transmission electron micrograph showing neutrophils (NG, arrowheads) apparently in the process of transmigrating through the epithelial wall of a cyst (EP) into the cyst lumen (LU). ST = subepithelial tissue; PC = plasma cells; MA = macrophages. Original magnification $\times 1,600$. Modified from Nair.⁵⁹

Figure 8 An intramural scanning electron microscopic view of a cyst luminal wall (LU, in **A**) enlarged in stages (**B, C, D**). Note the flat epithelial cells (EP) and the globular neutrophilic granulocytes (NG). The latter emerge through the interepithelial cell spaces into the cyst lumen. Original magnifications: **A** $\times 20$, **B** $\times 230$, **C** $\times 670$, **D** $\times 1,300$. Reproduced with permission from Nair.¹

Figure 9 Overview photomicrograph **A**, of an apical periodontitis lesion (AP). The resorbed root tip with widened apical foramen is magnified in **B**. Note the bacterial plaque (white arrow head, BA) at the apical foramen and the micro-abscess (MA) externalized by an epithelial (EP) ring attached to the root tip. The rectangular demarcated area in **A**, is magnified in **C**. Note the numerous subepithelial blood vessels (BV) that are further magnified in **D**. The bacteria (BA) attract neutrophils (NG) to form the micro-abscess in front of the apical foramen which probably is the initiation of a periapical pocket cyst. D = dentine. Original magnifications: **A** $\times 20$, **B** $\times 40$, **C** $\times 130$, **D** $\times 310$. Reproduced with permission from Nair.¹

Figure 10 High-magnification photomicrographs (**A–D**) of the bacterial plaque (BA) shown in Figure 8-9 and the micro-abscess containing clusters of bacterial colonies (BA) apparently held back by a wall of neutrophils (NG). D = dentine; EP = epithelium. Original magnifications: **A, C, D** $\times 800$; **B** $\times 520$. Reproduced with permission from Nair.¹

Figure 11 Photomicrograph of a well-developed pocket cyst **A**. Note the sac-like epithelial lumen (LU), enlarged in **B**. A sequential, axial serial section **C**, passing through the apical foramen in the root canal plane (RC) shows the continuity of the lumen to the root canal. D = dentine. Original magnification: **A, C** $\times 16$; **B, D** $\times 40$. Reproduced with permission from Nair.¹

space into the periapical area (Figures 11 and 12). It has been pointed out⁵⁰ that from the pathogenic, structural, tissue dynamic, host-benefit, and protection stand points, the epithelium-lined pouch-like extension of the root canal space of such lesions has much in common with a marginal periodontal pocket. This

appears to justify the terminology of “periapical pocket cyst” as opposed to the biologically meaningless term “bay cyst.”⁵¹ In this context, it is interesting to note that cystic lesions with morphologic features identical to those of pocket cysts have been histologically illustrated by Seltzer in a text book⁷²

Figure 12 Macrophotographs **A, B**, of a large apical periodontitis lesion removed in toto by apical surgery **A**. The specimen after decalcification and axial subdivision **B**, shows a voluminous lumen into which the root canal opens. Reproduced with permission from Nair.¹

and also experimentally induced in monkeys by Valderhaug.^{60,73} However, these authors neither differentiated nor interpreted the lesions in relation to the root canals of the involved teeth—a reminder that in microscopy, as in nature, one recognizes only what one already knows.

CYSTS AND PERIAPICAL HEALING

The occurrence of two distinct classes of radicular cysts and the low prevalence of true cysts (<10%) are both significant considerations in clinical management of primary and particularly posttreatment apical

periodontitis. Many clinicians hold the view that cysts do not heal and thus must be removed by surgery. It should be pointed out with emphasis that apical periodontitis lesions cannot be differentially diagnosed into cystic and noncystic lesions based on radiographs.^{10,11,17–20,74} However, routine histopathologic diagnostic reports and publications based on retrospective reviewing of such have perpetuated the notion that nearly half of all periapical lesions are radicular cysts. As a result, a disproportionately large number of apical surgeries are performed at the tooth apex to “enucleate” lesions that are clinically diagnosed as “cysts.” In fact, studies based on meticulous

serial sections have shown that the incidence of *true cysts* is less than 10% of all periapical lesions.^{31,50,51} This would imply that most of the cases in which apical surgery has been performed based on radiographic diagnosis of cysts might have resolved by nonsurgical root canal therapy.

The endodontic literature suggests that a great majority of cysts heal after nonsurgical root canal therapy. "Success rates" of 85% to 90% have been reported.⁷⁵⁻⁷⁷ However, the histologic status of any apical radiolucent lesion at the time of treatment is unknown to the clinician, who is also unaware of the differential diagnostic status of the "successful" and "failed" cases. Most of the cystic lesions must heal if one should reconcile the high healing rate after nonsurgical root canal treatment and the claimed high prevalence of radicular cysts. This conclusion is based purely on a deductive logic in the absence of any histologic basis. It must be noted that several investigators listed in Table 1 reached the erroneous conclusion on high prevalence of cyst based on an incorrect interpretation of epithelialized apical periodontitis lesions.

CLINICAL RELEVANCE OF CYSTS IN PRIMARY AND POSTTREATMENT APICAL PERIODONTITIS

The aim of nonsurgical root canal therapy is the elimination of infection from the root canal and the prevention of re-infection by root filling. Periapical pocket cysts, particularly the smaller ones,

may heal after root canal therapy.⁵¹ The tissue dynamics of a true cyst is *self-sustaining* as the lesion is no longer dependent on the presence or absence of root canal infection.^{50,51} Therefore, the true cysts, particularly the large ones, are less likely to be resolved by nonsurgical root canal therapy. This has been shown in a long-term radiographic follow-up (Figure 13) of a case and subsequent histologic analysis of the surgical block biopsy.²⁶ It can be argued that the prevalence of cysts in posttreatment apical periodontitis should be substantially higher than that in primary apical periodontitis. However, this suggestion has not been supported by data based on a statistically reliable number of specimens. Nevertheless, investigations^{26,78,79} of 16 histologically reliable block biopsies of posttreatment apical periodontitis lesions (Table 2) revealed 2 cystic specimens (13%), possibly true cysts, which is well above the 9% of true cysts observed in a large study⁵⁰ on mostly primary apical periodontitis lesions.

The presence of two distinct structural forms of cystic apical periodontitis and the low prevalence of periapical cysts would *question the rationale* behind some of the current diagnostic and therapeutic concepts such as (1) disproportionate application of apical surgery based on unfounded radiographic diagnosis of apical lesions as cysts, and (2) the widely held opinion that majority of cysts heal after nonsurgical root canal therapy. Nevertheless, it should be recognized that periapical cysts could sustain persistent apical

Figure 13 Longitudinal radiographs **A–D**, of a periapically affected central maxillary incisor of a 37-year-old woman for a period of 4 years and 9 months. Note the large radiolucent asymptomatic lesion before **A**, 44 months after root filling **B**, and immediately after periapical surgery **C**. The periapical area shows distinct bone healing **D**, after 1 year postoperatively. Histopathologic examination of the surgical specimen by modern tissue processing and step-serial sectioning technique confirmed that the lesion was a true radicular cyst that also contained cholesterol clefts. Selected radiographs from Nair et al.²⁶

Table 2 The Prevalence of Cysts Among Post-treatment Apical Periodontitis Lesions

radiolucencies. Therefore, clinicians should consider the option of apical surgery, particularly when previous orthograde re-treatment has not resulted in radiographic healing.

CHOLESTEROL AND APICAL PERIODONTITIS

The presence of cholesterol clefts in apical periodontitis has been a common histopathologic observation. Yet, its etiologic significance to posttreatment apical periodontitis has been appreciated only recently.^{26,80,81} Endogenous substances of crystalline fine particulate nature can be tissue irritating. The crystals induce cytokine-network-mediated inflammation, hard tissue resorption, and soft tissue damage. Endogenous crystalline substances that have been shown to cause pathogenic tissue reaction include monosodium urate (gout), calcium phosphate dihydrate (pseudogout), basic calcium phosphate (hydroxyapatite), and cholesterol.

Cholesterol⁹ is a steroid lipid present in all animal tissues. The term is derived from *Chole-stereos* meaning “bile-solid” because of its occurrence in gall stones. Cholesterol has the characteristic core of the “cyclopentanoperhydrophenanthrene” ring (Figure 14). It is abundant in “membrane-rich” tissues (myelin) and secretory cells and is the precursor of bile acids, provitamin D3, and several hormones.⁸² Cholesterol is essential to life and most of the body cholesterol is produced in the liver. The entire body requirement of cholesterol can be met by endogenous production. Nevertheless, dietary cholesterol is absorbed from the intestine and metabolized. Cholesterol, being insoluble in aqueous solution, is transported by the circulation as conjugates of lipoproteins.

CHOLESTEROL IN DISEASE

High blood level of cholesterol is suspected to play a role in atherosclerosis as a result of its deposition in the vascular walls.^{82,83} Atherosclerosis is a chronic, progressive, multifactorial disease that begins as an intracellular deposition of cholesterol in previously damaged sites on the inner arterial walls. The lesions

Figure 14 The parent compound of all steroids is *Cyclopentanoperhydrophenanthrine* with four saturated rings that are designated alphabetically as shown **A**. The structural formula of cholesterol **B**. Note the four cyclohexane rings and the standard numbering system of all the carbon atoms. Reproduced with permission from Nair.⁸¹

eventually become fibrous calcified plaques. The consequent hardening and narrowing of the arteries promote the formation of intravascular blood clots and infarction of the dependent tissue. Although atheromas can develop in many different blood vessels, they are most common in the coronary arteries. The resultant myocardial infarction is usually fatal and is the most common cause of death in western industrialized nations.⁸⁴ Deposition of crystalline cholesterol also occurs in other tissues and organs, as in the case of otitis media and the “pearly tumor” of the cranium.⁸⁵ In the oral region, accumulation of cholesterol crystals occurs in apical periodontitis lesions^{10,26,55,86–89} with clinical significance in endodontics and oral surgery.^{26,90}

CHOLESTEROL IN APICAL PERIODONTITIS

Apical periodontitis lesions often contain deposits of cholesterol crystals appearing as narrow, elongated tissue clefts in histopathologic sections. The crystals dissolve in fat solvents used for the tissue processing and leave behind the spaces they occupied as clefts. The reported prevalence of cholesterol clefts in apical periodontitis varies from 18% to 44%.^{55,86,88,89} The crystals are believed to be formed from cholesterol released by: (1) disintegrating erythrocytes of stagnant

blood vessels within the lesion,⁸⁸ (2) lymphocytes, plasma cells, and macrophages that die in great numbers and disintegrate in chronic periapical lesions,⁸⁹ and (3) the circulating plasma lipids.⁵⁵ All these sources may contribute to the concentration and crystallization of cholesterol in the periapical area. Nevertheless, inflammatory cells that die and disintegrate within the lesion may be the major source of cholesterol, as a result of its release from membranes of such cells in long-standing lesions.^{26,72} The crystals are initially formed in the inflamed periapical connective tissue, where they act as foreign bodies and provoke a giant cell reaction.

In histologic sections, numerous multinucleated giant cells can be observed around the cholesterol clefts (Figure 15). When a large number of crystals accumulate in the inflamed connective tissue, they

Figure 15 Cholesterol crystals and cystic condition of apical periodontitis as potential causes for endodontic failures. Overview of a histologic section (upper inset) of an asymptomatic apical periodontitis that persisted after conventional root canal treatment. Note the vast number of cholesterol clefts (CC) surrounded by giant cells (GC) of which a selected one with several nuclei (arrowheads) is magnified in the lower inset. D = dentine; CT = connective tissue; NT = necrotic tissue. Original magnifications: $\times 68$; upper inset $\times 11$; lower inset $\times 412$. Reproduced with permission from Nair.⁸¹

passively move in the direction of least resistance. If the lesion happens to be a radicular cyst, the crystals move in the direction of the epithelium-lined cyst cavity, as the outer collagenous capsule of the lesion is much tougher for the crystals to move through. The slow “glacier-like” movement of the crystal mass erodes the epithelial lining and empties the crystals into the cyst lumen (Figure 15).

Radicular cysts⁹¹ and apical granulomas¹⁰ in which cholesterol clefts form a major component are referred to as “cholesteatoma.” The term originates from general pathology where it refers to a local accumulation of cholesterol crystals that cause discomfort and dysfunction of the affected organs.⁸⁵ Therefore, the term should be used more specifically as “apical cholesteatoma” so as to distinguish the condition from cholesteatoma affecting other tissues and organs.

TISSUE REACTION TO CHOLESTEROL

Cholesterol crystals are intensely sclerogenic.^{92,93} They induce granulomatous lesions in dogs,⁹⁴ mice,^{92,93,95–97} and rabbits.^{95,98,99} The cholesterol was applied in those studies by direct injection of its suspension into arterial walls,⁹⁴ by subcutaneous deposition of cholesterol crystals,^{92,93,96,97} or by subcutaneous implantation of absorbable gelatin sponge that had been saturated with cholesterol in ether, and the solvent was allowed to evaporate before the implantation.^{95,99} These studies consistently showed that the cholesterol crystals were densely surrounded by macrophages and giant cells.

There appears to be only one experimental study reported in the literature that specifically addressed the potential association of cholesterol crystals and non-resolving apical periodontitis lesions.⁸⁰ In this study in guinea pigs, the tissue reaction to cholesterol crystals was investigated by using a Teflon cage model¹⁰⁰ that facilitated the intact surgical retrieval of the cholesterol crystals with the surrounding host tissue after the experimentation. The study was to answer the question as to whether aggregates of cholesterol crystals would induce and sustain a granulomatous tissue reaction in guinea pigs. Pure cholesterol crystals, prepared to a mushy form, were placed in Teflon cages that were implanted subcutaneously in guinea pigs. The cage contents were retrieved after 2, 4, and 32 weeks of implantation and processed for light and correlative transmission electron microscopy. The cages revealed delicate soft connective tissue that grew in through perforations on the cage wall. The crystals were densely surrounded by numerous macrophages and multinucleated giant cells (Figures 16 and 17), forming a well circumscribed area of tissue reaction. The cells,

Figure 16 Photomicrograph **A**, of guinea pig tissue reaction to aggregates of cholesterol crystals after an observation period of 32 weeks. The rectangular demarcated areas in **A**, **B**, and **C**, are magnified in **B**, **C**, and **D**, respectively. Note that rhomboid clefts left by cholesterol crystals (CC) surrounded by giant cells (GC) and numerous mononuclear cells (arrowheads in **D**). AT = adipose tissue; CT = connective tissue. however, were unable to eliminate the crystals during an observation period of 8 months.

The congregation of macrophages and giant cells around cholesterol crystals in the absence of other inflammatory cells such as neutrophils, lymphocytes, and plasma cells suggests that the crystals induced a typical foreign body reaction.^{101–103} Whereas most of the macrophages may be freshly recruited blood monocyte population,^{104,105} the giant cells are of local origin. Radioactive labeling studies^{106,107} have conclusively shown that giant cells are monocyte derivatives formed by fusion of macrophages. Investigations on the cytogenesis of multinucleate giant cells around cholesterol crystals in subcutaneous implants suggest that they are formed by a process of “circumfusion”⁹³ of macrophages around individual crystals. Once formed, the giant cells can also enlarge in size by synchronous division of their nuclei.¹⁰⁸

BODY CELLS CANNOT ELIMINATE CHOLESTEROL CRYSTALS

Tissue degradation of cholesterol crystals, if any, should happen via the phagocytic and/or biochemical pathways. Macrophages are efficient phagocytes¹⁰⁹ capable of ingesting and killing microorganisms, scavenging dead cells and necrotic tissue, and removing

small foreign particles.¹¹⁰ Cells belonging to the mononuclear phagocytic system¹¹¹ are involved in lipid uptake.¹¹² Macrophages have been shown to internalize cholesterol crystals *in vitro*.^{93,112} Fine suspensions of cholesterol crystals administered intraperitoneally in rats were found in sternal lymph node macrophages.^{113,114} In this apparently-phagocytic intake of particulate cholesterol, the size of the crystals must have been appropriately small for the macrophages to ingest them. However, when macrophages encounter larger foreign particles,^{101,103} or cholesterol crystals,^{92–96,99} they form multinucleate giant cells. The presence of giant cells in cholesterol granuloma is a clear sign of the large size of the crystals in relation to macrophages. However, the giant cells are poor phagocytes,^{107,115} their phagocytic efficiency declining with increasing size of the cells.^{116,117} The degradative power of multinucleate giant cells is mainly vested in their ability to resorb intrinsic and extrinsic substrates. Resorption is a highly specialized cellular activity in which the destruction of suitable substrates occurs extracellularly at the specialized cell/substrate interface by biochemical means.

In order to degrade tissue deposits of cholesterol crystals, the surrounding cells should have the ability to attack the crystals chemically so as to disperse them into the surrounding tissue fluid or to make them accessible to the cells themselves. Cholesterol crystals are highly hydrophobic, and their dispersal would necessitate making them hydrophilic and “soluble” in an aqueous medium.⁹² The granulomatous and sclerogenic effects of cholesterol crystals can be prevented by the incorporation of phospholipids into subcutaneous implants of cholesterol.⁹⁶ This beneficial effect of phospholipids has been attributed to their “detergent” property and their role as donors of polyunsaturated fatty acids during esterification of the cholesterol.^{92,97} The giant cells and macrophages are known to esterify and mobilize cholesterol in a lipid droplet form.⁹³ Macrophages can convert particulate cholesterol into a soluble form by incorporating it into a lipoprotein vehicle,^{112,118} so that the cholesterol can be readily esterified or added into the lipoprotein pool in circulation.

These cell biologic findings obviously support the possible ability of macrophages and giant cells to degrade particulate cholesterol. But they are not consistent with the histopathologic observation of spontaneous^{10,26,28} and experimentally-induced^{92–96,99} cholesterol granulomas. The characteristic feature of such lesions is the accumulation of macrophages and giant cells around the cholesterol clefts and their persistence for long periods of time. *Therefore, it is to be assumed that the macrophages and the multinucleate giant cells that congregate around cholesterol crystals are unable to destroy the crystals*

in a way beneficial to the host.⁸⁰ Therefore, massive accumulation of cholesterol crystals in apical periodontitis is clinically significant. The macrophages and giant cells that surround cholesterol crystals are not only unable to degrade the crystalline cholesterol but are major sources of apical inflammatory and bone resorptive mediators. Bone-resorbing activity of cholesterol-exposed macrophages due to enhanced expression of interleukin-1 has been experimentally shown.¹¹⁹ Based on these considerations, it was concluded in a long-term longitudinal follow-up of a case that “the presence of vast numbers of cholesterol crystals... would be sufficient to sustain the lesion indefinitely.”²⁶ The experimental results and other evidence presented from the literature substantiate that assumption.

FOREIGN BODIES

Foreign materials trapped in periapical tissues can cause pathologic tissue reaction. Particles of root-filling materials, other endodontic materials,^{101,120} and portions of foods¹²¹ can reach the periapical tissues and initiate a foreign body reaction that may be associated with periapical radiolucency.¹⁰¹

The most widely used solid root canal filling material is prepared from (*trans*-polyisoprene), the coagulated exudate from *Plaquium gutta* tree of Asia or from

similar latex derived from the *Mimisops globsa* tree of South America.¹²² Cones are composed of about 20% gutta-percha, 60% to 75% zinc oxide, and varying amounts of metal sulfates for radioopacity, waxes, and coloring agents. Based on implantation experiments in animals, cones are considered to be biocompatible and well tolerated by human tissues.^{123–125} This view has not been consistent with the observation that the presence of extruded gutta-percha is associated with delayed healing of the periapex.^{76,77,101,126,127} In general, bulk form of sterile materials with smooth surfaces placed within bone or soft tissue evoke a fibrous tissue encapsulation, while particulate materials induce a foreign body and chronic inflammatory reaction.^{128–132} Apart from the particle size, the chemical composition of gutta-percha is also of significance. Leaching zinc oxide from gutta-percha cones has been shown to be cytotoxic in vitro,^{133,134} tissue irritating in vivo, and associated with adjacent inflammatory reaction.^{103,135} Tissue response to gutta-percha was studied¹⁰³ using subcutaneously implanted Teflon cages in which the gutta-percha evoked two distinct types of tissue reaction. Large pieces of gutta-percha were encapsulated by collagen and the surrounding tissue was free of inflammation (Figure 18). But, fine particles of gutta-percha induced an intense, localized tissue response (Figure 19), characterized by the presence of macrophages and giant cells. The

Figure 18 Guinea pig tissue reaction to gutta-percha (GP) by 1 month after subcutaneous implantation **A**. Large pieces of gutta-percha are well encapsulated by collagen fibers that run parallel to the surface of the gutta-percha particle. The interface of the gutta-percha particle and the host tissue (arrow) is magnified in stages in **B**, and **C**. The gap between the implant and the collagen capsule is artifactual. Note the noninflamed, healthy soft delicate connective tissue. Original magnifications: **A** $\times 17$, **B** $\times 80$, **C** $\times 200$. Reproduced with permission from Nair.¹⁶³

Figure 19 Disintegrated gutta-percha as potential for maintaining posttreatment apical periodontitis. As clusters of fine particles (**A, B**), they induce intense circumscribed tissue reaction (TR) around. Note that the fine particles of gutta-percha (* in **C**, GP in **D**) are surrounded by numerous mononuclear cells (MNC). Original magnifications: **A** $\times 30$, **B** $\times 80$, **C** $\times 200$, **D** $\times 750$. From P.N.R. Nair, Pathobiology of the periapex. In: S. Cohen and R.C. Burns, editors, *Pathways of the pulp*, 8th ed., St Louis, 2002 Mosby©.

Figure 20 Two longitudinal radiographs (inset and **A**) of a root-filled and periapically affected left central maxillary incisor of a 54-year-old man. The first radiograph (inset) taken immediately after root filling in 1977 shows a small excess filling that protrudes into the periapex (arrowhead in inset). Note the excess filling has disappeared in the radiograph taken 10 years later (arrowhead in **A**) and shortly before surgery was performed. The apical block biopsy removed by surgery does not show any excess filling, as is evident from the macrophotograph of the decalcified and axially subdivided piece of the biopsy, **B**. RF = root filling; D = dentine; GR = granuloma. Original magnification: **B** $\times 10$. Reproduced with permission from Nair.¹⁰¹

accumulation of macrophages in conjunction with the fine particles of gutta-percha is significant for the clinically observed impairment in the healing of apical periodontitis, when teeth are root filled with excess of gutta-percha. Pieces of gutta-percha cones in periapical tissue can gradually fragment into fine particles that in turn can induce a typical foreign body reaction¹⁰¹⁻¹⁰³ and activate macrophages.¹³⁶ The latter release a battery of intercellular mediators that include proinflammatory cytokines and modulators that are involved in bone resorption.¹³⁷⁻¹⁴⁰

In addition, commercial gutta-percha cones may become contaminated with tissue-irritating substances that can initiate a foreign body reaction at

the periapex. In a follow-up study of nine asymptomatic persistent apical periodontitis lesions that were removed as surgical block biopsies and analyzed by correlative light and transmission electron microscopy, one biopsy (Figure 20) revealed the involvement of talc contaminated gutta-percha.¹⁰¹ The radiographic lesion persisted asymptotically and grew in size during a decade of posttreatment follow-up. The lesion was characterized by the presence of vast numbers of multinucleate giant cells with birefringent inclusion bodies (Figure 21). In transmission electron microscope, the birefringent bodies were found to be highly electron dense (Figure 22). Energy dispersive X-ray microanalysis of the

Figure 21 A bright-field photomicrograph of a plastic-embedded semithin ($2\ \mu\text{m}$ thick) section of the apical area shown in Figure 20B. Note the large apical periodontitis lesion (AP) **A**. The same field when viewed in polarized lights **B**. Note the birefringent bodies distributed throughout the lesion **B**. The apical foramen is magnified in **C**, and the dark arrow-headed cells in **C**, are further enlarged in **D**. Note the birefringence (BB) emerging from slit-like inclusion bodies in multinucleated (N) giant cells. B = bone; D = dentine. PittFord, editors, *Essential Endodontology*, Oxford, 1998, Blackwell©.

Figure 22 Low-magnification transmission electron micrograph showing the profiles of several giant cells within the apical periodontitis shown in Figures 20 and 21. Note the presence of many slit-like inclusion bodies (BB₁ to BB₆), which contain a highly electron-dense material. This material may remain intact within the inclusion body or may be pushed away from its original site (BB₂) or may appear disintegrated (BB₃ and BB₄) by the tissue processing. Note the lines of artifacts AL, which are created by portions of the electron-dense material having been carried away by the knife edge, leaving tracts behind. Original magnification: $\times 1,880$. From P.N.R. Nair et al.²⁷ Reproduced with permission from Nair.¹⁰¹

inclusion bodies using scanning transmission electron microscopy (STEM) revealed the presence of magnesium and silicon (Figure 23). These elements are presumably the remnants of talc-contaminated gutta-percha that protruded into the periapex and had been resorbed during the follow-up period.

ORAL PULSE GRANULOMA

It denotes a foreign body reaction to particles of vegetable foods, particularly leguminous seeds such as peas, beans, and lentils (pulses) that get lodged in the oral tissues. The lesions are also referred to as the giant cell hyaline angiopathy,^{141,142} vegetable granuloma,¹⁴³ and

Figure 23 High-magnification transmission electron micrograph **C**, of the intact birefringent body labeled BB1 in Figure 22. Note the distinct delimiting membrane around the birefringent body (BB). Energy-dispersive X-ray microanalysis of the electron-dense material done in scanning transmission electron microscope (STEM: done at the point where the two hairlines perpendicular to each other cross in the left inset) revealed the presence of silicon (Si), magnesium (Mg), and lead (Pb) in **A**, whereas another site in the neighboring cytoplasm of the same giant cell (arrowhead in right inset) does not show the presence of Si and Mg **B**. Lead and uranium (U) are used for section contrasting, and emission in copper (Cu) is from the section-supporting grid made of copper. Original magnification $\times 11,000$; insets $\times 3,300$. Reproduced with permission from Nair.¹⁰¹

food-induced granuloma.¹⁴⁴ Pulse granuloma has been reported in lungs,¹⁴⁵ stomach walls, and peritoneal cavities.¹⁴⁶ Experimental lesions have been induced in animals by intratracheal, intraperitoneal, and submucous introduction of leguminous seeds.^{147,148} Periapical pulse granulomas are associated with teeth grossly damaged by caries and with the history of endodontic therapy.^{121,149} Pulse granuloma is characterized by the presence of intensely iodine and periodic acid—Schiff-positive hyaline rings/bodies surrounded by giant cells and inflammatory cells.^{121,148–150} The cellulose in plants has been suggested to be the granuloma-inducing agent.¹⁴⁷ However, leguminous seeds are the most frequently involved vegetable in such granulomatous lesions. This indicates that other components in pulses, such as antigenic proteins and mitogenic phytohemagglutinins, may also be involved in the pathologic tissue response.¹⁴⁷ The pulse granulomas are clinically relevant because particles of vegetable foods can reach the periapical tissues via root canals of teeth exposed to the oral cavity by trauma, caries, or endodontic procedures.¹²¹ However, the incidence of pulse-induced apical periodontitis may be low, as only two such cases have been reported in the literature.^{121,150}

CELLULOSE GRANULOMA

Cellulose granuloma is pathologic tissue reaction to particles of predominantly cellulose-containing materials that are used in endodontic practice.^{151–154} Endodontic *paper points* are utilized for microbial sampling and drying of root canals. Medicated *cotton wool* has been used in root canals as well. Particles of these thermo-sterilized materials can easily dislodge or get pushed into the periapical tissue¹⁵⁴ so as to induce a foreign body reaction

at the periapex. Presence of cellulose fibers in periapical biopsies with a history of previous endodontic treatment has been reported.^{151–153} The overall incidence of cellulose-induced apical periodontitis is unknown. This may be partly due to the inconspicuous nature of cellulose material in periapical biopsies and the difficulty to identify them without the application of special stains or techniques. In two investigations in which 13 biopsies of posttreatment apical periodontitis were histologically examined, all displayed material consistent with cellulose fibers.^{151,152} The endodontic paper points and cotton wool consists of cellulose, which is neither digested by humans nor degraded by the body cells. They remain in tissues for long periods of time¹⁵³ and evoke a foreign body reaction around them. The particles, when viewed in polarized light, reveal birefringence due to the regular structural arrangement of the molecules within cellulose.¹⁵¹ Paper points infected with intraradicular microorganisms can project through the apical foramen into the periapical tissue (Figure 24) and allow a biofilm to grow around the paper point (Figure 24).

OTHER FOREIGN MATERIALS

Endodontic sealer cements, amalgam, and calcium salts derived from periapically extruded calcium hydroxide also occur in periapical tissues. In a histologic and X-ray microanalytic investigation of 29 apical biopsies, 31% of the specimens were found to contain materials compatible with amalgam and endodontic sealer components.¹²⁰ However, an etiologic significance of these materials has not been conclusively shown by experiments. It is possible that these materials might have been coexisting with unidentified etiologic agents such as the presence of intraradicular infection in those cases.

Figure 24 A massive paper-point granuloma affecting a root-canal-treated human tooth **A**. The demarcated area in **B**, is magnified in **C**, and that in the same is further magnified in **D**. Note the tip of the paper point (FB) projecting into the apical periodontitis lesion and the bacterial plaque (BP) adhering to the surface of the paper point. RT = root tip; EP = epithelium; PC = plant cell. Original magnifications: **A** $\times 20$, **B** $\times 40$, **C** $\times 60$, **D** $\times 150$. From P.N.R. Nair, Pathobiology of the periapex. In: S. Cohen and R.C. Burns, editors, *Pathways of the pulp*, 8th edition, St Louis, 2002 Mosby©.

Scar Tissue healing

There is evidence^{10,52,79,155} that unresolved periapical radiolucencies may occasionally be due to healing of

the lesion by scar tissue (Figure 25) that may be misdiagnosed as a radiographic sign of failed endodontic treatment. Certain deductions can be made from the

Figure 25 Periapical scar (SC) of a root canal (RC)-treated tooth after 5-year follow-up and surgery. The rectangular demarcated areas in **B–D**, are magnified in **C–E**, respectively. The scar tissue reveals bundles of collagen fibers (CO), blood vessels (BV), and erythrocytes due to hemorrhage. Infiltrating inflammatory cells are notably absent. Original magnifications: **A** $\times 14$, **B** $\times 35$, **C** $\times 90$, **D** $\times 340$, **E** $\times 560$. Modified from Nair et al.⁷⁹

data available on normal healing and guided regeneration of the marginal periodontium. Several cell populations participate in the periodontal healing process. The pattern of healing depends on several factors, two of which are decisive. They are the regeneration potential and the speed with which the tissue cells bordering the defect react.^{156–159} A periapical scar probably develops because precursors of soft connective tissue colonize both the root tip and periapical tissue; this may occur before the appropriate cells, which have the potential to restore various structural components of the apical periodontium, are able to do so.⁷⁹

Concluding Remarks

The presence of an intraradicular infection is the *essential cause* of primary apical periodontitis and the *major cause* of persistent apical radiolucencies.^{160,161} This means that microbial infection is not the only etiologic agent of apical radiolucencies persisting posttreatment. The nonmicrobial factors, discussed in this chapter, include (1) true cystic lesions, (2) extruded root canal filling or other exogenous materials that cause a foreign body reaction; (3) accumulation of endogenous cholesterol crystals that irritate periapical tissues; and (4) scar tissue healing of the lesion. Although true cysts, foreign body reaction, and scar tissue healing are of rare occurrence, they are of clinical significance.

Most of the cysts, particularly larger cysts, may not be amenable to root canal treatment alone. Whereas smaller pocket cysts are likely to heal after root canal treatment, very large pocket cysts and most of the true cysts may not heal. But there are no individual statistics on them. Cysts, nevertheless, represent only a small fraction of persistent apical radiolucencies.

The fact that persistent apical radiolucencies cannot be differentially diagnosed based on etiology is of no clinical significance but of academic interest only. This is because it is not guaranteed that root canal re-treatment of an otherwise well-treated tooth will result in the removal of intraradicular microbes located in the apical canal system, which is the single most important cause of persisting radiolucencies. Furthermore, apical radiolucencies persisting because of extraradicular factors discussed in this chapter, such as foreign body reaction, including those due to cholesterol crystals, cystic condition, and scar tissue are beyond root canal system and cannot be managed by root canal re-treatment.

Therefore, with cases of asymptomatic, persistent radiolucencies, clinicians should consider the neces-

sity of removing the extraradicular factors by an apical surgery,¹⁶² in order to improve the long-term result of treatment. An apical surgery enables to remove the extraradicular agents that sustain the radiolucency posttreatment and also allows a retrograde access to any infection in the apical portion of the root canal system that can also be removed or sealed within the canal by a retrograde root-end filling.¹⁶³

CHAPTER 9

INFLAMMATION AND IMMUNOLOGICAL
RESPONSES

ASHRAF F. FOUAD, GEORGE T.-J. HUANG

Endodontic pathosis is primarily caused by infectious agents that mediate a series of inflammatory and immunological responses in the dental pulp and periradicular tissues. This chapter will describe some of the fundamental immune reactions that take place in these tissues, as well as other tissues, and will outline the basic mechanisms involved in disease initiation and progression.

The science of immunology is constantly changing and remarkable discoveries are being made about the unique molecules, cells, tissues, and pathways of reactions that take place in response to an external and autogenic stimulation. While an attempt has been made to address most of the critical and well-understood immunological data, it is impossible to address all aspects in this chapter. Immunological reactions that are either not well described in, or not relevant to the dental pulp and periradicular tissues, or simply exceed the scope of this textbook include neoplastic changes, autoimmune reactions, and some congenital and postnatal abnormalities in gene expression. Indeed, the reason why neoplastic changes are not common in the dental pulp may be of fundamental importance in understanding the pathogenesis of neoplasia in general and may have relevance in the growing field of regenerative endodontics, particularly in gene therapy. Therefore, these topics will not be addressed in this chapter, and the reader is referred to specialized textbooks or journals for more information on these topics.

The reactions and mechanisms that will be covered here are those that primarily deal with the inflammatory response and that have been described to some degree in pulpal and periradicular tissues or are widely recognized in other tissues and presumed to be in operation in endodontic tissues. In fact,

wherever relevant, specific literature that addresses these questions will be cited in the text. The reader is also referred to Chapters 12 and 13 for more specific information on pulpal and periradicular inflammation and infection.

The material described in this chapter will be presented under discrete topics, for example, the individual cells and molecular mediators encountered in immunological reactions. However, the reader should always be cognizant of two fundamental concepts in immunology. The first is that there are many interrelationships between the pathways and mechanisms that will be presented, and many overlap among the functions of the cells to be described. This creates a large amount of redundancy that assures a competent and robust response. Indeed, it is commonly stated that the main purpose of treatment of various disease processes is to remove the source of irritation and provide a suitable environment for the body to heal itself, through its effective healing mechanisms. The second concept is that there is a substantial degree of variability among individuals in their response to a particular irritant. While some of this difference in response is quite extreme, and is explained by various hypersensitivity reactions, most of the variation is more subtle and is mediated by systemic conditions and diseases, or individual genetic polymorphism of different patients.

The concept of genetic polymorphism commonly refers to differences in the expression of certain inflammatory mediators or cellular activation or other immunological reactions. This variation may indeed render certain individuals more prone to a more dramatic expression of the disease process or delay in healing mechanisms. Genetic polymorphism may be explained by minor, perhaps a single nucleotide

variation in the genetic make up of particular genes. Thus it is commonly referred to as single nucleotide polymorphism or SNP. SNPs have been described with respect to the expression of a number of proteins, such as interleukin-1 (IL-1), and may explain why some inflammatory reactions to seemingly similar irritants have different clinical presentations and responses to treatment in different patients.

The immune system represents a complex system of cells, tissues, organs as well as molecular mediators that act in synchrony to assure the maintenance of health and defense against disease. Cells interact with microbial irritants as well as with each other via a large number of molecular mediators and cell surface receptors that together result in various phenotypic reactions. Various host reactions will be discussed in the context of a description of the main cells of the immune response, as these cells play a critical role in mobilizing the immune response. It is appropriate initially to present the ontogeny of immune cells from hematopoietic stem cells (Figure 1).¹ A description of the mature inflammatory cells and their

activities will follow, starting with the innate immune system.

Innate and Adaptive Immune Systems

The innate immune system is composed of a number of natural barriers, as well as cellular and molecular elements that represent the initial nonspecific reactions of the immune response. The barriers are epithelial, ectodermal, or ectomesenchymal in origin. Examples include the skin, oral mucosa, junctional and sulcular epithelium, as well as intact enamel and dentin. These barriers prevent the dissemination of bacteria and bacterial products into the subjacent connective tissue, which would result in a disease. Dental caries, fractures of teeth, or congenital anomalies that expose the dental pulp create a break in this barrier, resulting in the inflammation of the pulp and ultimate necrosis. Once the pulp is necrotic and the pulp space is occupied by microorganisms, there is no natural barrier to the dissemination of these irritants into the periradicular region and/or systemically through the apical, lateral, or accessory foramina. In fact, junctional complexes between odontoblasts in the vital pulp have been shown to play a role in preventing the leakage of bacterial irritants into the pulp.^{2,3}

Phagocytosis is another important component of innate immunity. Likewise, the presence of certain nonspecific proteins such as lysozyme or complement—or pattern recognition receptors (PRR) such as Toll-like receptors (TLRs) (see later)—on the surface of immune cells are also constituents of the innate immune system. Inflammation is associated with a number of vascular changes such as vasodilatation, increased capillary permeability and extravasation of blood cells and inflammatory mediators, together with reduced pain threshold. Many of these nonspecific changes are caused by neurogenic elements, such as neuropeptides. These concepts will be addressed later in the chapter. Therefore, innate immunity does not involve sensitization or priming, has uniform response to all irritants that are detected, lacks memory and aims at rapidly eliminating irritants.

CELLS OF INNATE IMMUNITY

Neutrophils, also known as polymorphonuclear leukocytes or PMNs, are the most numerous white blood cells, representing about 54% to 63% of peripheral blood leukocytes. They have a short half-life, generally circulating for about 6 hours, and if not recruited to a site of inflammation, they undergo apoptosis.

Figure 2 Experimental pulp exposure in a rodent molar, showing pulp necrosis, acute and chronic inflammation, and vasodilatation. Courtesy of Dr. Fouad.

PMNs represent the first defense line against microbial irritants, being mobilized in what is traditionally known as acute inflammation (Figure 2). PMNs utilize a large number of defense mechanisms to eliminate the invading pathogens and to inactivate their toxins. These include the production of lysosomal enzymes, cytokines, oxygen-derived free radicals, as well as phagocytosis.

Within PMNs, defense proteins are contained within two different types of granules: The first type is azurophil (large) granules (about 0.5 μm in diameter) that contain lysozyme, myeloperoxidase, defensins, acid hydrolases, and neutral hydrolases such as collagenases, elastase, cathepsin G, and other proteinases. The second type is specific (small) granules (about 0.2 μm in diameter) that contain lactoferrin, lysozyme, collagenases, plasminogen activator, histaminase, alkaline phosphatase, and membrane-bound cytochrome b_{558} . The cell also has abundant glycogen stores that enable the cell to utilize glycolysis to produce energy in anaerobic conditions,⁴ such as during an abscess formation.

Monocytes are circulating leukocytes that represent 4% to 8% of blood leukocytes. *Macrophages* reside within connective tissues. Certain macrophages become especially adapted for immunological functions in certain tissues. These cells are collectively referred to as members of the mononuclear phagocyte system. Examples of these cells are Kupfer cells in the liver, microglia in the central nervous system, or alveolar macrophages in the lungs. It is generally accepted now that both macrophages and osteoclasts

have a common lineage. Likewise a number of other cells commonly seen in inflammatory reaction or granulomatous disease, such as foam cells, epithelioid cells, or giant cells, may have a common lineage.

Macrophages have a relatively long half-life in tissues, commonly measured in months. They are considered among the principal inflammatory cells, commonly mobilized in areas of chronic inflammation. They possess major histocompatibility complex (MHC)-II receptor, have antigen-presenting capabilities, and are involved in phagocytosis. They are also among the principal producers of proinflammatory cytokines such as IL-1, IL-6, tumor necrosis factor- α (TNF- α), and IL-12.

Macrophages may be activated by activated Th1 cells of the specific arm of the immune response, or nonspecifically, such as by natural killer (NK) cells (Figure 3). They express surface receptors to a variety of pathogen-associated molecular patterns such as lipopolysaccharide (LPS) of gram-negative bacteria or peptidoglycan (PG) and lipoteichoic acid (LTA) of gram-positive bacteria. These receptors have intracytoplasmic component (homologous with the IL-1 receptor molecule) that transmits the signal through adapter molecules such as MyD88 and Trif to transcription factors such as NF- κ B, IRF3, IRF5, and others. Eventually, these transcription factors are translocated into the nucleus to activate gene transcription followed by mRNA translation to produce certain proinflammatory proteins, such as cytokines IL-1, IL-6, and TNF- α . Molecules such as LPS are very potent biological toxins, capable of causing septic shock and killing the host. Therefore, in addition

Figure 3 Macrophage activation and function. **A**, Cell is activated by cytokines from specific and nonspecific immune cells. **B**, Cell expresses various pattern recognition receptors to microbial molecules. **C**, Signal transduction through MyD88, Trif, or other intermediaries, transcription through nuclear factor kappa B, and mitogen-activated protein kinases that result in the translation of mRNA and the production of proinflammatory cytokines. Courtesy of Dr. Fouad.

to the membrane-bound TLRs, a number of circulating molecules such as CD14 are available that can bind to LPS in the blood rendering it less biologically active. This reaction is mediated by a plasma protein called LPS-binding protein (LBP). CD14 is also available in a membrane-bound form to the surface of macrophages and can bind LBP in this location; however, unlike TLRs, CD14 has no intracytoplasmic

component, and thus is not capable of initiating the signal transduction pathway to initiate the production of cytokines.

The PMNs and macrophages are the main cells involved in phagocytosis. The surface of phagocytes can bind to the pathogen surface pattern molecules by lectin, through complement C3b or C5b, or by binding to the Fc portion of an opsonizing antibody (Figure 4). After the initial binding of the pathogen, which is significantly enhanced by opsonins, pseudopodia develop to surround and engulf the pathogenic organism, leading to the formation of a phagosome. The final stage of phagocytosis involves lysosomal enzymes, which are released into the phagosome for degrading the microorganism or other foreign particles.

Microbial killing within the phagosome is effected through a series of oxidative reactions that require glycolysis, glycogenolysis, and the generation of reactive oxidative free radicals⁵ (Figure 5). The fusion of the membranes of a phagosome and the cell's lysosomal granules (such as the azurophilic granules of PMNs) results in an oxidative burst mediated by cytoplasmic- and membrane-bound oxidases. Through the action of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, superoxide ions and hydroxyl radicals are generated (see Figure 5). While these are sufficiently antimicrobial, lysosomes of PMNs contain myeloperoxidase, which through a halide intermediate can result in the generation of hypochlorous radicals (HOCl•). As is the case with exposure to sodium hypochlorite (NaOCl), HOCl• is a powerful oxidant and antimicrobial agent that kills bacteria by halogenation, or by protein or lipid

Figure 4 Phagocytic cell recognizes an opsonized bacterial cell and starts to form a phagosome (white arrows) to engulf it. Eventually, lysosomal enzymes open into the phagosome to digest the material. Courtesy of Dr. Fouad.

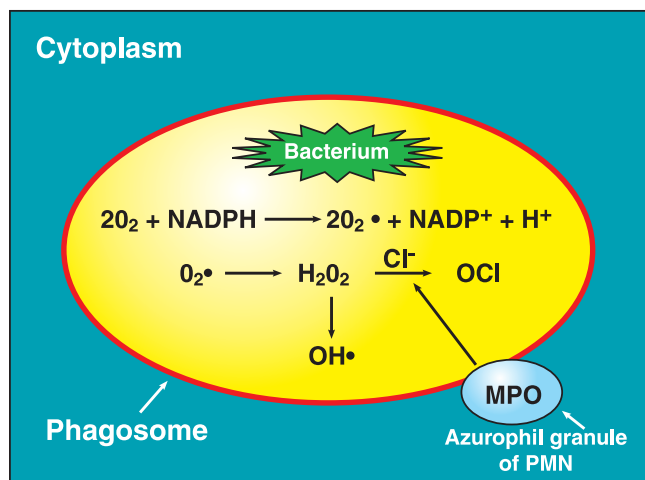

Figure 5 Oxidative burst reactions within a phagosome that result in the destruction of a pathogen. Courtesy of Dr. Fouad.

peroxidation. Within the phagosome, other mechanisms of bacterial killing include lysozyme, which causes the degradation of bacterial coat oligosaccharides, and defensins, which are peptides that kill bacteria by forming holes through their membranes.⁵

While phagocytosis is quite effective in eliminating microbial irritants, when they are isolated or individualized, it frequently cannot deal with a microbial biofilm. A microbial biofilm has a large number of microorganisms embedded in a polysaccharide matrix. An example of this that is relevant to endodontics is a periapical infection with *Actinomyces* spp, which is generally thought to occur in the form of microbial colonies within the lesions. Inflammatory cells usually surround these colonies and attempt to eliminate them by forming phagosomes, but instead result in the release of oxygen radicals and lysosomal enzymes into the periradicular tissues, causing tissue degradation. This is referred to sometimes as “frustrated phagocytosis.”

Like neutrophils, *eosinophils* are segmented leukocytes; however, they stain red with hematoxylin and eosin stains (thus the name). They are much less prevalent than PMNs, constituting only about 1 to 3% of circulating leukocytes. They are involved in allergic and some parasitic reactions. Their actions are primarily mediated by a low-affinity surface receptor for the Fc portion of the IgE molecule called FcεRII. Eosinophils express a number of inflammatory and healing mediators, most notably transforming growth factors (TGFs)-α and -β1.^{6–8} Eosinophils in human periapical cysts were shown to express

Table 1 Comparison of Mast Cells and Basophils

	Mast Cells	Basophils
Size: (μm)	10–15	5–7
Location	Connective tissue	Blood
Life span	Weeks or months	Days
Terminally differentiated	No	Yes
Granule content	Histamine, heparin, PAF	Histamine, heparin, PAF
High-affinity FcεRII	Yes	Yes

PAF, Platelet-activating factor.

TGF-α, and those in both cysts and granulomas also had TGF-β1, at the mRNA and protein levels.⁹

Basophils share some similarities in shape, size, and life span with neutrophils and eosinophils; however, they are more intimately involved in the mediation of allergic reactions. In this regard, they share some features with connective tissue mast cells (Table 1).

As noted in Table 1, *mast cells* reside in connective tissues for weeks to months. They are generally dormant with little activity until they are stimulated by IgE activity in type 1 hypersensitivity reactions (see below). Complement activation also results in the production of C3a and C5a, which are both described as anaphylatoxins as they initiate the acute responses effected by mast cell degranulation. Mast cell degranulation results in local (atopic) or systemic (anaphylactic) reactions. The primary outcomes of these reactions are vasodilation and bronchoconstriction. Anaphylactic reactions can be life threatening because of the resulting apnea and reduction in peripheral circulatory tone that dramatically reduces the blood pressure. These reactions are mediated by the release of granule contents, namely histamine, arachidonic acid metabolites (especially prostaglandins: PGE2 and PGI1, and leukotrienes: LTB4 and LTD4), platelet-activating factor (PAF), eosinophil chemotactic factor A, and a number of other enzymes that cause tissue damage.

Dendritic cells (DCs) are stellate-shaped and reside in a variety of tissues including blood, lymph, epidermis, dermis, and secondary lymphoid organs.¹⁰ They are also present in the dental pulp, where they are prevalent among the odontoblastic cell layer and around blood vessels,^{11,12} and in periodontal ligament¹³ and periradicular lesions.^{13,14} DCs lack an Fc receptor, lack long-term adherence to immune cells or molecules, and are not involved in phagocytosis. Like other antigen-presenting cells (APCs), namely macrophages, Langerhans cells (a subset of DCs present in the epidermis),

B cells, and endothelial cells, they express MHC-II. They have a variety of phenotypes, as determined by their morphology, surface markers, and the tissue where they reside. Circulating blood DCs have two different origins: myeloid (DC1) and plasmacytoid/lymphoid (DC2). The former is characterized by the CD11c+ marker, while the latter has the CD123⁺ marker that may have several subsets.¹⁰ Myeloid CD11C⁺ DCs, like macrophages, express a large number of TLRs to both bacterial and viral molecules. In contrast, CD123⁺ plasmacytoid DCs do not express TLR-2 and -4 and thus do not respond to bacterial molecules.¹⁵

NK cells are lymphocytes that do not require activation like CD4 or CD8 lymphocytes. Therefore, they are members of the innate immune response. They represent about 4% to 20% of circulating mononuclear cells. They produce interferon- γ (IFN- γ) and are thus capable of activating macrophages to produce proinflammatory cytokines, without the need for activated T-lymphocytes. NK cells are particularly effective in killing host cells infected with viruses or other intracellular microorganisms.

Odontoblasts are traditionally considered as merely dentin-producing cells originated from ectomesenchymal cells. However, due to their unique anatomic location, they are the first line of cells encountering foreign antigens after enamel and dentin breakdown, in which situation they are similar to epithelial cells. Epithelial cells have been considered as an integrate part of innate immunity for being capable of producing proinflammatory cytokines and expressing antimicrobial peptides β -defensins.^{16,17} Similarly, human odontoblasts have also been observed to express chemokines such as IL-8 and the antimicrobial peptides, defensins.^{18–20} Furthermore, odontoblasts express TLRs^{21,22} suggesting that odontoblasts play a significant role in the pulp innate immunity.

Cells of Adaptive Immunity

The adaptive immunity involves the development of specific receptor molecules made by lymphocytes that recognize and bind to foreign or self antigens. These specific receptor molecules on T cells are called T-cell antigen receptors (TCRs) and on B cells are B-cell antigen receptor (BCRs) or immunoglobulins. TCRs on T cells interact with antigens presented by MHC molecules along with other accessory molecules, whereas BCRs on B cells or as secreted form, generally known as antibodies, interact with antigens directly. The variable region of both TCR and BCR is rearranged at the genomic level via V(D)J segment recombination.

The estimated total diversity after this recombination for TCR is $\sim 10^{18}$ (for $\alpha\beta$ receptors that make up the majority of the TCR; the other minority is $\gamma\delta$ receptor) and for BCR it is $\sim 10^{14}$, which generates the repertoire of different individual T- and B-cell clones.²³

T cells are found in normal pulp.²⁴ They play a pivotal role in adaptive immunity and their development goes through a rather intricate process. Originated from bone marrow hematopoietic stem cells, the precursor T cells migrate to the thymus to undergo maturation in which they express different cell surface markers (e.g., CD44, CD3, CD4, CD8, and CD25) at various stages and are screened via positive and negative selection processes. About 97% of T cells undergo apoptosis and only a small percentage of these cells are exported to the periphery as mature T cells. During the positive selection, double-positive CD4⁺CD8⁺ T cells bearing TCRs that can interact with self peptide:self MHC complex on thymic epithelial cells are rescued from apoptosis. In the negative selection, these CD4⁺CD8⁺ T cells recognizing self peptide:self MHC complex too well are deleted via apoptosis. The positive selection ensures that mature T cells can recognize foreign antigen in the context of self MHC molecules that present the antigen, whereas the negative selection eliminates potentially self-reactive T-cell clones. Before exiting the thymus, these cells become single-positive either CD4⁺ or CD8⁺ along with other surface markers such as CD25. These naive T cells then circulate back and forth between the lymphatic system and blood until they encounter foreign antigens presented by APCs.²³

The interactions between TCR and antigen peptide:MHC and between costimulators CD28 and B7 activate signal transduction pathways in T cells leading to the synthesis of T-cell growth factor IL-2 and its receptor and T-cell clonal expansion/proliferation. Subsequently, T cells differentiate into armed effector T cells and some become memory cells. There are a number of T cell subpopulations categorized by their functions and some can be distinguished by their cell surface markers, cytokine profiles, or transcriptional factors. To date, there are four main subpopulations of T cells: T helper cells, T regulatory cells (Treg), T suppressor and T cytotoxic (cytolytic) cells.

Naive CD4 T cells upon antigen stimulation proliferate and differentiate into Th0, which subsequently commit into Th1 or Th2 cells. Monocytoid DC (DC1) induces T helper (Th) 1-type responses and plasmacytoid DC (DC2) selectively induces Th2 responses. Each subset has distinct functions and cytokine profiles as shown in Table 2. A Th1-specific T box transcription factor, T-bet, suppresses early Th2 cytokine production

Table 2 Subpopulations of T cells

Subtype	Main CD	Key Cytokine Profile	Transcriptional Factors*	Main Function
Th0	CD4		–	Challenged Naive T cells
Th1	CD4	IFN- γ , IL-2	T-bet	Pro-inflammatory
Th2	CD4	IL-4, -5, -10, -13	GATA-3	Anti-inflammatory
Th17	CD4	IL-17	–	Pro-inflammatory
Tr	CD4, CD25	IL-10	Foxp3	Anti-inflammatory
Tr-1	CD4, CD25	TGF, IL-10	–	Anti-inflammatory
Th3	CD4, CD25	TGF	–	Anti-inflammatory
Ts	CD8		–	Anti-inflammatory
Tc	CD8		–	Kill virus-infected cells

*Transcriptional factors identified as important markers for the respective T cell subsets.

and induces Th1 T-cell development via upregulation of *IFN- γ* gene transcription and IL-12Rb2 chain expression. The differentiation of Th2 is dependent on the induction of transcription factors STAT6, c-maf, and GATA-3.²⁵ Th1 cells mainly produce IL-2 and IFN- γ , activate macrophages, and induce B cells to produce opsonizing antibody. Th2 cells produce IL-4, -5, -10 and -13; activate B cells to make neutralizing antibody; and have various effects on macrophages. Overall, Th1 and Th2 have mutually modulatory effect.²⁵

Th17 cells are recently recognized Th cells that are closely associated with Th1 in diseased tissues and may be directly derived from naive CD4⁺ T cells.^{26–28} Th17 produces IL-17 and its development can be induced by IL-23, which also stimulates Th1 production of IL-17—a cytokine that is linked to autoimmune and inflammatory diseases including rheumatoid arthritis and lupus.

Treg have the cell surface markers CD4 and CD25 and therefore are generally named CD4⁺CD25⁺ Treg. They play an essential role in mediating immunosuppression and maintenance of tolerance. Those T-cell clones that may react to self antigens but are not deleted via negative selection in the thymus are considered to be suppressed by Treg cells in the periphery. Therefore, dysregulation of Treg function may illicit autoimmune diseases. There are subtypes of Treg cells based on their origin and the mechanisms of action and function.

Treg cells or naturally occurring Tr arise either in the thymus and reside in the blood and peripheral lymphoid tissues or in the periphery induced by antigen. Human Tr potently suppress the proliferation and effector functions in a cell contact-dependent manner or by acting on APCs.^{29,30} The transcriptional factor FoxP3 is important to their development and a marker. Human Tr can be further divided into two subsets with distinct functions based on differential expression of

integrins. $\alpha 4\beta 7$ integrin-expressing Tr cells induce de novo differentiation of IL-10-producing Tr1 cells. $\alpha 4\beta 1$ -expressing Tr cells induce the differentiation of TGF- β -producing Th3 cells.

Tr1 cells (CD4⁺ type-1 Treg) arise in the periphery upon encountering an antigen presented by tolerogenic DCs which process requires IL-10. Tr1 cells produce high levels of IL-10 themselves and mediate IL-10-dependent suppression of T-cell response. In contrast, Tr cells do not produce IL-10. Defining Tr1 phenotype currently is solely based on cytokine production—IL-10, but not IL-4 and they express variable CD25. Tr1 cells regulate the response of naive and memory T cells in vitro and in vivo and can suppress both Th1 and Th2 cell-mediated pathologies. Tr1-cell clones suppress the production of immunoglobulin by B cells. The major function of Tr1 cells is to control homeostasis of the response to foreign antigens in the periphery.³⁰

Although *Th3 cells* are named under T helper cells, they are grouped with Tr cells due to their close functionality to Tr-1 cells. They are CD4⁺ T cells that produce TGF- β . Similar to Tr1 cells, these T cells are generated in the periphery induced by oral antigen in the mesenteric lymph nodes. They express variable CD25 and produce TGF- β and varying amounts of IL-4 and IL-10. They also inhibit Th1- and Th2-mediated adaptive immune responses. It is speculated that Tr1 and Th3 cells derive from the same population and perhaps represent adaptive Tregs, as they have a similar phenotype and usually mediate their suppressive activities via the release of IL-10 and/or TGF- β ^{31,32} (Figure 6).

There is a controversy regarding the recognition of *T suppressor (CD8⁺ T suppressor cells or Ts)* as a distinct subset of CD8⁺ T cells. There is also a disputable hypothesis that CD8⁺ Ts cells are merely cytotoxic T lymphocytes (CD8⁺ CTLs) based on the finding that

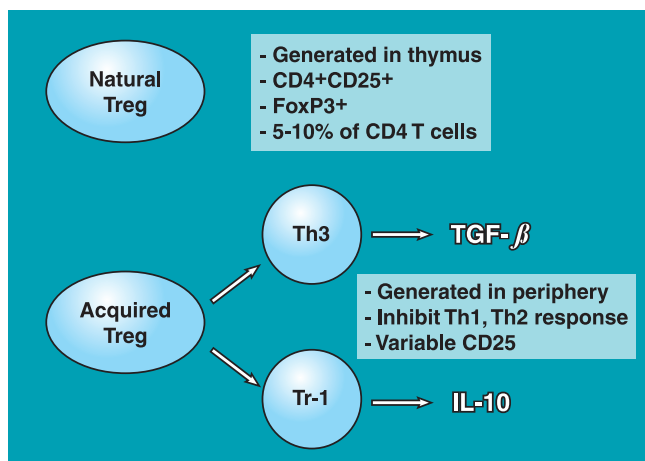

Figure 6 Regulatory T lymphocytes. Redrawn from van Oosterhout and Bloksma, Eur Respir J 2005;26:918–32. Courtesy of Dr. Huang.

both CD8⁺ Ts and CTL play roles in immunosuppressive activities and maintenance of tolerance. Evidence has suggested that CD8⁺ Ts and CD8⁺ CTLs represent distinct subpopulations of CD8⁺ T cells. Human CD8⁺CD28⁻ T cells have also considered another subtype of Ts cells. These cells are MHC class I-restricted CD8⁺CD28⁻ Ts cells that act on APCs by a contact-dependent manner, rendering them tolerogenic to Th cells. They inhibit the proliferation of Th by blocking the activation of APC and preventing the upregulation of costimulatory molecules required for efficient help. CD8⁺CD28⁻ Tregs can block the upregulation of costimulatory molecules on APCs such as CD80, CD86, CD54, and CD58. Suppressor function could not be abrogated using neutralizing antibodies against IL-4, IL-10, TGF- β , and CTLA-4. In contrast to the suppression of costimulatory molecules, CD8⁺CD28⁺ Treg have been demonstrated to upregulate the inhibitory immunoglobulin-like transcript 3 (ILT3) and ILT4 receptors on DCs. Taken together, these results suggest that CD8⁺CD28⁻ Tregs suppress immune responses by directly interacting with DCs and rendering these cells tolerogenic.³³

T cytotoxic cells (CD8⁺ T cytotoxic cells or Tc), also known as cytolytic T lymphocytes (CTLs), are a subset of T cells that kill target cells expressing MHC-associated peptide antigens, such as virus infected cells. The majority of Tc express CD8 and recognize antigens degraded in the cytosol and expressed on the class I MHC molecules of the target cells. Tc develop from “pre-Tc” that lack cytolytic functions. Two separate kinds of signals are needed for pre-Tc to differentiate to functional Tc. One is specific recognition of antigen on a target cell and the other may be provided either

by costimulators expressed on professional APCs or by cytokines produced by Th cells. Functional Tc acquire specific membrane-bound cytoplasmic granules including a membrane pore-forming protein called perforin or cytolytic and enzymes called granzymes. Tc also express FasL that can deliver apoptosis-inducing signals to target cells expressing Fas protein. The killing of target cells require cell contact and is antigen-specific, that is, killing of the target cells bearing the same class I MHC-associated antigen that triggered the pre-Tc differentiation.²³

B cells are rarely found in normal pulps.²⁴ Their role in adaptive immunity mainly lies in the production of antibodies that constitute the host humoral immune response. The rise and the development of B cells take place in bone marrow where the progenitor B cells rearrange their immunoglobulin (Ig) genes and turn into immature B cells with assembled antigen receptors (BCRs) in the form of cell surface IgM. The commitment to B-cell lineage occurs prior to Ig gene rearrangement. This commitment is controlled by the expression of Pax5 transcriptional factor. The bone marrow stromal cells interact with progenitor B cells and provide signals and growth factors (e.g., IL-7) important for B-cell development.

The productive and sequential rearrangement of heavy- and light-chain gene dictates the survival of B cells—positive selection. Those cells that failed to rearrange their Ig gene segments to form functional heavy- and light-chain pairs will be lost. The V(D)J gene recombination occurs in both heavy and light (κ and λ) chains. A recombinase system, which is an enzymatic complex consisting of several enzymes including recombination-activating genes 1 and 2 (RAG-1, RAG-2), terminal deoxynucleotidyl transferase (TdT), DNA ligase IV, Ku proteins, and XRCC4, is essential to the recombination process. This recombinase system is also used for TCR recombination.²³

Similar to T-cell selection, B cells also undergo negative selection. Developing B cells expressing BCRs that recognize self cell-surface molecules are deleted via apoptosis. Immature B cells that bind soluble self antigens are rendered unresponsive to the antigen—aneuric. Only those B cells that do not interact with self antigens mature normally and enter the peripheral lymphoid tissues bearing both IgM and IgD on their surface. Mature IgM/IgD coexpressing B cells undergo isotype switching via a process called switch recombination after encountering antigen. The rearranged V(D)J gene segment recombines with a downstream C region gene (γ , ϵ , or α) and the intervening

DNA sequence is deleted. This gives rise to other classes of Ig, that is, IgG, IgE, and IgA besides IgM. In addition to isotype switching, activated B cells undergo somatic mutation in V region gene leading to affinity maturation of antibodies and alternative splicing of VDJ RNA to membrane or secreted Ig mRNA. A large quantity of antibody is secreted when B cells terminally differentiate into plasma cells.²³

MHC AND ANTIGEN PRESENTATION

Multistep antigen-processing pathways within the APC are involved in the generation of cell-surface antigen:MHC complex. Distinct subcellular pathways take place to generate complexes of peptides with class I versus class II.

Class I MHC molecule consists of α (heavy) chain and β chain (β 2 microglobulin that is located only extracellularly). Almost all cells express class I MHC that display peptide antigens presented to $CD8^+$ TCRs. Endogenously synthesized foreign proteins (e.g., viral proteins) or products of mutated genes in tumor cells are degraded into peptides by proteasomes in the cytosol and transported via transporter associated with antigen processing (TAP) peptide transporter into ER in which the peptides are bound onto assembled class I

MHC. Subsequently, this peptide:MHC complex is transported onto the cell surface. $CD8^+$ T cells (mostly CTLs) recognize the peptide antigen associated with class I MHC.

The molecules involved in the interactions between peptide antigen:class I MHC complex and TCR include CD8, CD3/ ζ , CD2, CD28 and LFA-1 (on T cells) and ICAM-1, LFA-3, and B7-1/B7-2 on APC (Figure 7).

Class II MHC molecules are composed of two noncovalently associated polypeptide chains— α and β chains, both of which have peptide-binding, immunoglobulin-like, transmembrane, and cytoplasmic domains. Unlike MHC class I, only restricted group of cells normally express class II MHC. They are APCs: (1) DCs, (2) macrophages, (3) B cells, (4) vascular endothelial cells, and (5) epithelial cells. The former three are considered professional APCs. The latter two nonprofessional APCs are induced by IFN- γ to express class II MHC.

DCs and macrophages phagocytose antigens while B cells utilize the membrane immunoglobulin to bind and internalize antigens. Other nonprofessional APCs endocytose antigens into cytoplasm for antigen processing. These internalized antigens are localized in endosomes in which the antigens are

Figure 7 Cells and molecules involved in the interaction of antigen-presenting cells (APCs) and CD4/CD8 T lymphocytes. Courtesy of Dr. Huang.

degraded and then further processed in lysosomes. The processed antigens turn into small peptides, and many of them are 10–30 amino acid long and are capable of binding onto the newly synthesized class II MHC molecules within intracellular vesicles before this antigen: class II MHC complex is transported to the surface of cells and presented to TCRs of CD4⁺ T cells (see Figure 7).

Molecular Mediators of the Proinflammatory Response

CHEMOKINES

Chemokines are a group of about 45 to 47 chemoattractant cytokines. There are two main types of chemokines:

1. *CC Chemokines*. Macrophage/monocyte chemoattractant proteins (MCP-1–4); macrophage inflammatory protein (MIP)-1 α , MIP-1 β , eotaxin, RANTES.
2. *CXC Chemokines*. IFN-inducible protein 10 (IP-10); monokine-inducible IFN- γ (MIG); interleukin-8 (IL-8/CXCL8). These chemokines have currently been renamed to include CXCL1–16; XCL1, 2; CX3CL1; and CCL1–28.

Table 3 lists different names of the commonly studied chemokines. Chemokines are primarily involved in trafficking of cells of the innate immune system toward the site of an inflammatory response or during lymphoid organ development and angiogenesis.⁴ Among the first recognized and the most studied

chemokines is IL-8 (CXCL8), which has also been most studied in endodontic pathosis.^{18,19,34–37} There is some redundancy with respect to the cells that express chemokine receptors and receptor specificity for various chemokines (see Table 3).

ADHESION MOLECULES

There are a variety of adhesion molecule classes that are expressed at the site of an inflammatory process (Table 4). Adhesion molecules that serve a critical role with respect to halting the inflammatory cells that are circulating in the capillaries at high speed and that are then through the function of chemokines are directed to the site of inflammation. This process is achieved in steps: the cells initially slow down, they roll on the endothelial wall, and then start to bind to the endothelial cells. Eventually, they become extravasated through diapedesis and migrate to the area of inflammation. The slowing down of circulating leukocytes is mediated by selectins, then integrins, and Ig superfamily proteins mediate the binding of the cells to endothelial cells. The expression of these adhesion molecules is mediated by a number of inflammatory mediators, most notable IL-1 and TNF- α .

PLATELET-ACTIVATING FACTOR

PAF is a ubiquitous factor that is secreted by many different cells and plays a role in a number of immune mechanisms. It is secreted by platelets, basophils, monocytes/macrophages, PMNs, and endothelial cells. It is primarily involved in leukocyte adhesion to endothelial cells, production of prostaglandins and thromboxane and in chemotaxis. In low doses, PAF

Table 3 Common Chemokines, Their Receptors and the Cells that They Target^{4,38,39}

Chemokine	Other Name	Cell for Chemotaxis	Receptor
CXCL8	IL-8	Neutro	CXCR1, CXCR2
CXCL9	Mig	T cells (T), NK cells (NK)	CXCR3-A, CXCR3-B
CXCL10	IP-10	T, NK cells	CXCR3-A, CXCR3-B
CCL2	MCP-1/MCAF	T, NK cells, dendritic cells (DC), monocytes (Mono), basophils (Baso)	CCR2
CCL3	MIP-1 α	T, NK cells, DC, Mono, eosinophils (Eosino)	CCR1, CCR5
CCL4	MIP-1 β	T, NK cells, DC, Mono	CCR5
CCL5	RANTES	T, NK cells, DC, Mono, Eosino, Baso	CCR1, CCR3, CCR5
CCL7	MCP-3	T, NK cells, DC, Mono, Eosino, Baso	CCR1, CCR2, CCR3
CCL8	MCP-2	T, NK cells, DC, Mono, Baso	CCR3
CCL11	Eotaxin-1	T, DC, Eosino, Baso	CCR3
CCL13	MCP-4	T, NK cells, DC, Mono, Eosino, Baso	CCR2, CCR3
CCL24	Eotaxin-2	T, DC, Eosino, Baso	CCR3
CCL26	Eotaxin-3	T	CCR3

DC, Dendritic cells; NK, natural killer.

Table 4 Important Adhesion Molecules, Their Tissue Distribution and Ligands²³

	Name	Tissue Distribution	Ligand
Selectins	P-selectin (PADGEM)	Activated endothelium and platelets,	PSGL-1, Sialyl-Lewis
Bind carbohydrates. Initiate leukocyte-endothelial interaction	E-selectin (PADGEM)	Activated endothelium	Sialyl-Lewis
Integrins	$\alpha_L : \beta_2$ (LFA-1, CD11a/CD18)	Monocytes, T cells, macrophages, neutrophils, dendritic cells	ICAMs
Bind to cell-adhesion molecules and extracellular matrix.	$\alpha_M : \beta_2$ (CR3, Mac-1, CD11b/CD18)	Neutrophils, monocytes, macrophages,	ICAM-1, iC3b, fibrinogen
Strong adhesion	$\alpha_X : \beta_2$ (CR4, p150.95, CD11c/CD18)	Dendritic cells, macrophages, neutrophils	iC3b
Immunoglobulin superfamily	$\alpha_5 : \beta_1$ (VLA-1, CD49d/CD29)	Monocytes, macrophages	Fibronectin
Various roles in cell adhesion. Ligand for integrins	ICAM-1 (CD54)	Activated endothelium	LFA-1, Mac-1
	ICAM-2 (CD102)	Resting endothelium, dendritic cells	LFA-1
	VCAM-1 (CD106)	Activated endothelium	VLA-4
	PECAM (CD31)	Activated leukocytes, endothelial cell-cell junctions	CD31

may cause vasodilatation; however, in regular doses, it is involved in vasoconstriction.

PLASMA PROTEASES

There are a large number of enzymatic changes that take place during an immune response and that aim to remove antigenic or foreign material, kill microbial cells, control hemorrhage, as well as initiate and pro-

note the healing process that takes place following the elimination of irritants. These enzymatic processes are closely regulated so that the response is proportionate to the irritation; however, they frequently result in side effects causing break down of host tissues, which frequently accompanies an inflammatory response. The main pathways that are involved in these reactions will be described here. The principal mediators and interactions of these pathways are summarized in Figure 8.

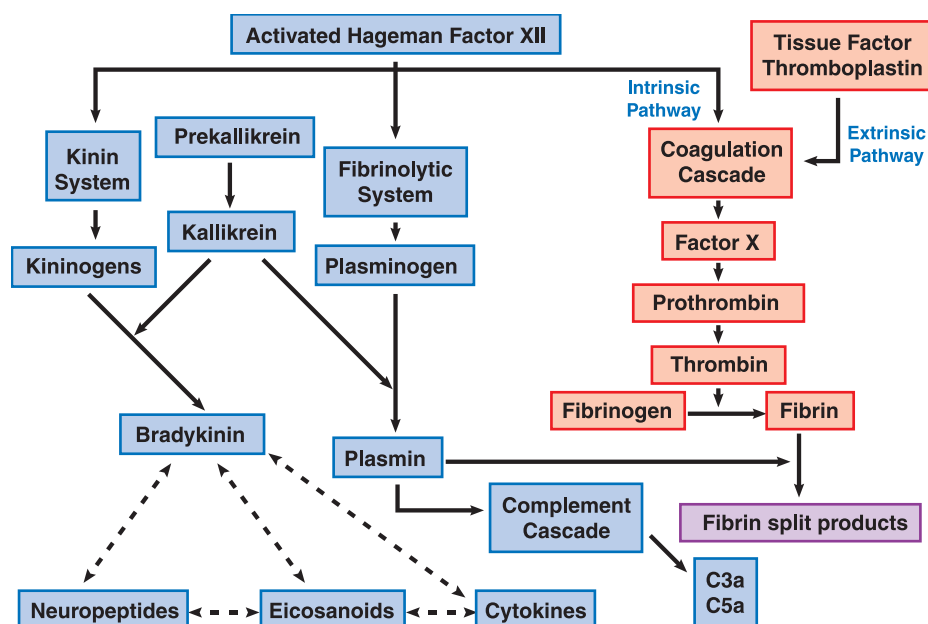

Figure 8 Diagram showing various pathways that are activated during an inflammatory response. Dotted lines indicate a synergistic or costimulatory function. Courtesy of Dr. Fouad.

Kinin System: Bradykinin

As can be seen in Figure 8, the activated Hageman factor causes the formation of kinins from kininogen, a reaction that is mediated by kallikrein. The most important of the kinins is bradykinin. This protein causes vasodilatation, extravasation of plasma proteins, and reduction of pain threshold.⁴⁰ Bradykinin performs its actions through the binding with two receptors, B1 and B2. B1 is primarily associated with chronic pain syndromes, while B2 is constitutively present in tissues and is over expressed in acute pain situations,⁴¹ including pulpal pain.⁴² It has been shown that bradykinin can act synergistically with neuropeptides, thrombin, and other factors to enhance the production of a number of eicosanoids, such as PGE2, and cytokines, such as IL-1 and TNF- α .⁴³⁻⁴⁶ Once released, bradykinin levels are controlled by a number of kininases, and their effects on pain are controlled by endogenous opiates and steroids. Nonsteroidal anti-inflammatory drugs (NSAIDs) have also been shown to reduce bradykinin levels.⁴⁷

The Coagulation Cascade and Fibrinolytic Systems

Tissue injury and severe inflammation frequently result in hemorrhage, at macroscopic or microscopic levels. Therefore, one of the principal initial mechanisms of healing is the coagulation cascade. Traditionally, the coagulation cascade has been divided into intrinsic and extrinsic pathways (see Figure 8). This was due to the fact that the intrinsic pathway could occur *in vitro* by the Hageman factor, in the absence of thromboplastin. However, there are many interactions between both pathways, and the distinction is now less critical.⁵ Through a series of localized enzymatic activations, the Hageman factor/thromboplastin result in the formation of Factor X; this in turn results in the formation of thrombin from prothrombin. Thrombin (activated Factor II) has a number of critical functions, including positive feedback activation of a number of other factors such as Factors VIII and V, but essentially forms the insoluble fibrin clot from the soluble protein fibrinogen. In order to limit the size of the clot and prevent disseminated coagulation, the fibrinolytic system is activated and results in the formation of plasmin.

Complement System

The complement system consists of a series of about 20 proteins that play a number of critical roles in the immune system (Figure 9). Complement is activated through one of the two main pathways. The classical

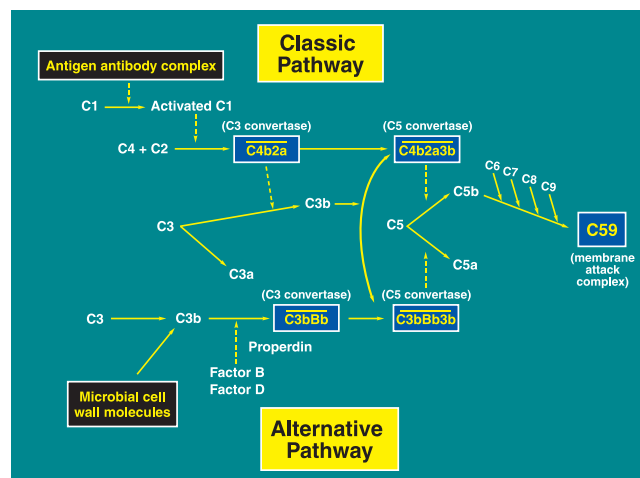

Figure 9 Complement cascade. Courtesy of Dr. Fouad.

pathway involves antigen–antibody reaction and results in the activation of C1 to form a molecule commonly referred to as C3 convertase. Certain microbial cell wall molecules such as LPS can activate the alternate pathway in which C3 through coenzymatic interaction from Factors B and D and a protein called properdin result in the formation of another C3 convertase of a different structure. The enzyme C3 convertase, in whichever formulation, mediates the formation of C3b from C3, with C3a as a by product. Together with C5 convertases, C3b activates C5 to C5b, with C5a as a by-product. C5b combines with C6, C7, C8, and C9 to form a complex that forms holes through the bacterial cell membrane resulting in death of the cell. Complement molecules may also act as opsonins for phagocytosis, as discussed previously. Finally, C3a and C5a are known as anaphylatoxins because they cause degranulation of mast cells with the release of histamine, which causes vasodilatation and increased vascular permeability. C5a activates the lipoxygenase pathway of arachidonic acid in neutrophils and monocytes and is itself a potent chemotactic agent for these cells.

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are a number of endopeptidases (Table 5) that are responsible for tissue remodeling during structural development and for tissue break down during pathological states such as the inflammatory and neoplastic changes and carries. Occasionally, some of these enzymes, such as collagenase, may be of microbial origin. Host MMPs are typically modulated by levels of cytokines and growth factors in various tissues. They are

Table 5 Commonly Identified Matrix Metalloproteinases that are Zinc-dependant Endopeptidases

Common Name	MMP
Collagenases	1, 8, 13,18
Gelatinases	2, 9
Stromelysins	3, 10, 11
Membrane Ttype MMPs (MT MMPs)	14, 15, 16, 17, 24, 25
Minimal domain MMPs	7, 26
Others MMPs	12, 19, 20, 21, 22, 23, 27, 28

MMP, Matrix metalloproteinases.

upregulated by IL-1 β and TNF- α and by growth factors such as platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and nerve growth factor (NGF). They are abrogated by IFN- γ and TGF- β .⁴⁰ They are also inactivated by a group of molecules collectively known as tissue inhibitors of metalloproteinases (TIMPs) and by α_2 -macroglobulin (which also inhibits neutrophil elastase—see below). MMPs and tissue inhibitors of metalloproteinases have been identified in the dental tissues during health and disease.^{48–52} It is noteworthy, though, that in the oral cavity, MMPs can be released in saliva, and so the sources of MMPs that degrade dentin matrix in caries may be salivary rather than pulpal.

It has been documented through a significant body of evidence that tetracyclines and some tetracycline analogues and chemically modified tetracyclines may degrade MMPs at subantibiotic levels.^{53,54} This is thought to be one of a number of anti-inflammatory properties that are exhibited by some antibiotics.⁵⁵

Neutrophil Elastase

During pulpal and periradicular tissue inflammation, a number of other proteases may contribute to the tissue destruction frequently encountered. Among these proteolytic enzymes is neutrophil elastase, a neutral serine protease that is released from azurophilic granules in the PMNs during the activation of these cells. Neutrophil elastase can cleave a wide variety of structurally important proteins and glycoproteins, such as elastin, type III and IV collagen, fibronectin, and core proteins of proteoglycan molecules. It was recently reported that neutrophil elastase was increased in periradicular lesions that were symptomatic,⁵⁶ and that its levels although correlated with prostaglandin E2 did not change following root canal instrumentation.⁵⁷

NITRIC OXIDE

Nitric oxide (NO) is a gaseous free radical that has been described to have several proinflammatory and modulatory effects in tissues. It is produced through a reaction that involves the enzyme NO synthase (NOS) and several cofactors including NADPH. Several NOS isoforms are present, including inducible (iNOS), neuronal (nNOS), and endothelial (eNOS). The nNOS and eNOS are constitutively expressed in the respective tissues and are calcium-dependent, whereas the iNOS is induced in macrophages and a number of other cells, primarily by cytokines such as IL-1 and TNF- α or microbial products such as LPS, and are calcium-independent.⁴⁰ Because it is relatively volatile and short-lived, the detection of NO is frequently assessed through the presence of NOS, particularly iNOS.

Under normal conditions, NO is primarily involved in vasodilatation through the relaxation of smooth muscles and prevention of adhesion of leukocytes to endothelial wall, which is considered as an anti-inflammatory function. However, during inflammation, including that of the pulp and periradicular tissues, and due to the action of cytokines, large amounts of NO are released.^{58–63} NO contributes to the killing of microbial cells and tumor cells by macrophages through its interaction with superoxide free radical as follows⁵:

NO is also an antagonist for platelet activation, adhesion, and degranulation. Moreover, it was recently shown that NO can regulate the proliferation, growth and apoptosis of pulp cells in vitro.⁶⁴

OXYGEN-DERIVED FREE RADICALS

These are highly reactive, short-lived molecules produced by macrophages and neutrophils in normal and pathological states. The most important molecules are the superoxide anion ($\text{O}_2^{\bullet-}$), which eventually is converted to hydrogen peroxide (H_2O_2), and the hydroxyl radical (OH^{\bullet}) and toxic NO derivatives.⁵ The main role that these molecules play is to increase the inflammatory response by increasing cytokines, chemokines, and adhesion molecules. However, in large amounts they cause thrombosis and tissue damage. The antioxidant activity is mediated through enzymes such as catalase, glutathione peroxidases, and superoxide dismutase (SOD). There are two main forms of SODs: copper–zinc (Cu, Zn-SOD) found primarily in cytoplasm and manganese (Mn-SOD) found primarily in mitochondria. While the presence of SOD in normal pulp has been described

a long time ago,⁶⁵ the effect of inflammation on the levels of both isoforms of this enzyme has been controversial. Several studies have shown an increase of SOD,^{65,66} or both Cu, Zn-SOD and Mn-SOD,⁶⁷ in pulpal inflammation. In fact, one study showed an anti-inflammatory effect that Cu, Zn-SOD has on pulpal inflammation in an animal model.⁶⁸ However, a more recent study showed that there is a reduction of Cu, Zn-SOD in human pulpitis, possibly due to depletion.⁶⁹ Using quantitative real-time RT-PCR, which is more sensitive than traditional protein assays, it has just been reported that the expression of mRNA for both enzymes does increase in pulpitis in patients and that the elevation of Mn-SOD is significantly higher than that of Cu, Zn-SOD.⁷⁰

CYTOKINES

Cytokines are low molecular weight proteins that stimulate or inhibit proliferation, differentiation, or function of immune cells.⁴ Approximately 40 cytokines have been described with various functions that mediate or modulate the immune system and bone resorption. Cytokines may exert their actions through autocrine (acting on receptors of the same cell that produced them), paracrine (acting on other cells in

the local vicinity), and endocrine (acting systemically) modes. Because of the involvement of cytokines in several areas of interest in endodontics, their various roles and functions have been and will be described in various sections of this chapter and in other chapters dealing with pulpal and periradicular pathosis. In order to avoid redundancy, a brief description of the main features of some cytokines will be described here, with other information provided elsewhere in the chapter. Table 6 presents a summary of the role, sources, and main actions of cytokines.

Proinflammatory Cytokines

TNF- α is the principal mediator of the response to gram-negative bacteria. LPS stimulates the functions of mononuclear phagocytes and acts as a polyclonal activator of B cells, thus contributing to the elimination of the invading bacteria. The major cellular source of TNF is the LPS-activated mononuclear phagocyte and the minor source is antigen-stimulated T cells, activated NK cells, and activated mast cells. IL-1 derived from mononuclear phagocytes has a principal function, similar to TNF, as a mediator of the host inflammatory response in innate immunity. LPS can trigger monocytes to secrete IL-1 or TNF. T cells are more effective

Table 6 Summary of the Origin and Actions of the Commonly Investigated Cytokines^{1,4,23}

Cytokine	Special Function*	Secreted by	Effector Function
<i>Interleukins</i> IL-1 α , IL-1 β	Pro-inflammatory; bone-resorptive	Mono, M Φ , DC, NK, B, Endo	Co-stimulates T activation by enhancing the production of cytokines including IL-2 and its receptor; enhances B proliferation and maturation; NK cytotoxicity; induces IL-1, -6, -8, TNF, GM-CSF, and PGE ₂ by M Φ ; proinflammatory by inducing chemokines and ICAM-1 and VCAM-1 on endothelium; induces fever, APP, bone resorption by osteoclasts
IL-2	Pro-inflammatory	Th1	Induces proliferation of activated T- and B-cells; enhances NK cytotoxicity and killing of tumor cells and bacteria by monocytes and M Φ
IL-3		T, NK, MC	Growth and differentiation of hematopoietic precursors; MC growth
IL-4	Anti-inflammatory; bone modulatory	Th2, Tc2, NK, NKT, $\gamma\delta$ T, MC	Induces Th2 cells; stimulates proliferation of activated B, T, MC; upregulates MHC class II on B and M Φ , and CD23 on B; downregulates IL-12 production and thereby inhibits Th1 differentiation, increases M Φ phagocytosis; induces switch to IgG1 and IgE
IL-5	Anti-inflammatory	Th2, MC	Induces proliferation of eosino and activated B; induces switch to IgA
IL-6	Pro-/Anti-inflammatory; bone modulatory	Th2, Mono, M Φ , DC, BM stroma	Differentiation of myeloid stem cells and of B into plasma cells; induces APP; enhances T proliferation
IL-7		BM and thymic stroma	Induces differentiation of lymphoid stem cells into progenitor T and B; activates mature T
IL-8		Neutro; Mono, M Φ , Endo	Chemokine; mediates chemotaxis and activation of neutrophils

Table 6 Continued on Page 357

Table 6 Continued from Page 356

IL-9		Th	Induces proliferation of thymocytes; enhances MC growth; synergizes with IL-4 in switch to IgG1 and IgE
IL-10	Anti-inflammatory; bone modulatory	Th (Th2 in mouse), Tc, B, Mono, MΦ	Inhibits IFN-γ secretion by mouse, and IL-2 by human, Th1 cells; downregulates MHC class II and cytokine (including IL-12) production by Mono, MΦ and DC, thereby inhibiting Th1; differentiation; inhibits T proliferation; enhances B differentiation
IL-11	Bone resorptive	BM stroma	Promotes differentiation of pro-B and megakaryocytes; induces APP
IL-12	Pro-inflammatory	Mono, MΦ, DC, B	Critical cytokine for Th1 differentiation; induces proliferation and IFN-γ production by Th1, CD8 ⁺ and γδ T and NK; enhances NK and CD8 ⁺ T cytotoxicity; but may inhibit osteoclast formation in vitro
IL-13	Anti-inflammatory	Th2, MC	Inhibits activation and cytokine secretion by MΦ; co-activates B proliferation; upregulates MHC class II and CD23 on B and Mono; induces switch to IgG1 and IgE; induces VCAM-1 on endo
IL-14			
IL-15		T, NK, Mono, MΦ, DC, B	Induces proliferation of T-, NK and activated B and cytokine production and cytotoxicity in NK and CD8 ⁺ T; chemotactic for T; stimulates growth of intestinal epithelium
IL-16		Th, Tc	Chemoattractant for CD4 T, Mono and eosino; induces MHC class II
IL-17		T	Proinflammatory; stimulates production of cytokines including TNF, IL-1β, -6, -8, G-CSF
IL-18	Bone resorptive	MΦ, DC	Induces IFN-γ production by T; enhances NK cytotoxicity; but may inhibit osteoclast formation in vitro
IL-19		Mono	Modulation of Th1 activity
IL-20		Mono, keratinocytes	Regulation of inflammatory responses to skin
IL-21–33			(Sources and actions of these cytokines are overlapping and not well characterized. The reader is referred to reference [4] for a complete list)
<i>Tumor Necrosis Factors</i>			
TNF-α	Pro-inflammatory; bone resorptive	Th, Mono, MΦ, DC, MC, NK, B	Tumor cytotoxicity; cachexia (weight loss); induces cytokine secretion; induces E-selectin on endo; activates MΦ; antiviral
Lymphotoxin (LT), TNF-β	Pro-inflammatory	Th1, Tc	Tumor cytotoxicity; enhances phagocytosis by neutro and MΦ; involved in lymphoid organ development, antiviral
<i>Interferons</i>			
IFN-α		Leukocytes	Inhibits viral replication; enhances MHC class I
IFN-β		Fibroblasts	Inhibits viral replication; enhances MHC class I
IFN-γ	Pro-inflammatory	Th1, Tc1, NK	Inhibits viral replication; enhances MHC class I and II; activates MΦ; induces switch to IgG2a; antagonizes several IL-4 actions; inhibits proliferation of Th2
<i>Colony-Stimulating Factors</i>			
GM-CSF	Pro-inflammatory	Th, MΦ, Fibro, MC, Endo	Stimulates growth of progenitors of mMono, neutro, eosino and baso; activates MΦ
G-CSF	Pro-inflammatory	Fibro, Endo	Stimulates growth of neutro progenitors
M-CSF	Pro-inflammatory	Fibro, Endo, Epith	Stimulates growth of mMono progenitors
SLF		BM stroma	Stimulates stem cell division (c-kit ligand)
<i>Others</i>			
TGFβ		Th3, B, MΦ, MC	Not only proinflammatory by, for example, chemoattraction of Mono and MΦ but also anti-inflammatory by, for example, inhibiting lymphocyte proliferation; induces switch to IgA; promotes tissue repair
LIF		Thymic epith, BM stroma	Induces APP
Eta-1		T	Stimulates IL-12 production and inhibits IL-10 production by MΦ
Oncostatin M		T, MΦ	Induces APP

APP, acute phase proteins; B, B cell; baso, basophile; BM, bone marrow; Endo, endothelium; eosino, eosinophil; Epith, epithelium; Fibro, fibroblast; GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukin; LIF, leukemia inhibitory factor; MΦ, macrophage; MC, mast cell; Mono, monocyte; neutro, neutrophil; NK, natural killer; SLF, steel locus factor; T, T cell; TGF-β, transforming growth factor-β. Note that there is no interleukin-14. This designation was given to an activity that, upon further investigation, could not be unambiguously assigned to a single cytokine. IL-30 also awaits assignment. IL-8 is a member of the chemokine family. These cytokines are listed separately in Table 9.5.

*Recognized actions in pulpal and periradicular lesions.

than LPS at eliciting IL-1 synthesis by monocytes. IL-1 is made by diverse cell types, epithelium and endothelium providing local sources of IL-1 in the absence of macrophage-rich infiltrate.

The effect of IL-1 is similar to that of TNF. At low quantity, it acts on endothelium to increase the expression of adhesion molecules and on monocytes to secrete chemokines. It shares many features of TNF but is also different; for example, it enhances rather than suppresses the actions of colony-stimulating factors (CSFs) (see Table 6) on bone marrow cells. IL-6 serves as a growth factor for activated B cells.^{71,72}

Systemic Effects of Cytokines

As noted before, during an acute infection or after tissue injury, there is an increase in the concentration of proinflammatory cytokines in the blood, primarily IL-1, TNF, and IL-6. IL-1 and TNF cause fever through their action on the thermoregulatory center in the hypothalamus due to the release of local eicosanoids.⁵ IL-1 causes an increase in IL-6 that acts on hepatocytes to synthesize a number of plasma proteins called acute phase proteins, and the reaction is known as acute phase reaction. Among the most intensely secreted proteins are C-reactive protein (CRP), mannose-binding lectin (MBL), serum amyloid P component (SAP) and α_1 -acid glycoprotein. CRP and MBL are important in fixing complement and deposit C3b, which is an opsonin, on the microbial cell.⁴ SAP can, together with chondroitin sulfate, bind to lysosomal enzymes such as cathepsin B released in inflammation. This complex becomes a component of the amyloid fibrillar deposits that accompany chronic infections.⁴ Other proteins that are released in moderate amounts in an acute phase reaction include fibrinogen, fibronectin, haptoglobin, angiotensin, ceruloplasmin, complement proteins C3, C9, and factor B, α_1 -proteinase inhibitors and α_1 -antichymotrypsin. Finally, cytokines may also act on bone marrow to cause the increased production of white cells causing leukocytosis, where white cells may reach 15,000 to 20,000/ μ L rather than the 4,000 to 10,000/ μ L normal count.⁵

The discussion of bone-resorptive cytokines and bone resorption modulatory actions of cytokines will be provided under the role of cytokines in bone resorption (see page 42). The discussion of anti-inflammatory cytokines is under molecular mediators of anti-inflammatory reactions (see page 42).

NEUROPEPTIDES

Neuropeptides are proteins produced by neural tissues and are released at the sites of nerve endings. Under

normal conditions they function to maintain the vascular tone of blood vessels, thus modulating the vascularity and regulating the innervation of the tissue. During an inflammatory response, there is vasodilation, extravasation of plasma proteins, and sprouting of nerve endings within the inflamed tissue. These changes result in an increase in the levels of certain neuropeptides. It is now recognized that certain neuropeptides such as Substance P (SP) have decidedly proinflammatory actions, whereas a number of other neuropeptides such as vasoactive intestinal peptide (VIP), α -melanocyte-stimulating hormone, neuropeptide Y (NPY), and somatostatin are members of an anti-inflammatory repertoire of immune modulators.^{73,74} The newly discovered neuropeptides, such as urocortin, adrenomedullin, and cortistatin, also appear to have anti-inflammatory actions in that they inhibit T-cell proliferation, Th1 response, and IL-2 production.⁷⁴ Calcitonin gene-related peptide (CGRP) may have proinflammatory as well as anti-inflammatory actions.⁷⁴ SP was the first neuropeptide described around 1931; it is localized in sensory nerves, is related to neurokinins A and B, and its receptors are NK1, NK2, and NK3.⁷⁵ CGRP was described in 1983 and it binds to CGRP1, CGRP2, and AM2, whereas NPY was discovered in 1982, is localized in sympathetic, cholinergic, sensory, enteric, and central neurons and binds to Y1, Y2, Y4, and Y5 receptors.⁷⁵

With respect to pulpal and periradicular region, denervation experiments have shown that, in the pulp, SP-, neurokinin A-, and CGRP-containing nerve fibers originate from the trigeminal ganglion and that NPY-containing nerve fibers come from the superior cervical ganglion. The origin of VIP-containing fibers may be parasympathetic nerve fibers since it has been associated with acetylcholine in other tissues.^{40,76}

Since the dental pulp is highly innervated, neuropeptides play a significant role in mediating and modulating the inflammatory response in it. The neuropeptides that have been studied the most in endodontic pathosis are SP and CGRP and to a lesser degree VIP and NPY. In the normal rat molar pulp, SP and CGRP were shown to be present in close proximity to macrophages, an association that was more prevalent in the odontoblastic layer than in the central pulp.⁷⁷ During inflammation, sprouting of pulpal nerve fibers was shown to be associated with an increased expression of SP and CGRP closely surrounding the areas of irritation.^{78,79} However, severe irritation by experimental pulp exposures caused a drop in the overall pulpal levels of SP and CGRP, possibly due to the depletion of neuropeptide stores in the nerve endings.⁸⁰ In vitro experiments showed that below a certain threshold, the addition of SP increased, and CGRP

decreased, the proliferation of T cells that were cocultured with rat pulp cells.⁷⁷ CGRP addition to human pulp cells in vitro caused a two-fold increase in the levels of bone morphogenetic protein 2 (BMP-2), a member of TGF- β superfamily, that has the capacity to induce dentin regeneration.⁸¹ Clearly, these findings suggest that neurogenic inflammation effected by neuropeptides plays an active and dynamic role in modulating pulpal inflammation.

There are a number of mechanisms by which neuropeptides are thought to contribute to the inflammatory process. SP and CGRP,⁸² together with VIP, are potent vasodilators; however, NPY is a vasoconstrictor.⁷⁶ SP also causes increased vascular permeability and plasma extravasation.⁸³

Neuropeptides may reduce the threshold of pain in the pulp, accounting for symptoms associated with certain cases of pulpitis. The association of SP with the extent of caries and pain from caries was investigated in permanent molars of children.⁸⁴ The percentage of neuronal areas that positively stained for SP was found to be significantly more in gross carious lesions than in moderate or no lesions and significantly more in painful lesions. These findings were true at all levels of coronal pulp studied, which included the pulp horn, subodontoblastic nerve plexus, and mid-coronal pulp. The fact that not all cases of irreversible pulpitis are associated with pain may be explained by the actions of inhibitors of neurotransmitters like γ -aminobutyric acid (GABA) or gastrin-releasing peptide (GRP). GABA-like and GRP-like immunoreactivity has been identified in the dental pulp.⁸⁵ It was also recently shown that NPY is capable of inhibiting capsaicin-sensitive afferent neurons at the spinal level, perhaps explaining the mechanisms for spinal NPY-induced antinociception.⁸⁶ Local opioid receptors in the pulp may also play a role in suppressing pulpal pain.⁸⁷ On the other hand, it was recently shown that dental pulp nociceptors, collected from patients with caries, express TLR-4 and CD-14, indicating a direct mechanism for bacterial LPS to activate these nociceptors.⁸⁸

Neuropeptides may contribute to the inflammatory process by a number of other mechanisms. These include the release of inflammatory mediators, such as histamine, PGE₂, collagenase, IL-1, IL-6, and TNF, the enhancement of chemotaxis, phagocytosis, and the expression of adhesion molecules, and lymphocyte proliferation and IL-2 production.^{83,89,90} The interactions between eicosanoids, bradykinin, and various neuropeptides suggest synergistic action with CGRP⁹¹ or modulatory action with NPY⁹² and illustrate the complex interplay between various elements of the immune response. It is interesting to note that animal

studies have shown a reduction of the neuropeptides SP and CGRP with age.⁹³

TOLL-LIKE RECEPTORS

Innate immunity has been considered to be a nonspecific process in reacting with antigens. However, recent studies have shown that this innate response has a considerable specificity in discriminating between commensal and pathogenic microbes as well as between individual species of microbes. This immune discrimination is achieved through the recognition of multiple microbe-specific surface molecules by PRR⁹⁴ present on host cells, for example, TLR and the receptors for complement. These receptors are related to the toll protein, which is a phylogenetically old molecule first described in insects, as a protein that allows them to resist fungal infections. TLRs share homology with other host molecules, such as the IL-1 receptor transmembrane molecule. The PRR-recognized molecules on the microbes include surface proteins, nucleic acids, and carbohydrates (e.g., LPS, PG, LTAs). This is known as microbe-associated molecular patterns (MAMPs)^{94,95} (Table 7).

TLRs, as PRR, are a family of 12 members identified in mammals so far and are further divided into several subfamilies. The subfamily of TLR1, TLR2, and TLR6 recognizes lipids, whereas the highly related TLR7, TLR8, and TLR9 recognize nucleic acids. TLR4 recognizes ligands such as LPS, fibronectin, and heat-shock proteins, all of which have different structures.

TLRs are expressed on various immune cells, including macrophages, DCs, B cells, specific types of T cells, and on nonimmune cells such as fibroblasts and

Table 7 Examples of TLR Recognition of Microbial Components

Molecule	Microorganism Type/Species	TLR
LPS	G(-) bacteria	TLR4
Lipoteichoic acid (LTA)	Group B Streptococcus	TLR6/2
Peptidoglycan	G(+) bacteria	TLR2
Flagellin	Flagellated bacteria	TLR5
CpG-DNA	Bacteria and mycobacteria	TLR9
Not determined	Uropathogenic bacteria	TLR11
Zymosan	<i>Saccharomyces cerevisiae</i>	TLR6/2
Mannan	<i>Candida albicans</i>	TLR4
Viral DNA	Virus	TLR9

TLR, Toll-like receptor.

epithelial cells. Expression of TLRs is modulated rapidly in response to pathogens, a variety of cytokines, and environmental stresses. TLRs may be expressed extra- or intracellularly. For example, TLRs 1, 2, 4, 5, and 6 are expressed on the cell surface, others (TLRs 3, 7, 8, and 9) are found almost exclusively in intracellular compartments such as endosomes.

β-DEFENSINS

Human β-defensins (hBDs or DEFB) are potent antimicrobial peptides effective against a broad spectrum of bacteria, including gram-positive bacteria, gram-negative bacteria, and fungi. Among these microbes, *Streptococcus mutans* and *Lactobacillus acidophilus*, which are associated with dental caries, and certain strains of periodontal bacteria such as *Aggregatibacter (Actinobacillus) actinomycetemcomitans* and *Porphyromonas gingivalis* have been shown to be sensitive to hBD-2.^{96,97} hBDs are expressed mostly in epithelia.^{17,98–101} Besides the cloned, sequenced, and well-characterized hBD-1, -2, -3, and -4, there appears to be at least 28 more hBDs existing based on the genomic surveys.¹⁰² Fourteen hBDs or DEFB gene transcripts (DEFB-1, -4 and DEFB-103 to -114) have been detected in gingival keratinocytes.¹⁰³ Periodontal bacteria *Fusobacterium nucleatum* and *A. actinomycetem-*

comitans induce hBD-2 and hBD-3, respectively, in oral epithelial cells.¹⁰⁴

GROWTH FACTORS

Growth factors are peptide molecules that transmit signals between cells and tissue, which may result in differentiation, proliferation or activation of cells or inhibition of these functions. In general, growth factors promote and accelerate the structural development or the healing of tissues following injury. Some growth factors, such as angiogenic growth factors, have also been implicated in the pathogenesis of neoplastic changes within tissues. Most growth factors are named after the original tissue in which they were identified, a fact that could be misleading because the growth factors typically are ubiquitous in that they perform their actions in a wide range of tissues. As was mentioned for cytokines, growth factors can perform their actions in an autocrine, paracrine, or endocrine manner. Table 8 lists a classification and nomenclature of some of the main classes of growth factors.

Many growth factors are not only mediators of hard tissue matrix deposition but also become entrapped within the matrix as it becomes calcified. This has led to a great interest in osteoinductive growth factors such as the bone morphogenetic proteins BMP-2 or BMP-7, enamel matrix derivatives

Table 8 Classification of the More Commonly Recognized and Studied Growth Factors

Superfamily	Family	Abbreviated name
Transforming growth factor-β	Transforming growth factor-βs	TGF-β
	Inhibins	Inhibin/Activin
	Bone morphogenetic proteins	BMP
	Vg-1	Vg-1, GDF-1, DPP
Platelet-derived growth factor	Platelet-derived growth factors	PDGF
	Vascular endothelial growth factors	VEGF
	Connective tissue growth factors	CTGF
Epidermal growth factor	Epidermal growth factor	EGF
	Transforming growth factor-α	TGF-α
Enamel matrix derivatives	Amelogenin	Collectively known as EMD
	Enamelin (Enam)	
	Tuftelin	
Other large peptide growth factor families	Fibroblast growth factors	FGF
	Insulin-like growth factors	IGF
	Nerve growth factor	NGF
	Hepatocyte growth factor	HGF
	Tumor necrosis factors*	TNF

*As noted before, TNF-α and TNF-β are usually classified as proinflammatory cytokines, but sometimes considered within growth factor classifications.¹¹¹

(EMDs), PDGF, and insulin-like growth factor (IGF). These proteins have been extensively investigated with respect to their ability to induce, potentiate, and accelerate bone regeneration, whether as purified proteins or as components of demineralized freeze-dried bones.^{9,105–110}

There have been considerable interests in whether BMPs,^{112–115} TGF- β ,^{116–120} EMD,¹²¹ or other growth factors may enhance the formation of reparative dentin following pulp exposure. In vivo trials in animal models have initially been conducted via protein deposition directly on experimentally exposed pulp.^{114,122,123} However, more recently gene transfer strategies have been employed to assure prolonged effect of the induced protein^{112,118} or transplantation of cells in which the growth factor genes have been induced in vitro to a polyglycolic acid scaffold in the pulp.¹²⁴ However, it was later realized that in the presence of inflammation, as induced by applying LPS to the model, these strategies fail to produce the desired outcome.^{112,113}

Within a pathological pulpal or periapical tissue, or even during an orthodontic movement, growth factors are frequently expressed and are thought to modulate the inflammatory process and aid in the healing that ensues after the removal of irritants.^{9,125–131} For example, it has been shown that TGF- β 1 downregu-

lates the expression of matrix metalloprotein-8 (MMP-8) in human odontoblasts and dental pulp cells in vitro.⁴⁹

Molecular Mediators of Anti-Inflammatory Reactions

MEMBRANE PHOSPHOLIPIDS/ ARACHIDONIC ACID METABOLIC PATHWAYS

An inflammatory process is fine tuned by proinflammatory and anti-inflammatory mediators. There is more information known about proinflammatory mediators, whereas less is known regarding anti-inflammatory factors. In fact, in the pathways leading to the production of proinflammatory mediators such as prostaglandins and leukotrienes, there is also the production of anti-inflammatory mediators such as lipoxins (Figure 10). In the host defense mechanism, acute inflammation executed by neutrophils is resolved by proceeding to chronic inflammation in which proinflammatory mediators are produced or to resolution in which protective mediators are released.^{132–136}

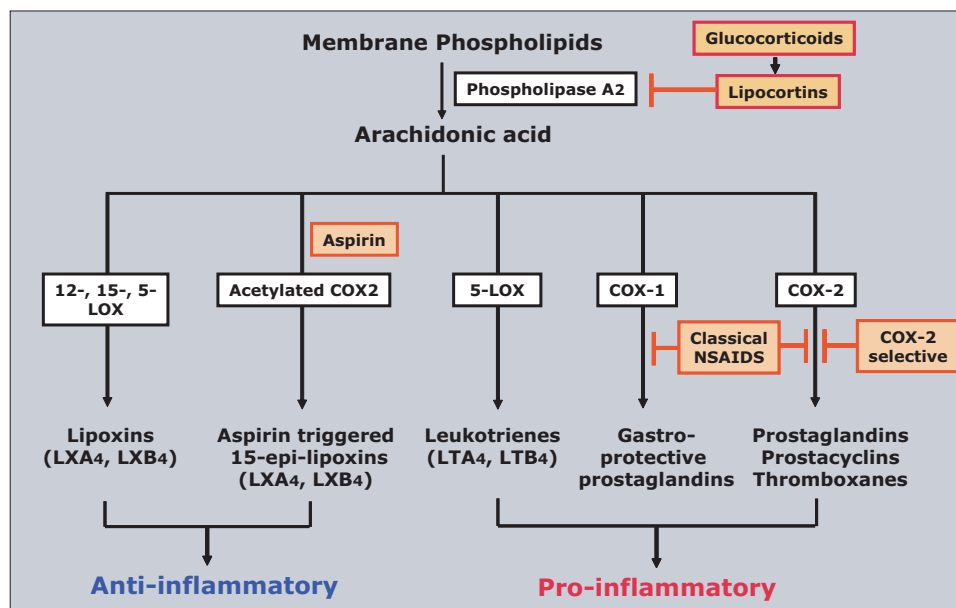

Figure 10 Pathways of lipid mediator production from membrane phospholipids. LOX, lipoxygenase; COX, cyclooxygenase; NSAIDs, nonsteroidal anti-inflammatory drugs; LX, lipoxin. Courtesy of Dr. Huang.

This proresolution against acute inflammation is an active process that involves the activation of specific biochemical and cellular programs of resolution. Lipoxins are potent counter-regulatory signals for endogenous proinflammatory mediators, including lipids (e.g., leukotrienes) and cytokines (TNF- α and IL-6), resulting in the inhibition of leukocyte-dependent inflammation. Lipoxins are rapidly biosynthesized in response to stimuli, act locally, and then are rapidly enzymatically inactivated.^{133,137–139}

ANTI-INFLAMMATORY CYTOKINES: IL-10, TGF- β , IL-4, AND IL-6

Several cytokines have predominantly anti-inflammatory effects including IL-1 receptor antagonist (IL-1Ra), TGF- β , and IL-10. Monocytes and B cells are the major sources of IL-10 in human subjects. The primary T-cell source for IL-10 is regulatory T lymphocytes (Tr), as mentioned above. IL-10 inhibits the production of many proinflammatory cytokines such as IL-1 β , IL-6, IL-8, IL-12, IFN- γ , and TNF- α . In addition, IL-10 inhibits MHC class II, CD23, intercellular adhesion molecule 1 (ICAM-1), and CD80/CD86 expression by DCs and other APCs. IL-10 plays an important role in human allergic diseases. Asthma and allergic rhinitis are associated with diminished IL-10 expression in the allergic airway by both alveolar macrophages and DCs. Newer members of the IL-10 family include IL-19, IL-20, IL-22, IL-24, and IL-26; however, none of these cytokines significantly inhibits cytokine synthesis, an activity that remains unique for IL-10.¹⁴⁰ Besides the antigen-driven IL-10-producing Treg, Th3 (TGF- β -Treg) cells also regulate immunosuppression via secretion of TGF- β . The production and the action of these two cytokines are inter-related and likely involve a positive feedback loop in which IL-10 enhances the expression of TGF- β and vice versa.^{140–143} TGF- β has a broad spectrum of activities including the induction of oral tolerance, potent anti-inflammatory effects, and downregulation of Th1 activities and MHC class II expression. TGF- β gene knockout mice develop multifocal inflammatory disease resulting in death.¹⁴⁴

IL-4, as a Th2 cytokine, suppresses IL-2 production and promotes the expression of anti-inflammatory cytokines such as TGF- β ₁. In addition, IL-4 inhibits the expression of MMP-9 and MMP-1 in monocytes and macrophages.¹⁴⁵ IL-6 is a highly pleiotropic cytokine that mediates the host response to injury and infection and is considered both a proinflammatory and an anti-inflammatory cytokine; it is secreted during inflammation and after TNF- α and IL-1 secretion.

IL-6 subsequently inhibits the secretion of TNF- α and IL-1.¹⁴⁶

Intracellular Signaling Pathways of Inflammatory Mediators

TLR SIGNAL TRANSDUCTION PATHWAYS

Upon binding the ligands, TLRs activate the same signaling molecules that are used for IL-1R signaling,¹⁴⁷ triggering downstream signaling cascades that leads to the activation of proinflammatory cytokine and chemokine genes. The stimulation of most TLRs leads to Th1 rather than Th2 differentiation. Thus, innate immunity is a key element in the inflammatory response as well as the immune response against pathogens. Microbial cell-wall components stimulate immune cells and serve as pathogen associated molecular patterns (PAMPs), recognized by individual TLRs. LPS, also known as an endotoxin, is generally the most potent immunostimulant among these cell-wall components. Earlier studies have shown that endotoxin plays an important role in the initiating and perpetuating of periradicular inflammation and bone resorption.^{148–151} LPS liberated from gram-negative bacteria binds LBPs that are present in the bloodstream, and then binds to CD14 expressed on the cell surface of phagocytes. Subsequently, LPS is transferred to MD-2, which associates with the extracellular portion of TLR4, followed by oligomerization of TLR4, a key molecule of LPS signaling.^{152,153} LPS does not have a direct apoptotic effect on osteoblasts or PDL cells, but can activate macrophages to induce apoptosis in osteoblasts and PDL cells via released TNF- α .¹⁵⁴

NF- κ B AND NF- κ B-ACTIVATING PATHWAYS

The transcription factor NF- κ B plays a pivotal role in a series of cellular processes, particularly those involved in inflammation, immunity, cell proliferation, and apoptosis. It consists of homo- or heterodimers of a group of five proteins, NF- κ B1 (p50), NF- κ B2 (p52), p65/RelA, c-Rel, and RelB. In resting, NF- κ B is in the cytoplasm and is bound by the inhibitory proteins I κ Bs. Upon cell stimulation, I κ Bs are rapidly phosphorylated and degraded, freeing the NF- κ B to translocate into the nucleus and bind onto the transcriptional regulatory sequence motifs of multiple target genes. NF- κ B activation is divided into two main pathways—the classical and the alternative pathways of NF- κ B activation. The

classical pathway is induced by a variety of innate and adaptive immunity mediators including proinflammatory cytokines (TNF- α and IL-1 β), TLRs, and antigen receptors (TCR and BCR) ligation. While these NF- κ B inducers signal through different receptors and adaptor proteins, all converge to the activation of I κ B-kinase (IKK) complex, which phosphorylates I κ B leading to its degradation. The freed NF- κ B then translocates into the nucleus where it activates the transcription of target genes such as cytokines, chemokines, adhesion molecules, and inhibitors of apoptosis (see Figure 3). The alternative pathway of NF- κ B activation is important for secondary lymphoid organ development, homeostasis, and adaptive immunity. It is induced by B cell-activating factor, lymphotoxin b, CD40 ligand, and human T-cell leukemia and Epstein-Barr virus. It enhances NF- κ B inducing kinase- and IKK α -dependent processing of p100 into p52, which binds DNA in association with its partners, like RelB. These stimuli also activate the classical pathway. NF- κ B inducers trigger the formation of reactive oxygen species (ROS), which may be the reason why that such a diversity of inducers activates NF- κ B via the same IKK-dependent pathway. Both IL-1 β and TNF- α activation of NF- κ B involve ROS.¹⁵⁵

Inflammation-Induced Bone Resorption

The formation of periradicular lesion as the result of pulpal infection involves features that are somewhat different from a typical microbial infection of other tissues. Pulp tissue ends and transits into the periodontal ligament tissue at the apical cementodentinal junction. Apical periodontal ligament begins to be affected as the pulpal inflammation spread toward it. Inflamed apical portion of the pulp and the periodontal ligament releases factors that induce bone resorption to build and maintain a defense line against the incoming microbial invasion. The resorbed bone space is replaced with abscesses and/or granulomatous tissue rife with inflammatory cells and fibroblasts. The proliferation of epithelial cell rest of Malassez leads to scattered epithelial cell clusters within the inflamed periradicular lesion. With time, these epithelial cell clusters may form a cyst that occurs in 7% to 54% of the periradicular lesions examined.^{156–162} Nair found that 52% (133/256) of the periradicular lesions examined histologically demonstrated epithelial proliferation, but only 15% were actually determined to be periapical cysts.¹⁶³

The epithelial cells in the PDL are involved not only in the formation of cysts but may also be in the regulation of cementum and bone metabolism as they

express osteopontin and osteoprotegerin (OPG) that are not expressed in gingival epithelial cells.¹⁶⁴ Based on animal studies, periradicular lesions expand in the early phase of the lesion formation and become self-limited at later stage.

MICROBIAL ROLE IN THE PATHOGENESIS OF PERIRADICULAR LESION

Although inflammation is generally associated with infection, inflammation can be the mere result of an aseptic trauma or a dysregulated immune reaction. The classic study by Kakehashi et al. (1965)¹⁶⁵ verified this notion that without the presence of microbes, exposed pulp tissue will heal after a transient inflammatory response without the development of periradicular lesions. Endodontic infection is characterized as a polymicrobial infection with predominately anaerobes, many of which are gram-negative. The damage of host tissues from infection is the result of (1) direct infliction from microbial products such as collagenase, trypsin-like enzymes, and fibronectin-degrading enzymes and (2) host immune response that leads to the destruction of tissue such as periradicular bone.

As mentioned above, host innate immunity experts certain extent of specificity to the microbial components via PRRs such as TLRs. TLR4-mutated C3H/HeJ mice (LPS hyporesponsive) have reduced response to gram-negative bacteria and are highly susceptible to infection by *Salmonella typhimurium* or *Neisseria meningitis*.¹⁶⁶ There is a reduced expression of IL-1 and IL-12 and a decreased periradicular bone destruction in TLR-4-deficient mice when subjected to pulpal exposure and infection with a mixture of four anaerobic pathogens, *Prevotella intermedia*, *F. nucleatum*, *Streptococcus intermedius* (gram-negative), and *Peptostreptococcus micros* (gram-positive). Also, no dissemination of infection occurs in the TLR-4-deficient mice.¹⁶⁷

If the pulp is exposed to the microorganisms in the oral environment, these LPS hyporesponsive mice do not show significant difference in the level of cytokine production or periradicular bone destruction from the normal controls.¹⁶⁸ Studies have indicated that the variations of microflora obtained from molar surfaces of mouse within a same experimental group are as great as the variation between mice in different groups,¹⁶⁹ which could contribute to the discrepancies of findings by different investigators.

Components such as LTA of gram-positive bacterial cell walls can also stimulate innate immunity in a similar manner as LPS. TLR2 plays a major role in detecting gram-positive bacteria and is involved in the

recognition of a variety of microbial components, including LTA, lipoproteins, and PG. The importance of TLR2 in the host defense against gram-positive bacteria has been demonstrated using TLR2-deficient (TLR2^{-/-}) mice that were found to be highly susceptible to challenge with *Staphylococcus aureus* or *Streptococcus pneumoniae*.^{170,171}

LTA can cause apoptotic cell damage including that of *Enterococcus faecalis*, which induces apoptosis in osteoblasts, osteoclasts, periodontal ligament fibroblasts, macrophages, and neutrophils. It also stimulates leukocytes to release mediators that are known to play a role in various phases of the inflammatory response including TNF- α , IL-1 β , IL-6, IL-8, and PGE2. These factors have all been detected in periapical samples, and each has a well-known tissue-damaging property.¹⁷²

ROLE OF IMMUNE CELLS IN PERIAPICAL LESION FORMATION

Immune cells present in human periradicular lesion consist of lymphocytes, macrophages, plasma cells, neutrophils, and NK cells with the former two types as the majority.^{173,174} Within lymphocytes, T cells are in greater number or equal to B cells.¹⁷⁵ APCs and T suppressor/cytotoxic cells are associated with both pre-existing and newly formed epithelium.¹⁷⁴

By using rodents as study models, the dynamics of periradicular lesion development in rodents is characterized by having an active bone resorption phase within 15 days after pulp exposure followed by a chronic phase with little lesion expansion.^{176–179} Th cells are predominant during the active phase, whereas increased numbers of Ts cells are associated with chronicity. The subpopulations of specific Th cells involved in the periradicular lesion development remain unclear.

The role of lymphocyte subpopulations in the formation of periradicular lesions was studied using lymphocyte-deficient rodents. T cell-deficient rodents develop periradicular lesion in a similar manner compared to the normal counter animals except some minor differences. Wallstrom et al.¹⁸⁰ used athymic rat model (T cell-deficient) and found no significant difference between periapical tissue responses of the conventional and athymic groups. Tani et al. (1995) used nude mice (T cell-deficient) and immunostaining to study the involvement of lymphocytes in the kinetics of periradicular lesion development. They found that at 2 weeks after pulp exposure, nude mice develop larger periradicular lesion than normal mice, but the lesion sizes are similar between the two experimental groups at 4 and 6 weeks after pulp exposure. At 8 weeks,

however, normal mice have slightly larger lesion size. No T cells and reduced number of B cells are present in the lesions of nude mice. T cells (more Th than Ts) begin to emerge in lesions after 4 weeks in normal mice.¹⁸¹ Fouad¹⁸² employed severe combined immunodeficiency (SCID, T-, and B cell-deficient) mice as a study model and found that the SCID mice lesions are significantly smaller than the controls at only the 3-week period. In these studies, the pulp was exposed to oral microbes.

By using RAG-2 SCID mice (both T and B cell-deficient) and an infection protocol—equalized bacterial challenge of the exposed pulp with mixed microbes *P. intermedia*, *F. nucleatum*, *P. micros*, and *S. intermedius* and the access sealed—Teles et al.¹⁸³ found that approximately one-third of the RAG-2 mice develop endodontic abscesses, while no immunocompetent controls have abscesses. In another study, specific knockout (k/o) mice RAG 2, Igh-6 (B cell-deficient, Ig heavy chain k/o), Tcrb Tcrd (T cell-deficient, β and δ chain TCR k/o), and Hc⁰ (C5-deficient) were used to determine which immune element is important for the defense mechanism in endodontic infection. Their results demonstrate that B cells, not T cells or C5, play a pivotal role in preventing the dissemination of endodontic infection.¹⁸⁴

MECHANISMS OF BONE RESORPTION: REGULATION OF OSTEOCLAST FORMATION AND ACTIVATION

Under normal conditions, osteoclastogenesis mainly occurs within the bone marrow as a continuing process of bone modeling and remodeling. Compared to the generalized bone loss seen in osteoporosis, localized bone loss in jaw bones resulting from endodontic infection is a combination of a focal inflammatory immune reaction and a localized osteoclastogenesis. Inflammatory cells, including lymphocytes and macrophages, produce cytokines, such as TNF and IL-1, and chemokines to recruit and activate more inflammatory cells (Table 9). Lymphocytes, monocytes and DCs found in

Table 9 Mediators Promote or Inhibit Bone Resorption

Action	Mediator
Promote bone resorption	IL-1, TNF- α , PGE2, IL-6, IL-11, RANK/RANKL, M-CSF, IGF-I
Inhibit bone resorption	IL12, IL-18, IL-4, OPG
Dual functions	PGs, TGF- β , IFN- γ , glucocorticoids

periapical granulomas synthesize receptor activator of nuclear factor- κ B ligand (RANKL). There is a significantly higher RANKL gene expression in the granulomas compared with the control tissues in both humans and rats.^{185–187} Macrophage colony-stimulating factor (M-CSF) and RANKL are two cytokines essential for promoting the differentiation of osteoclast precursors (OCPs) into mature osteoclasts. OCPs, generated in the bone marrow from hematopoietic stem cells, mobilize to diseased sites through the bloodstream and differentiate into osteoclasts to resorb bones. OCPs migrate along chemokine gradients.

The RANKL/RANK system is essential for mature osteoclast formation, a critical player in T-lymphocyte-mediated osteoclastogenesis, and induces OCPs to produce proinflammatory cytokines and chemokines.^{188–190} RANKL not only delivers a final differentiation signal, but also activates osteoclasts and promotes their survival. Mature B and T cells do not form osteoclasts but affect osteoclastogenesis indirectly by producing RANKL or OPG, a soluble decoy RANKL receptor (Figure 11). OPG binds RANKL thereby preventing RANKL activity. OPG is expressed in the human pulp of healthy and inflamed tissues¹⁹¹; however its role in pulp tissue is unclear. The expression

of OPG in periradicular lesion has not been reported. The influence of immune cells on osteoclastogenesis becomes significant when they accelerate osteoclast formation, and then both cell types contribute to the pathogenesis of the disease, as seen in inflammatory arthritis or periodontal disease.

RANKL is expressed by almost all cell types in the body. In the immune system, RANKL is expressed by activated T cells, B cells, and DCs (see Figure 11). OPG is produced by cells of mesenchymal origin. RANKL and OPG expression is regulated by many factors, and the ratio of RANKL/OPG controls osteoclastogenesis in vivo and in vitro. Periodontal ligament cells produce both RANKL and OPG.^{192,193} In contrast to the broad expression of RANKL, RANK, the receptor for RANKL, is identified only on mature osteoclasts, DCs, and OCPs, which are therefore the major target cells for RANKL and OPG. TNF is overproduced by many cell types at inflammatory foci, including macrophages, T cells, DCs, osteoclasts, and OCPs.^{194,195}

INHIBITION OF BONE RESORPTION BY BISPHOSPHONATES

Bisphosphonates (BPs) have a unique high-affinity binding property to hydroxyapatite mineral, generating high local concentrations of drug on bone surfaces where these agents can preferentially interfere with osteoclast-mediated bone resorption. BPs comprise amino- and nonamino-containing compounds. Aminobisphosphonates such as pamidronate, alendronate, risedronate, and zoledronate exert their inhibitory effects on osteoclast function by inhibiting farnesyl pyrophosphate synthase, an enzyme in the mevalonate pathway necessary for lipid modification (prenylation) of small guanosine triphosphate (GTP)-binding proteins. Interference with the activity of the binding proteins alters cytoskeletal organization and intracellular trafficking in osteoclasts, resulting in the inhibition of osteoclast function. Ruffled border formation is a process that is highly dependent on cytoskeletal function, strongly regulated by geranylgeranylated GTP-binding proteins, such as Rac, Rho. Nonaminobisphosphonates such as etidronate and clodronate are metabolized to nonhydrolysable analogues of adenosine triphosphate (ATP) and act as inhibitors of ATP-dependent enzymes, leading to enhanced osteoclast apoptosis (Figure 12).¹⁹⁶

The mechanism of osteonecrosis of the jaw (ONJ) by BPs is not completely clear. There are two possibilities:

- (1) BPs are antiangiogenic.
- (2) Osteoclast functional inhibition may affect normal homeostasis of bone.

Precipitating factors of ONJ include severe periodontitis, spontaneous exposure, periodontal surgery, dental implants, and root canal surgery.¹⁹⁷⁻¹⁹⁹

ROLES OF CYTOKINES IN PERIRADICULAR BONE RESORPTION

Many cytokines are involved in the initiation and maintenance of inflammation, some of which are also responsible directly or indirectly for the induction of bone resorption. Periradicular bone resorption induced by cytokines is a destructive and an undesirable process indicative of the magnitude of endodontic infection. On the other hand, cytokines are also important for the establishment of local immune defense mechanism. The role of specific cytokines in a variety of immune and inflammatory diseases, including endodontic pathoses, is difficult to elucidate due to the intricate and overlapping functions of these inflammatory cytokines and mediators.

Cytokines, TNF- α , IL-1, IL-6, and IL-11 are involved in promoting bone resorption and mediating inflammation both systemically and locally. In human dental granulomas, there is a correlation between the intensity of inflammatory infiltrate and the percentage of mononuclear cells positive for IL-4, suggesting a predominant Th2 response. There is also a correlation between the frequency of cells expressing IL-6 and TNF- α , suggesting synergistic activities of IL-6 and TNF- α in granulomas. The number of inflammatory cells expressing the anti-inflammatory molecules far

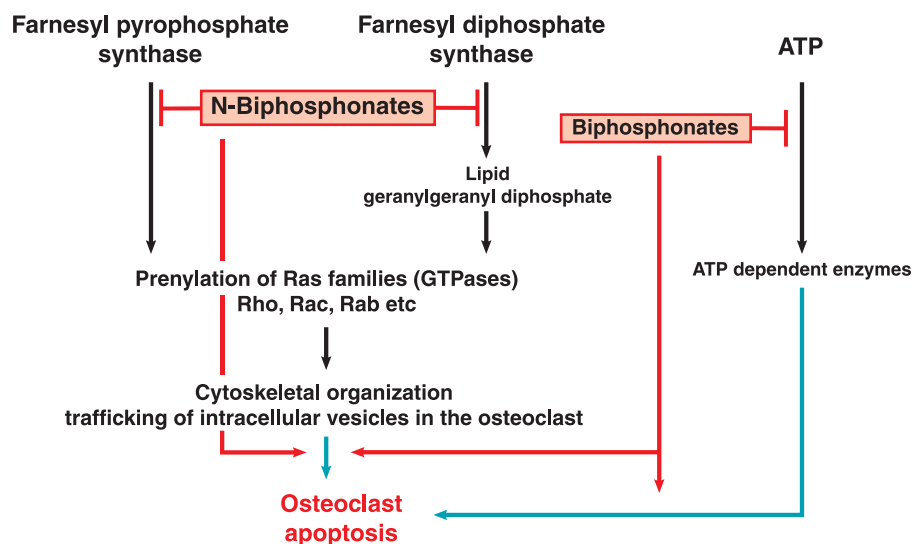

Figure 12 Mechanism of bisphosphonate (BP)-induced, osteoclast apoptosis. Courtesy of Dr. Huang.

outnumbered the cells that expressed proinflammatory cytokines.^{200,201}

In mice, TNF- α and IL-1 α are highly expressed in areas that contain a mixed inflammatory infiltrate or fibroblasts in periradicular lesions. The number of cells expressing these two cytokines is proportional to the lesion size.¹⁸² The expression of IL-11 is not modulated by pulp exposure. Most of the Th1-type cytokines, including IL-2, IL-12, and IFN- γ , increase in mRNA and/or protein expression in periapical lesions after pulpal exposure; the expression of Th2-type cytokines (IL-4, IL-6, IL-10, and IL-13) is similarly increased, but declines after 28 days. Th1-modulated pro-inflammatory pathways appears to predominate during periapical bone destruction in mice.^{202–206}

The role of specific cytokines in the development of periradicular lesions has been studied using mice with gene knockouts of different cytokines or their receptors, such as IL-1, IL-6, and TNF.^{169,207,208} Mice with functional deletions of receptors to IL-1 (IL-1RI(-/-)), TNF (TNFRp55(-/-)-p75(-/-)), or both (TNFRp55(-/-)-IL-1RI(-/-)) infected with multiple anaerobic pathogens after pulp exposure lead to increased polymorphonuclear and mononuclear phagocyte recruitment in the periradicular lesions and bacterial penetration into the host tissue. Osteolytic lesion formation is also greater in animals lacking TNF and/or IL-1 receptors than in control mice, indicating that IL-1 or TNF receptor signaling is not required for bacteria-induced osteoclastogenesis and bone loss, but does play a critical role in protecting the host against mixed anaerobic infections. Although TNF- α enhances osteoclastogenesis and mediates LPS-induced bone loss, deletions of TNFRp55(-/-) do not reduce bacteria-induced bone resorption.²⁰⁷ Between IL-1 and TNF- α , IL-1 receptor signaling is more important than TNF receptor signaling in preventing the spread of infection into the surrounding fascial planes.²⁰⁹

IL-6 production in mouse periapical lesions reaches its peak (~two-fold higher than the baseline) on day 14 after pulpal exposure and then decreases to the basal level after 28 days.²⁰⁴ Depleting IL-6 negatively affects the host defense mechanism against local infection in the periradicular area.^{169,208} In IL-6(-/-) mice, periradicular lesions rapidly develop in week 2, whereas in the IL-6+/+ mice the development of the lesion is 1 week slower.¹⁶⁹ The increased bone resorption in IL-6-deficient animals correlated with increases in osteoclast numbers, as well as with elevated expression of bone-resorptive cytokines IL-1 α and IL-1 β , in periapical lesions and with decreased expression of the anti-inflammatory cytokine IL-10. These data demonstrate that endogenous IL-6 expression has significant

anti-inflammatory effects in modulating infection-stimulated bone destruction in vivo.²⁰⁸

The functional role of the Th2-type cytokines IL-4 and IL-10 in infection-stimulated bone resorption in vivo has also been assessed using gene knock-out mice. IL-10(-/-) mice have significantly greater infection-stimulated bone resorption compared with wild-type mice, while IL-4(-/-) have no increased resorption. IL-10(-/-) mice show markedly elevated IL-1 α production within periapical inflammatory tissues (>10-fold), whereas IL-4(-/-) exhibit decreased IL-1 α production. These findings suggest that IL-10, but not IL-4, is an important endogenous suppressor of infection-stimulated bone resorption in vivo, likely acting via inhibition of IL-1 α expression.²¹⁰

The functional roles of the Th1 cytokine IFN- γ and IFN- γ -inducing cytokines IL-12 and IL-18 has also been determined with a similar approach using IL-12(-/-), IL-18(-/-) and IFN-gamma(-/-) mice.²¹¹ Although in vitro evidence has demonstrated that IL-12 and IL-18 have inhibitory effects on osteoclast formation,²¹² no difference was found in the infection-stimulated periapical bone resorption between knock-out and wild-type control mice.²¹¹ Therefore, it appears that there is a functional redundancy in proinflammatory pathways.

Hypersensitivity Reactions

Hypersensitivity reactions represent a group of immunological responses where the reaction observed by the host far exceeds that normally triggered in the immune response described before. This results in excessive tissue damage and even death in certain cases. There are four types of immunological hypersensitivity reactions recognized. They vary in their severity and extent from a mild subclinical response to a life-threatening reaction. It is important for the clinician to understand the underlying mechanisms of these conditions in order to recognize and manage these reactions in their patients effectively.

Type I: IgE-mediated degranulation of mast cells and basophils, with release of histamine. This may be either systemic (anaphylaxis) or local (atopy). Type 1 hypersensitivity is fundamentally caused by the initial sensitization of the patient to a particular allergen. Some of the common allergens here include penicillin, certain foods, pollen, and insect bite. Upon exposure to a second challenge to this allergen, cross-linking of IgE on the surface of mast cells occurs, and release of C3a and C5a complement molecules cause degranulation of mast cells and release of inflammatory mediators. The most important of these mediators is histamine; however, other mediators including eicosanoids, Th2 cytokines, and

chemokines are released. The patient experiences vasodilatation, which may be local or systemic, as well as bronchoconstriction, which causes wheezing and may cause asphyxia. The patient is considered to have a medical emergency that should be immediately managed with subcutaneous injection of epinephrine. A proportion of patients with chronic exposure to allergens develop asthma.

Type II: Antibody-dependent cytotoxic hypersensitivity. Antigens on the cell surface can cause cell damage through the interaction with inflammatory cells that have Fc γ or C3b receptors. Recall from the discussion of phagocytosis that this reaction primes the microbial surface by opsonins that aid in phagocytosis. In this case, however, phagocytosis does not occur, occasionally because the target is too large for phagocytosis such as for large target cells or in parasitic infections. Examples of type II reactions include blood factor (ABO) or rhesus (Rh) factor incompatibility and autoimmune hemolytic anemia.

Type III: Immune complex-mediated hypersensitivity. Excessive accumulation of antigen-antibody complexes in tissues, such as when there is excessive chronic accumulation of antigen, can stimulate an immune response through phagocyte-, complement-, and/or cytokine-mediated reactions. Frequently, neutrophils and macrophages attempt to perform phagocytosis, but due to the large amount of antigen, such as a microbial colony, they spill their proteases and oxygen- and nitrogen-reactive intermediates in the tissue causing tissue damage. Examples of this reaction include arthus reactions, serum sickness, systemic lupus erythematosus, and immune complex glomerulonephritis.

Type IV: Cell-mediated (delayed-type) hypersensitivity. This reaction is mediated by T_H1, CD4⁺, or CD8⁺ cells, causing cytokine-mediated tissue damage. Examples of this reaction include allergic reactions to bacteria, viruses and fungi, contact dermatitis reactions, chronic granulomas such as tuberculosis and leprosy, and the skin tuberculin test (Mantoux reaction) in which subcutaneous administration of antigen causes accumulation of mononuclear inflammatory cells within 24 to 48 hours.

Type V: Stimulatory hypersensitivity. The prime example of this reaction is Graves disease, in which plasma cells continue to produce a self antibody against the thyroid-stimulating hormone (TSH) receptor in the thyroid gland, which itself stimulates the gland to keep producing thyroxine, and does not respond to negative feedback mechanisms.

Innate hypersensitivity reactions. The severe disseminated reaction to LPS in gram-negative bacteria is known as septic shock syndrome. In this reaction, LPS causes the

release of systemic cytokines IL-1, TNF- α , and IL-6, which in excessive amounts activate complement, cause respiratory distress by excess circulating neutrophils, and disseminated intravascular coagulation. More recently, gram-positive septic shock has also been recognized due to enterotoxins of streptococci or staphylococci.

CHAPTER 10

MECHANISMS OF ODONTOGENIC AND NON-ODONTOGENIC PAIN

JENNIFER L. GIBBS, KENNETH M. HARGREAVES

Overview of the Trigeminal Pain System

Perceived association of pain with endodontic therapy represents a source of fear for many of our patients and equally represents a meaningful challenge to many practitioners. However, considerable and ongoing research now provides a solid framework for understanding the biological basis of odontogenic and non-odontogenic pain. Moreover, it is our belief that effective diagnosis and treatment flows from this conceptual framework. Accordingly, this chapter provides a comprehensive review of pain mechanisms that forms the basis for clinical recommendations of the diagnosis and management of orofacial pain detailed in other chapters (see Chapters 11 and 21).

Organization and Function of the Peripheral Trigeminal Pain System

A fundamental function of the peripheral nervous system is detecting the magnitude, quality, location, and temporal characteristics of innocuous (light touch, vibration, warm, and cool) and noxious (thermal, mechanical, and chemical) sensory input. This detection is mediated by receptors expressed on subclasses of primary afferent neurons that are activated by various stimuli,¹ leading to intracellular changes. As detailed below, these intracellular changes may activate neurons, inhibit neurons, or alter their responsiveness to subsequent stimuli. The cell bodies of nearly all nociceptive neurons innervating the oral and craniofacial region are found in the trigeminal ganglia. The cell body is classically viewed where protein synthesis of receptors as well as peptidergic neurotransmitters takes place (Figure 1), although emerging evidence now

points to protein synthesis occurring at terminal endings as well.² The synthesis of receptors and peptidergic neurotransmitters by the trigeminal ganglia is a dynamic process that is very sensitive to injury and inflammation detected in the peripheral terminals. For example, animal studies have demonstrated the amount of certain neurotransmitters such as neuropeptide Y, substance P (SP), and galanin detected in the trigeminal ganglia will change dramatically after a peripheral injury such as a tooth extraction or pulpitis.^{3,4} Moreover, nerve injury induces a rapid trafficking of sodium channels from the cell body out to the terminal endings.⁵ Collectively, these studies demonstrate the potential for striking plasticity of the sensory neurons in response to tissue injury or inflammation.

As illustrated in Figure 1, the pain system can be conceptualized as having three main organizational elements: *detection*, *processing*, and *perception*. Although the anatomical basis is considerably more complex than illustrated, and still incompletely understood, this model provides a framework for interpretation of experimental findings and for developing a biological basis for pain diagnoses and pain management strategies.

Upon detection of an appropriate stimulus, primary afferent neurons encode this information by the frequency and temporal characteristics (e.g., duration) of action potential discharge, and this digitized information is conveyed to second-order neurons by the release of neurotransmitters such as glutamate, SP and calcitonin gene-related peptide (CGRP) from the central terminal of the primary afferent neuron. In addition to the central release of neurotransmitters, primary afferent neurons also release these substances from the peripheral terminals located in dental pulp and periradicular tissue.^{6–14} Several dental pulp

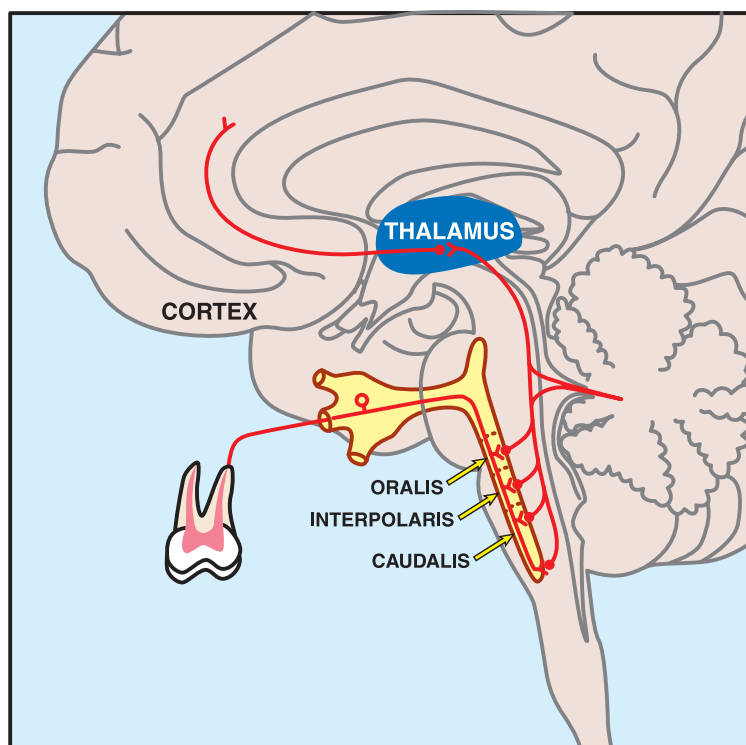

Figure 1 A conceptual model for the trigeminal pain system. Acute dental pain is due to detection of peripheral stimuli by sensory nociceptive neurons that innervate teeth and the periodontal ligament and convey information on stimulus intensity, location, and duration to the nuclei oralis, interpolaris, and caudalis of the trigeminal brainstem complex. Considerable processing occurs in these central sites leading to either an amplification of the nociceptive signal (e.g., central sensitization) or an inhibition of the signal (due to activity of endogenous analgesic systems). Finally, nociceptive information is integrated in cortical structures with affective, psychosocial, and other cognitive elements resulting in the perception of pain.

studies have demonstrated the presence, as well as the stimulated release, of SP and CGRP.^{15–18} The release of these peptides is important for causing vasodilation and plasma extravasation and is critical for the recruitment of immune cells to the site of injury.

With advancements in neuroscience research, the classification of peripheral sensory neurons has become increasingly complex. The classic scheme for categorizing neurons was based historically on the diameter and the amount of myelination of the neurons as well as their conduction velocity, which is a function of both of these factors. Based on this classification system, we can identify three broad categories of primary afferents (Table 1). The A β class of sensory neurons is heavily myelinated and has a large diameter that allows for rapid transmission of information to the central nervous system. This fiber class detects stimuli such as touch, vibration, and pressure. Although the A β class of afferent fibers is classically described as conveying innocuous mechanical stimuli, it should be recognized that they innervate dentinal tubules and are capable of encoding stimuli that

Table 1 Classification Scheme of Peripheral Neurons

Fiber	Function	Size (μm)	Conduction Velocity (m/s)
A α	Motor, propriocept	12–20	60–120
A β	Touch, pressure	5–10	35–70
A γ	Muscle spindles	3–6	15–30
A δ	Pain, temperature, touch	2–5	12–30
B	Pre-ganglionic autonomic nervous system (ANS)	<3	3–15
C	Pain, sympathetic	0.5–1	0.5–2

induce dentinal pain in humans and, in addition, may be important in certain chronic pain conditions.^{19–22} The two classic neuronal categories of nociceptors are the A δ and the C fibers. The A δ class of primary afferents has a smaller diameter than the A β class, is lightly myelinated, and has a higher threshold of activation. These neurons function in

the transmission of “first” pain that is perceived as sharp or “bright” in perceptual quality and can be stimulated by mechanical, chemical, or thermal noxious stimuli. The C fibers transmit “second pain” that is perceived as a dull ache. These fibers are of the smallest diameter, have the slowest conduction velocity, and a high threshold of activation. The differences between first and second pain sensations are derived from studies in which noxious stimuli are applied to peripheral tissues (usually arm or leg) and are interpreted to be due to differences in conduction velocity between the $A\delta$ (“first” pain) and the C fibers (“second” pain).

More contemporary schemes classify afferent neurons based upon genetics of development or the expression of certain neurochemical markers in the adult.^{23,24} For example, C fibers can be subdivided into those expressing peptidergic neurotransmitters such as CGRP and SP and the nerve growth factor (NGF) receptor *trkA* and those which bind the plant lectin, IB4, and generally have low to non-detectable amounts of CGRP and SP (the so-called non-peptidergic nociceptors).²⁵ This classification has functional significance as the *trkA* subpopulation is thought to primarily encode inflammatory pain while the IB4 subpopulation is thought to be more responsible for neuropathic pain.²⁶ This finding is of clear endodontic significance as the development of pulpal necrosis represents a unique tissue condition that has some similarity to both inflammatory and neuropathic pain conditions.²⁷ In addition, this neurochemical classification has a correlation with the anatomic organization of the central terminals of these neurons in the spinal and medullary dorsal horns.^{23,28,29} However, the relative contribution of the *trkA* and IB4 subpopulations of nociceptors in mediating odontogenic pain over the course of pulpitis to pulpal necrosis still remains unclear. Interestingly, the dental pulp is apparently unique in which the IB4 population of C fibers represents a much lower proportion of the neurons compared to other peripheral tissues such as skin.³⁰

Innervation of the Pulp–Dentin Complex

Given that pain is the dominant, although not exclusive,³¹ sensory modality elicited by stimulation of the pulpodentin complex, it is not surprising that the dental pulp is densely innervated by nociceptive sensory neurons.^{20,32–35} Sensory neurons in the dental pulp travel in nerve bundles through the apical and midroot portions of the pulp and then branch exten-

Figure 2 Innervation of human dental pulp. Following informed consent, anesthesia, and extraction, a first molar was split and processed for immunohistochemistry using antibodies directed to nerve filament proteins (N52 and PGP9.5), and the image of the coronal pulp was collected by confocal microscopy. For orientation, the fibers traverse through the odontoblastic layer to the dentinal tubules (on the right). Reproduced with permission from Henry MA and Hargreaves KM.¹

sively in the coronal pulp (Figure 2). The nerve terminals are either found in the pulp proper (generally the unmyelinated C fibers) or they can travel through the odontoblast layer and terminate a short distance (150–200 μm) within the dentinal tubule (generally the $A\delta$ or $A\beta$ fibers). An intricate layer of neuronal branching is found below the odontoblast layer and is termed the plexus of Rashkow. This branching is especially dense and complex within the pulp horns. The dense innervation of the pulpo–dentin border found in the coronal region is reduced in cervical regions. Studies have demonstrated that approximately 50% of the tubules present in the area of the cusp tips contain nerve fibers while dentinal tubules in the cervical region are much less innervated.³⁶

Anatomic and electrophysiologic studies have demonstrated the presence of $A\delta$, C, and $A\beta$ fibers in the dental pulp,^{30,37,38} although the myelin sheaths are lost as the axons traverse the apical foramen and are thus not apparent in pulpal histological images. These fibers appear to be organized anatomically in a manner consistent with their observed functionality. For

example, small myelinated fibers (likely A δ) generally terminate in the dentin, pre-dentin, and odontoblast regions of the pulp. Electrophysiologic recordings of the dental pulp demonstrate that A δ fibers are activated by hydrodynamic stimuli such as the application of a burst of air onto exposed dentin, drilling, and rapid temperature change.^{21,39,40} The hydrodynamic theory and its relation to dental pain will be discussed in more detail later in this chapter. Application of hydrodynamic-type stimuli in human volunteers elicits a quick, sharp, or bright type pain consistent with perceptual qualities from activation of A δ fibers.⁴¹ In contrast to the superficial localization of the A δ fibers, the pulpal C fibers are found deeper within the pulp and often adjacent to blood vessels. Electrophysiologic studies demonstrate that C fibers are more likely to become activated by inflammatory mediators such as bradykinin, prostaglandins, and histamine.^{42,43} They also can respond to intense heat or cold and it is surmised that the delayed response likely corresponds to the time it takes for detection of the temperature change in the well-insulated mass of the pulp tissue.^{42–44} Studies in human volunteers have demonstrated that the same stimuli which activate pulpal C fibers in vitro produce a dull, throbbing, or burning pain which is often difficult to localize when applied in vivo.⁴⁵

It is somewhat surprising that A β fibers are found within the pulp, as these fibers are classically not associated with detection of painful stimuli. However, anatomic and electrophysiologic studies have demonstrated their presence in dental pulp and their responsiveness to noxious stimuli. In dental pulp, these fibers are functionally indistinct from A δ fibers and as such primarily respond to hydrodynamic stimuli.³⁵ They generally terminate at the dentin–pulp border and innervate dentinal tubules particularly at the pulp horn tip.^{37,46} Other neuronal structures innervating the dental pulp include postganglionic sympathetic fibers that cause vasoconstriction in the pulp when activated,^{47–49} and the resulting reduced pulpal blood flow may be due to both direct vasoconstriction and indirect mechanisms via inhibition of CGRP release from afferent neurons.^{10,11} Comparatively less is known about parasympathetic innervation in dental pulp.^{50–53}

It has long been debated whether odontoblasts, that are obviously non-neuronal cells, are involved in the sensory function of the dental pulp. Ultrastructure studies have demonstrated that although odontoblasts come in close contact with pulpal neurons they do not form a classical synaptic-like connection and therefore likely are not responsible for directly activating pulpal neurons.^{54,55} However, recent studies demonstrating

that odontoblasts are capable of generating action potentials⁵⁶ and express the transient receptor potential V1 also known as the capsaicin receptor (TRPV1)⁵⁷ and sodium channels (discussed in the Peripheral Pain Mechanisms Section) suggest that this debate is likely to continue.

Organization and Function of the Central Trigeminal Pain System

The second major functional element of the pain system is processing and this is thought to occur, at least in part, in the trigeminal nuclei. Peripheral trigeminal neurons enter the medulla forming the trigeminal spinal tract and terminate in the trigeminal brainstem nuclear complex (VBSNC). The VBSNC consists of the principle sensory nucleus of V, which receives non-nociceptive sensory input, and the spinal tract nucleus of V. The spinal tract nucleus of V is further divided in a rostro-caudal direction into the nucleus caudalis (most caudal section), the nucleus interpolaris, and the nucleus oralis (most rostral section) (see Figure 1). The nucleus caudalis is a primary site for integration and processing of orofacial nociceptive input. The nucleus caudalis is a laminated structure similar to the spinal dorsal horn, and in fact, the most caudal extent of this nucleus is continuous with the cervical spinal dorsal horn. For this reason, this region is often referred to as the medullary dorsal horn. However, despite these similarities, numerous studies have demonstrated that there are several unique features of the nucleus caudalis that distinguish it from the spinal dorsal horn.^{58–61} For example, the neuronal inputs from peripheral tissues often terminate over a broader region in the VBSNC, whereas the spinal dorsal horn is organized in more of a segmental manner (e.g., C1-C2-C3). Specifically, anatomic and electrophysiologic studies have demonstrated that pulpal neurons terminate in the nucleus caudalis, nucleus interpolaris, and nucleus oralis.^{62–65} This may partially account for the clinical observation of patients experiencing symptomatic pulpitis and having difficulty localizing the painful tooth. Furthermore, the observation that all three nuclei as well as other regions (e.g., cervical dorsal spinal cord) receive orofacial nociceptive input indicates nociceptive processing in the trigeminal system is multifocal.⁵⁹

The processing of a nociceptive signal that takes place in the VBSNC is highly complex involving numerous neurons and supportive structures and

Figure 3 Illustration of a wide dynamic range (WDR) projection neuron in the medullary dorsal horn and the major components that alter the processing of nociceptive input from a C nociceptor. 5HT = serotonin; CGRP = calcitonin gene-related peptide; COX = cyclooxygenase; Glu = glutamate; NE = norepinephrine; NO = nitric oxide; NOS = nitric oxide synthase; PG = prostaglandin; SP = substance P; Tg = trigeminal ganglia.

can result in either the amplification or the diminution of a peripheral nociceptive signal (Figure 3). The key components mediating this process include (1) the central terminal of the primary afferent fiber; (2) the interneurons; (3) the descending neurons; (4) the glia; and finally (5) the projection neurons.

When a noxious stimulus activates a peripheral trigeminal nociceptor, an action potential is generated that propagates the length of the neuron and ultimately results in the release of neurotransmitters from the central terminals, including the excitatory amino acid glutamate, as well as neuropeptides such as CGRP and SP. Although activation of many of the cognate receptors for these neurotransmitters plays a role in the generation of pain, the glutamate receptors are particularly relevant. Glutamate activates the NMDA and AMPA receptors, and numerous studies

have demonstrated that these receptors are critical for the generation of hyperalgesia and mediate certain phenomena such as central sensitization, described in the Central Mechanisms section.⁶⁶

Local interneurons make connections between different neurons within the medullary dorsal horn, and depending upon the neurotransmitters they express and can either inhibit or facilitate nociceptive transmission.

The third component of the medullary dorsal horn is the terminals of the descending neurons. These neurons arise from higher level structures in the brain such as the periaquiductal gray and the rostral ventromedial medulla and descend to modulate the nociceptive signal at the level of the projection neuron. Both inhibitory function and excitatory modulation of the descending neurons has been

demonstrated.⁶⁷ The endogenous opioid system is an important component of this descending modulation. We know from clinical studies that the endogenous opioid system is important in modulating dental pain. Prior to a dental procedure, administration of the opioid receptor antagonist naloxone significantly increases the perception of pain.^{68–70}

The fourth component of nociceptive processing in the medullary dorsal horn is the glia. These are the microglia and astrocytes that until recently were only believed to function as supportive structure for neurons. Glia are now known to express receptors for many neurotransmitters involved in pain and activated glia-release cytokines and prostaglandins that can subsequently activate or sensitize neighboring neurons.^{71,72} Accordingly, the central mechanism of action for the non-steroidal anti-inflammatory drugs (NSAID) is thought to be mediated by inhibition of central cyclooxygenase.

The final component of the medullary dorsal horn is the projection neuron whose activity is modulated by all of the previously described components. After processing peripheral neuronal input, these neurons project to the thalamus via the trigeminothalamic tract. The thalamocortical tract relays sensory information from the thalamus to the cerebral cortex, where perception occurs. The three major classes of projection neurons are the low-threshold mechanoreceptor (LTM) neurons, the wide dynamic range (WDR) neurons, and the nociceptive-specific (NS) neurons. The LTM projection neurons receive input from non-nociceptive fibers (i.e., A β fibers). The WDR neurons receive input from both nociceptive and non-nociceptive fibers while the NS projection neurons only receive input from nociceptors.⁵⁸

An important concept in understanding the implications of central processing at the level of the projection neurons is that of convergence. One projection neuron can often receive afferent input from numerous distinct afferent inputs, such as cutaneous tissues, dental pulp, dura, and/or cornea.^{58,73} This represents the physiologic basis for referred pain. Referred pain is frequently encountered by endodontists. For example, a patient with irreversible pulpitis in a mandibular first molar may also complain of pain in the right pre-auricular region. Referred pain can also work in the other direction where a fibromyalgia patient with a trigger point in the lower belly of the masseter muscle might present with a chief complaint of throbbing pain in the mandibular first premolar on the same side. Both of these scenarios can be explained by the concept of central convergence.

The Inflamed Dental Pulp

Under normal conditions, the nociceptors of dental pulp are thought to be quiescent. In the absence of any pathology, pulpal nociceptors are usually not activated by the modest temperature changes they are exposed to when eating or drinking a hot or cold substance, and they are protected from chemical or mechanical activation by dentin and enamel. However, in the presence of tissue injury, such as caries, trauma, or enamel abrasion, the nociceptors are readily activated by various stimuli. The development of pulpitis and apical periodontitis and the experience of pain that often (but not always) accompanies them involve complex neuro-immune interactions. Both the peripheral primary afferent neuron and the central projection neurons are critical for the initiation and maintenance of pain, and important features of these mechanisms are described below.

The three characteristics of an acute inflammatory process are (1) allodynia or a decreased threshold for detecting painful stimuli, whereby an innocuous stimulus is able to produce a sensation of pain; (2) hyperalgesia or an enhanced response to a frankly noxious stimulus; and (3) spontaneous pain. These characteristics are present in patients experiencing symptomatic pulpitis and/or symptomatic apical periodontitis. For example, a patient with acute apical periodontitis might report pain on chewing (i.e., mechanical allodynia). Moreover, an exaggerated painful response to the cold test and percussion test are signs of thermal and mechanical hyperalgesia, respectively.

Peripheral Pain Mechanisms

The activity of nociceptors in an inflamed environment is markedly altered from those in a native or uninjured state. When present in sufficient concentration, inflammatory mediators can either activate (e.g., bradykinin) or sensitize (e.g., prostaglandins such as prostaglandin E₂) nociceptors via interactions with their receptors. Sensitization is characterized as a decrease in threshold (i.e., contributing to allodynia), an increased response to suprathreshold stimuli (i.e., contributing to hyperalgesia), and spontaneous activity (i.e., contributing to spontaneous pain). Although some inflammatory mediators are capable of immediately activating peripheral nociceptors, many other inflammatory mediators primarily function to change the transduction sensitivity of the peripheral neuron. Peripheral sensitization refers to the altered activity and excitability of peripheral neurons in the presence

Figure 4 A schematic illustration of the primary families of receptor or ion channels expressed on peripheral terminals of dental nociceptors that serve to detect physical stimuli and chemical substances, leading to altered nerve activity. Not all receptors/ion channels are present on all neurons, and several have been shown to be altered during inflammation or nerve injury. PAR-2 = protease-activated receptor subtype 2; PG = prostaglandin; TRPA1= transient receptor potential A1; TRPM8 = transient receptor potential M8; TRPV1 = transient receptor potential V1 aka the capsaicin receptor; VGCC = voltage-gated calcium channel; VGKC = voltage-gated potassium channel; VGSC = voltage-gated sodium channel. of inflammatory mediators and is one peripheral mechanism mediating inflammatory pain.

A key concept in understanding the function of peripheral nociceptors is their expression of receptors and ion channels. Peripheral terminals of nociceptors express receptors that detect chemical or physical stimuli resulting in activation of ion channels leading to generation of action potentials sent back to the brain (Figure 4). Although considerable research has focused on receptors that increase nociceptor activity (e.g., receptors for bradykinin, prostaglandins), it should be appreciated that receptors are present that inhibit nociceptor activity (e.g., receptors for opioid or adrenergic drugs) and thus overall activity is due to an integration of these receptor signaling pathways. The activation of certain G protein-coupled receptors (GPCR) can lead to activation of intracellular signaling pathways leading to G_s stimulation of protein kinase A (e.g., Prostaglandin E₂ (PGE₂) or to G_q activation of protein kinase C (e.g., bradykinin). Both of these pathways phosphorylate key receptors, altering their kinetics, and increasing the overall excitability of the neuron. Conversely, many peripheral analgesic drugs bind to GPCRs coupled to the G_i protein that inhibits Protein kinase A (PKA) activity contributing to reduced nociceptor function. An example of this interaction is presented in (Figure 5). Capsaicin is the active ingredient in hot chili peppers and activates nociceptors by binding to the TRPV1 channel (see Figure 4), resulting in chemical activation of pulpal nociceptors. When applied to isolated superfused dental pulp, capsaicin evokes a significant activation of pulpal nociceptors as indicated by release of CGRP (see Figure 5). However, if the pulpal neurons are first pretreated with

epinephrine, a drug that binds to adrenergic receptors coupled to G_i , there is an inhibition of nociceptor activity. Thus, an understanding of receptors and signaling pathways allows one to predict whether a drug might increase or inhibit pain perception. Moreover, these data suggest that the epinephrine contained in local anesthetic cartridges might have direct peripheral analgesic properties independent of the “vasoconstrictor” effect of the drug.¹⁰

Numerous inflammatory mediators and their corresponding receptors are present in dental pulp including bradykinin, arachidonic acid metabolites

Figure 5 Effect of pretreatment with epinephrine or vehicle on the release of immunoreactive calcitonin gene-related peptide (iCGRP) evoked by capsaicin. Bovine dental pulp was sliced into 200 μm^2 slices, superfused with oxygenated Krebs' buffer, and the iCGRP released over a 28-minute period was measured by radioimmunoassay. Epinephrine (10 nM) or vehicle was administered before and concurrently with capsaicin (10 μM). Error bars are SEM ** $p < 0.01$ versus vehicle. $N = 7$ to 8 per group. (e.g., prostaglandins and leukotrienes), histamine, serotonin, cytokines, protons, and adenosine and adenosine phosphates (e.g., AMP, ADP, and ATP). Because inflammatory mediators evoke their effects by binding to protein receptors, their tissue concentration must be sufficient to occupy an appreciable fraction of the receptors on the cell's membrane. Thus, interventions that reduce tissue levels of inflammatory mediators (e.g., NSAID reduction of PGE2 levels) lead to reduced activation of these receptors. Other pharmacological interventions work by blocking the receptor to prevent endogenous mediators from activating it (e.g., antihistamine blockade of the histamine receptor). Also, the combination of inflammatory mediators present is important as many inflammatory mediators activate receptors leading to a rich potential for interactions that could substantially increase nociceptor activities. For example, the pain evoked in human volunteers by infusion of a mixture of inflammatory mediators into the skin was 10-fold greater when the skin was previously exposed to a low pH (i.e., higher proton concentration).⁷⁴ Studies in the dental pulp have also demonstrated that a positive interaction exists between bradykinin and prostaglandin E2 signaling in nociceptors.¹³

Trophic factors such as NGF, that play an important role in neural development, are also important in

inflammation. Cytokines increase NGF production in inflamed tissues, including dental pulp, and NGF can sensitize nociceptors as well as mediate some of the transcriptional changes which occur after inflammatory injury.^{75,76} Specifically, NGF has been demonstrated to increase expression of TRPV1, transient receptor potential A1 (TRPA1), as well as the sodium channels Na_v 1.8.⁷⁷⁻⁷⁹ For example, the local infusion of NGF evokes a three-fold increase in the expression of TRPA1 transcripts (Figure 6A) and significantly increased the neuronal depolarization induced by a chemical stimulus of the TRPA1 channel (see Figure 6B). The importance of these receptors to inflammatory pain is described below. It is important to note that these changes contribute to the phenomenon of peripheral sensitization, but because they are transcription dependent (i.e., requiring synthesis of new proteins), they manifest over a time from hours to days.

The use of local anesthetics is essential to the practice of endodontics. Therefore, the target of local anesthetics, voltage-gated sodium channels (VGSC), is clearly an important molecular target when discussing pain management (see Figure 4). These sodium channels are termed "voltage gated" as the channels undergo a conformation change in response to application of a voltage, leading to sodium influx and membrane depolarization. Dentists take advantage of this property by using electrical pulp tests that apply

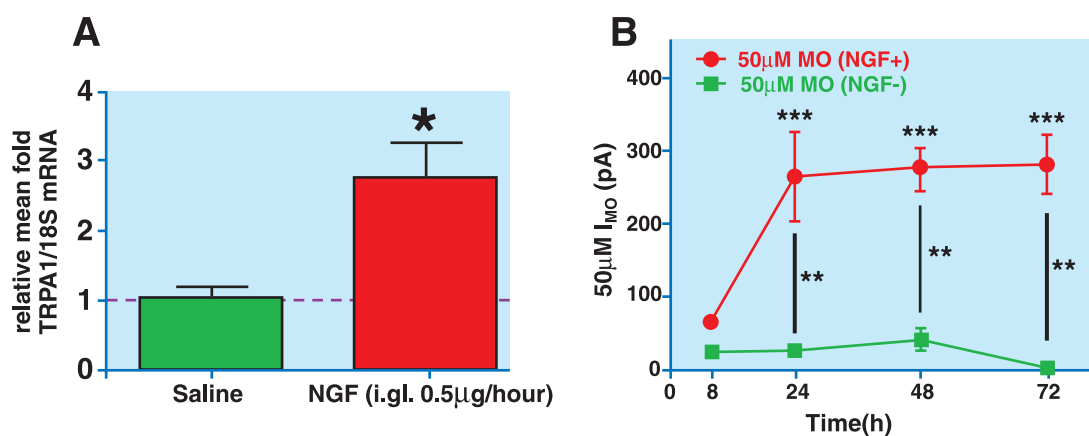

Figure 6 A, Local administration of nerve growth factor (NGF) significantly upregulated the expression of transient receptor potential A1 (TRPA1) mRNA in the trigeminal (TG) neurons in vivo. Rats received intraganglionic (i.g.l.) infusion of NGF at a constant rate of 0.5 µg/h/7 d or vehicle via a cannula attached to a osmotic mini pump. Real time reverse transcriptase-polymerase chain reaction was performed with specific primers against the TRPA1 sequence, and the data were normalized to the mRNA levels found in the contralateral ganglion for each rat per group. **B**, The exposure of TG neurons to NGF (100 ng/ml) time dependently increased mustard oil-evoked currents (iMO) (red line) as compared to vehicle-treated neurons (green line). TG neurons were grown in culture for a total of 72 hours in the presence of NGF (100 ng/ml) or vehicle. Whole-cell patch voltage clamp was performed at 8, 24, 48, and 72 hours of culture. Data are presented as mean ± SEM ($N = 8-16$, *** $p < 0.001$ for time 0 hours versus 8, 24, 48, 72 hours within each treatment group, and ** $p < 0.01$ NGF⁻ versus NGF⁺ for each time point; two-way analysis of variance with Bonferroni's post hoc test). Reproduced with permission from Diogenes A et al.⁷⁷

an ascending ramp of voltage across pulpal tissue leading to activation of the channels and the brief sensation of pain. There are several subtypes of sodium channels, and although most are involved in the transmission of non-noxious sensory information via action potential initiation and propagation, a few of these channels may be nociceptor specific and therefore are more favorable therapeutic targets for drug development (for reviews see refs 80–82). The first evidence in support of the hypothesis of nociceptor-specific (or “nociceptor enriched”) expression of certain VGSCs was a result of the observation that sodium currents in nociceptors have the distinct physical property of resistance to tetrodotoxin (TTX) and that sodium currents in A β sized neurons were TTX-sensitive; importantly, the TTX-resistant currents were increased following exposure to inflammatory mediators.^{83–85}

Molecular cloning led to the identification of the Nav1.8 and Nav1.9 sodium channels subtypes as mediating the TTX-resistant current.^{86,87} Further studies demonstrate that the Nav1.8 channel mediates the majority of the TTX-resistant current and that this channel plays a key role in the generation and maintenance of inflammatory pain. It was demonstrated that inflammatory mediators, including prostaglandins, alter the kinetics of the channels activity resulting in increased neural depolarization or firing.^{84,88} Also, the channel itself is expressed at higher levels under conditions of inflammation.^{89–91} Finally, using animal studies evaluating pain behaviors, the knock-down or elimination of the Nav1.8 channel has been demonstrated to attenuate inflammatory pain in most,^{79,92–95} but not all,⁷⁹ studies. Other sodium channels, that potentially play a role in mediating inflammatory pain, are Nav1.7 and Nav1.9.^{81,96,97}

These changes under inflammatory conditions possibly account for the clinical observation that teeth with irreversible pulpitis are more difficult to anesthetize. Pre-treatment with ibuprofen inhibits the increased sodium channel production observed after inflammation in animal studies.⁸⁹ This is likely related to clinical trials indicating that local anesthesia in irreversible pulpitis patients may be improved by premedication with ibuprofen.^{98,99} Therefore, for patients who can tolerate NSAIDs, it is possible that the preoperative administration of fast-acting NSAIDs to patients experiencing acute symptoms will provide improved local anesthetic efficacy.

Recently, several lines of evidence have led to the observation that some members of the transient receptor potential (TRP) family of ion channels are able to respond to temperature changes and are important for the development of inflammatory pain.¹⁰⁰ The most

well-studied channel to date is the TRPV1 channel that is activated by noxious heat (>43°C) as well as capsaicin, the pungent ingredient of chili peppers that produces a burning sensation when administered to human volunteers.¹⁰¹ Inflammatory mediators such as PGE2 and bradykinin (BK) can sensitize the TRPV1 channel, and mice that have been genetically altered so as to not express the TRPV1 channel exhibit less thermal hyperalgesia/allodynia after inflammatory injury.^{25,102,103} Other TRP receptors such as TRPV2, TRPM8, and TRPA1 have been identified which have different temperature activation thresholds and chemical activators.¹⁰⁴ Given the exquisite temperature sensitivity present in many irreversible pulpitis patients, it is likely that certain TRP receptors at least partially mediate pain of pulpal origin. Several studies have demonstrated the presence of TRP receptors in the dental pulp, but the role of these receptors has yet to be clearly defined and is an important area for future research.^{105,106} Several TRP antagonists have been developed and are now being evaluated as a potential novel class of analgesic drugs.¹⁰⁷

Central Mechanisms

In addition to the neuronal changes that occur in peripheral nociceptors during inflammation, changes can occur in the central projection neurons that can cause expansion of the receptive field, an increased spontaneous firing (i.e., contributing to spontaneous pain), increased response to noxious stimuli (i.e., contributing to hyperalgesia), and a lowered threshold for nociceptor activation (i.e., contributing to allodynia). This increase in excitation of the central neuron is initiated by input from peripheral nociceptors, but once established becomes less dependent on peripheral input for its maintenance.

Central sensitization is the increased excitability of central neurons and is a major mechanism of hyperalgesia and allodynia.^{19,108,109} The sensitization of a central neuron is initiated by a barrage of input from C fibers. When the C-fiber input is of sufficient intensity and duration (e.g., that which occurs in symptomatic pulpitis), neuronal changes occur in the central projection neurons whereby they exist in an excited state. The C fibers release neurotransmitters including glutamate and SP that act on post-synaptic NMDA and AMPA receptors or NK1 receptors, respectively. A signal transduction cascade is initiated in the central neuron involving numerous cellular signals of which nitric oxide and protein kinase C are particularly important.^{110–112} Central sensitization can also affect low-threshold A β fibers. These changes cause an

Figure 7 Three alternative hypotheses to explain the presence of mechanical allodynia in patients with irreversible pulpitis. **A**, Pulpal mechanoreceptive nociceptors. Diagrammatic representation of mechanical allodynia due to activation of pulpal mechanoreceptive neurons. Carious lesion allows bacteria and bacterial byproducts access to pulp tissue. Inflammation develops causing activation of pulpal mechanoreceptors by bacterial byproducts and inflammatory mediators and subsequent mechanical allodynia. **B**, Periradicular mechanoreceptive nociceptors. Diagrammatic representation of mechanical allodynia due to activation of periradicular mechanoreceptive neurons. Inflammatory mediators and bacterial byproducts from dental pulp diffuse apically into periradicular tissues causing inflammation, activation of periradicular mechanoreceptors, and subsequent mechanical allodynia. **C**, Central sensitization. Diagrammatic representation of mechanical allodynia due to central sensitization. Bacterial byproducts and inflammatory mediators activate nociceptors on pulpal nociceptive neurons. This afferent barrage causes central sensitization in the medullary dorsal horn leading to rapid expansion of the receptive fields leading to the development of mechanical allodynia at distant sites. Reproduced with permission from Owatz C et al.¹²⁸

amplification of noxious and non-noxious input to the central neuron.

The process of central sensitization plays a significant role in the pain experienced by patients who are experiencing symptomatic irreversible pulpitis. We know from animal studies that central sensitization occurs in the nucleus caudalis after induction of inflammation in the dental pulp.^{66,113} Clinically, central sensitization plays a role in the maintenance of pain after seemingly successful endodontic treatment. Central sensitization is also an important mechanism of referred pain and certain chronic pain conditions.

A recent series of studies has evaluated mechanical allodynia in odontogenic pain patients. Mechanical

allodynia is defined as a reduction in pain thresholds where innocuous mechanical stimuli are now capable of causing pain. In the first study, approximately 1,000 patients were surveyed for pain reports prior to dental procedures, and 57% of patients diagnosed with irreversible pulpitis reported mechanical allodynia in response to a percussion test.¹¹⁴ As shown in Figure 7, mechanical allodynia that is due to irreversible pulpitis might be due to activation of pulpal mechanonociceptive neurons and application of periapical mechanonociceptive neurons or due to central sensitization. In follow-up studies, a digital bite force device was constructed that permitted quantitative measurement of mechanical pain thresholds.¹¹⁵ Using this device,

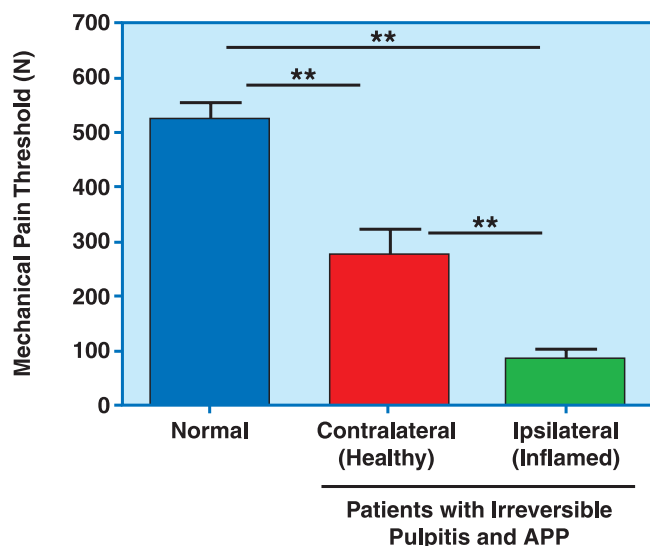

Figure 8 Mechanical pain thresholds of the first molars of subjects with no odontogenic or orofacial pain ($n = 40$) as compared with that of subjects with a clinical diagnosis of irreversible pulpitis and acute periradicular periodontitis ($n = 30$). Data were analyzed by using one-way analysis of variance and Newman–Keuls multiple comparison test. $**p < 0.001$. Reproduced with permission from Khan AA, et al.¹¹⁶

patients with irreversible pulpitis were found to have a 77% reduction in mechanical pain thresholds compared to their contralateral teeth (Figure 8).¹¹⁶ These findings are consistent with the hypothesis that central sensitization occurs in patients with irreversible pulpitis as the contralateral teeth, which had no detectable pathosis, exhibited mechanical pain thresholds that were reduced by 50% as compared to healthy control patients without any intraoral pathosis.

Transcription-Dependent Changes

When peripheral neurons are exposed to inflammatory mediators, they become sensitized which leads to an increase in peripheral input to the central projection neuron. This input initiates and sustains central sensitization. These processes also cause transcription-dependent changes, in other words a change in the expression pattern of proteins (such as peptidergic neurotransmitters and receptors) in the affected neurons, fundamentally altering their function for extended periods. An example of transcription-dependent changes is the increased expression of the sodium channel Nav1.8 and peptidergic neurotransmitters such as CGRP and SP under conditions of inflammation. Transcription-dependent changes can occur in the peripheral

nociceptor (increased Nav1.8 and TRPV1 expression) as well as in the central projection neuron (i.e., induction of the SP receptor NK1 and COX-2).^{117,118} Growth factors such as NGF and Brain-derived neurotrophic factor (BDNF) play an important role in this. Byers and Taylor¹¹⁹ elegantly demonstrated the upregulation of CGRP expression in sprouting fibers in the dental pulp after inducing inflammation by preparing a cavity into the cervical dentin.

Dentinal Hypersensitivity

The sensitivity of dentin is attributed to the mechanical activation of A fibers by various stimuli that cause the movement of fluid in the dentinal tubules. The hydrodynamic theory of activation of pulpal nociceptors is well described.^{20,35,120} The pulp is usually protected from these types of stimuli by intact enamel and cementum. However, in the presence of caries, leaking restorations, or enamel and/or cementum abrasion or absence, dentinal tubules can become exposed. When patent dentinal tubules are exposed, the A fibers either innervating the dentinal tubules or located in the pulp adjacent to the tubules can be activated by stimuli such as air blast from an air/water syringe, scratching the dentin with an explorer tip, rapid cooling, or the presence of a hypertonic solution (usually sweets). Numerous studies have demonstrated that these stimuli cause a transient, sharp pain in human subjects and that similar stimuli applied to the teeth in animal studies causes activation of A fibers.^{20,35,43} It is also clear that the patency of the dentinal tubules is critical to activate A fibers by hydrodynamic stimuli, as removal of the smear layer is critical for eliciting the response, and occlusion of the dentinal tubules with resin can prevent the activation of A fibers by hydrodynamic stimuli.^{121,122}

Although dentin sensitivity is usually not an issue in intact teeth, it is possible to activate neurons with a high intensity stimulus such as that occurs during vital pulp testing with ethyl chloride spray to evaluate a response to cold. This scenario represents normal dentinal sensitivity. On the other hand, dentinal hypersensitivity describes the clinical situation where the dentin is more sensitive than normal. Pain is commonly evoked in these patients by cold stimuli as well as mechanical (i.e., probing with explorer tip) and hypertonic stimuli (i.e., sweets).^{123–125} There is evidence that A fibers can be sensitized to

hydrodynamic stimuli in the presence of inflammatory mediators.²⁰ This indicates first that pulpal inflammation can contribute to the symptoms of dentinal hypersensitivity and second that there is some evidence for the blurring of diagnostic categories of reversible and irreversible pulpitis and dentinal hypersensitivity. It is up to the astute clinician to consider all of the contributing factors and come up with an appropriate diagnosis. Typically, the symptoms of dentinal hypersensitivity are reversible, even when presenting with concomitant symptoms of pulpal inflammation. There is evidence supporting the use of toothpaste, gels, or mouthwash containing potassium salts for the treatment dentinal hypersensitivity.¹²⁶ There is also evidence that the application of resins to exposed dentinal tubules^{121,127} can effectively treat dentinal hypersensitivity.

To date, the majority of studies support the hypothesis that hydrodynamic stimuli activate neurons located in or near dentinal tubules. However, it has also been hypothesized that odontoblasts, in addition to their function in dentinogenesis, could function as a sensory receptor cell. Histological studies have failed to demonstrate anatomic evidence of synapse or gap-junction type connections forming between odontoblasts and neurons.^{128,129} However, electrophysiological evidence has demonstrated that odontoblasts have membrane potentials similar to those found in excitable cells.¹³⁰ A recent study demonstrated that odontoblasts contain the same subtypes of sodium channels as found in neural tissues and that under in vitro conditions these cells can be depolarized and generate action potentials.⁵⁶ This study also demonstrated a clustering of these receptors in regions of apparent odontoblast to neuron contact. In addition, another recent study suggests the presence of the TRPV1 receptor in odontoblasts, giving further evidence that this cell is potentially functioning in a sensory capacity.⁵⁷

In summary, there is a good deal of evidence in support of the theory that dentinal sensitivity and hypersensitivity is due to the detection of movement of fluid in dentinal tubules. The question remains whether the detection occurs by direct activation of pulpal nociceptors or whether the nociceptors are indirectly activated by odontoblasts that may be functioning as the primary or secondary sensory cell in the dentin. Also, if pulpal nociceptors are directly activated by movement of fluid in the dentinal tubules, what is the molecular receptor mediating the mechanical activation of these neurons?

Conclusions

Research conducted in the last two decades has led to a dramatically increased understanding of orofacial pain mechanisms. Our knowledge of the biological basis of pain offers, for the first time, new opportunities to develop and evaluate analgesics designed to improve our ability to care for our patients. This conceptual framework, when combined with subsequent chapters on clinical pharmacology, provides a strong basis for improved diagnosis and treatment of odontogenic pain conditions.

CHAPTER 11

NON-ODONTOGENIC TOOTHACHE AND CHRONIC HEAD AND NECK PAIN

BERNADETTE JAEGER, MARCELA ROMERO REYES

Pain is perfect misery, the worst of evils; and excessive, overturns all patience.

—John Milton, *Paradise Lost*

Patients with chronic oral or facial pain, or headache, present a true diagnostic and therapeutic challenge to the practitioner. For many in the dental profession, the only solution to problems of pain lies with a scalpel, forceps, or ever-increasing doses of analgesics, narcotics, or sedatives. Many patients with chronic pain have suffered this mistreatment and stand as an indictment of a poorly trained, insecure, and disinterested segment of dentistry. Attending to patients who have been unable to obtain resolution of their pain complaint, despite extensive evaluation and treatment, requires a compassionate reappraisal and fresh approach. Fortunately, accurate diagnosis and successful management of these patients can be among the most rewarding experiences in dental or medical practice.

What Is Pain?

Pain is not a simple sensation but rather a complex neurobehavioral event involving at least two components. First is an individual's discernment or perception of the stimulation of specialized nerve endings designed to transmit information concerning potential or actual tissue damage (nociception). Second is the individual's reaction to this perceived sensation (pain behavior). This is any behavior, physical or emotional, that follows pain perception. Culture or environment often influences these behaviors. Beyond this is the suffering or emotional toll the pain has on

any given individual. Suffering is so personal that it is difficult to quantify, evaluate, and treat.

The fact that pain is difficult to define, quantify, and understand is reflected in the numerous ways in which it has been described. *Dorland's Medical Dictionary* defines pain as "a more or less localized sensation of discomfort, distress, or agony resulting from the stimulation of specialized nerve endings."¹ In this definition, the behavioral reaction to nociception is already assumed to be distress or agony, which is not always the case. Take, for example, the observations made by Beecher in 1956 that only 25% of soldiers wounded in battle requested narcotic medications for pain relief, compared to more than 80% of civilian patients with surgical wounds of a similar magnitude.² Clearly, the behavioral reaction to similar nociceptive stimuli varies from person to person and depends on a number of factors, including the significance of the injury to that individual. The wounded soldier may be relieved to be out of a life-threatening situation; the surgical patient may be concerned about recurrence of a tumor just removed. *Dorland's* definition also implies that stimulation of nociceptors is required for perception of pain, yet the dental patient who has been anxious for weeks in anticipation of the "needle" at the dentist's office may jump in agony at the slightest touch of his cheek.

Fields³ defined pain as "an unpleasant sensation that is perceived as arising from a specific region of the body and is commonly produced by processes that damage or are capable of damaging bodily tissue." He emphasized the need to be able to localize the painful source in order to distinguish it from psychological pain and suffering, for example, the "pain" of a broken heart.

A more complete definition is cast by the *International Association for the Study of Pain (IASP)* in its taxonomy of painful disorders.⁴ That definition of pain is as follows: “An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” Added to this definition, however, is the following, emphasizing the subjective nature of pain that distinguishes and separates it from the simple stimulation of nociceptors:

Pain is always subjective. Each individual learns the application of the word through experiences related to injury in early life. It is unquestionably a sensation in a part of the body, but it is also always unpleasant and therefore also an emotional experience. Many people report pain in the absence of tissue damage or any likely pathophysiological cause, usually this happens for psychological reasons. There is no way to distinguish their experience from that due to tissue damage, if we take the subjective report. If they regard their experience as pain and if they report it in the same ways as pain caused by tissue damage, it should be accepted as pain. This definition avoids tying pain to a stimulus. The activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not pain, which is always a psychological state, even though we may well appreciate that pain most often has a proximate physical cause.⁴

The IASP definition of pain makes the point that *pain is pain even if a nociceptive source is not readily identified*. Pain owing to psychological causes is as real as any pain associated with actual nociception and should be treated as such.

To understand pain better, this chapter first looks at what is currently known about the anatomy and physiology of the nociceptive pathways and some of the modulating influences that modify the nociceptive input into the central nervous system (CNS). Following this, various psychological and behavioral factors that influence the perception of, and the reaction to pain, are reviewed.

Neurophysiology of Pain

The following summarizes what is known about the basic anatomy and physiology of pain under normal physiological conditions.⁵

ACUTE PAIN PATHWAYS

The body has specialized neurons that respond only to noxious or potentially noxious stimulation. These neurons are called primary afferent nociceptors and are very complex in structure. They express several types of receptors such as ion channels and G protein-coupled receptors that are implicated in inflammation and pain activation signaling^{6,7} and are made up of

Figure 1 Components of a typical cutaneous nerve. **A**, It illustrates that there are two distinct functional categories of axon: primary afferents with cell bodies in the dorsal root ganglion and sympathetic postganglionic fibers with cell bodies in the sympathetic ganglion. Primary afferents include those with large-diameter myelinated ($A\alpha$), small-diameter myelinated ($A\delta$), and unmyelinated (C) axons. All sympathetic postganglionic fibers are unmyelinated. **B**, Electron micrograph of cross section of a cutaneous nerve illustrating the relative size and degree of myelination of its complement of axons. The myelin appears as black rings of varying thickness. The unmyelinated axons (C) occur singly or in clusters. Reproduced with permission from Ochoa JL [and Dyck PJ et al. (eds)] First edn. WB Saunders: 1975.

small-diameter thinly myelinated $A\delta$ and unmyelinated C fibers (Figure 1). Other types of nociceptors are known as “silent” and respond only to tissue injury.⁸ These primary sensory neurons synapse in the substantia gelatinosa of the dorsal horn of the spinal cord with neurons known as second-order pain transmission neurons. From here the signals are transmitted along specialized pathways (spinothalamic and reticulothalamic tracts) to the medial and lateral regions of the thalamus and then to the brain (Figure 2).

Fields³ divided the processing of pain from the stimulation of primary afferent nociceptors to the subjective experience of pain into four steps: transduction, transmission, modulation, and perception. *Transduction* is the activation of the primary afferent nociceptor. Primary afferent nociceptors can be activated by intense thermal, mechanical stimuli, noxious chemicals, and immunological stimuli.⁹ Stimulation from endogenous inflammatory mediators is produced in response to tissue injury, immune effectors,

Figure 2 A diagrammatic outline of major neural structures relevant to pain. Sequence of events leading to pain perception begins in the transmission system with transduction (lower left), in which a noxious stimulus produces nerve impulses in the primary afferent nociceptor. These impulses are conducted to the spinal cord, where primary afferent nociceptors contact central pain transmission cells that relay the message to the thalamus either directly via the spinothalamic tract or indirectly via the reticular formation and the reticulothalamic pathway. From the thalamus, the message is relayed to the cerebral cortex and the hypothalamus (H). The outflow is through the midbrain and the medulla to the dorsal horn of the spinal cord, where it inhibits pain transmission cells, thereby reducing the intensity of perceived pain. Reproduced with permission from National Academy of Sciences; 1987.

and glia,^{10,11} producing an “inflammatory soup” and plasma extravasation (Figure 3). These mediators are bradykinin, neuropeptides such as the potent vasodilator calcitonin gene-related peptide (CGRP), and substance P, growth factors, cytokines, chemokines, amines, purines, protons, ions, and arachidonic acid.^{12,13} These inflammatory mediators interact with the multiple receptors expressed in the nociceptive afferences inducing their excitation.

Arachidonic acid is processed by two different enzyme systems to produce *prostaglandins* and *leukotrienes*, which, along with bradykinin, act as inflammatory mediators (see Figure 3). Whereas prostaglandins stimulate the primary afferent nociceptor directly, the leukotrienes contribute indirectly by causing *polymorphonuclear neutrophil leukocytes* to release another chemical that, in turn, stimulates the nociceptor. Bradykinin further contributes by causing the *sympathetic nerve terminal* to release a prostaglandin that also stimulates the nociceptor.¹⁴ Additionally, in an area of injury or inflammation, the *sympathetic nerve terminal* will release yet another prostaglandin in response to its own neurotransmitter, *norepinephrine*. The presence of

such an ongoing inflammatory state causes physiological sensitization of the primary afferent nociceptors.¹⁴ Sensitized nociceptors display ongoing discharge, a lowered activation threshold to *normally nonpainful stimuli* (*allodynia*), and an *exaggerated response* to noxious stimuli (*primary hyperalgesia*).¹⁵

In addition to sending nociceptive impulses to synapse in the dorsal horn of the spinal cord or, in the case of trigeminal input, to synapse in the trigeminal nucleus, activation of cutaneous C fibers causes their cell bodies to synthesize the neuropeptides, *substance P* and *CGRP*. These neuropeptides are then antidromically transported along axon branches to the periphery by an axon transport system where they induce further plasma extravasation and increase inflammation. The release of these algogenic substances at the peripheral axon injury site produces the flare commonly seen around an injury site and is referred to as *neurogenic inflammation*,^{7,16–18} or the *axon reflex*^{15,19,20} (Figure 4). *Transmission* refers to the process by which peripheral nociceptive information is relayed to the CNS. The primary afferent nociceptor synapses with a second-order pain transmission

Figure 3 Membrane lipids produce arachidonic acid, which is converted to prostaglandins by the cyclooxygenase enzyme and to leukotriene B4 by the lipoxygenase enzyme. Prostaglandins act directly on the primary afferent nociceptor to lower the firing threshold and therefore cause "sensitization." Leukotriene B4 causes polymorphonuclear neutrophil leukocytes to produce another leukotriene that, in turn, acts on the primary afferent nociceptor to cause sensitization. Steroids prevent the synthesis of arachidonic acid altogether, thus inhibiting both pathways of prostaglandin production. Nonsteroidal anti-inflammatory drugs (NSAIDs), on the other hand, inhibit only the cyclooxygenase pathway.

Figure 4 The axon reflex. Activation of cutaneous nociceptive C fibers elicits impulses that are conveyed centrally to induce pain and antidromically via axon branches (A). The antidromically excited peripheral C-fiber terminals release vasoactive substances, for example, calcitonin gene-related peptide (CGRP) and substance P (SP), causing cutaneous vasodilation, which produces the flare that develops around the site of noxious stimulation. Reproduced with permission from Field HL et al. *Neurobiol Dis*; 1998.

Figure 5 Central sensitization and allodynia. Input from C-nociceptors enhances the response of dorsal horn pain-signaling neurons to subsequent afferent inputs (central sensitization). This involves neuropeptides such as substance P (SP) acting at neurokinin receptors (NKr) and excitatory amino acids (EAA) acting at both the AMPA/KA and *N*-methyl-*D*-aspartate (NMDA) receptors, triggering secondary nitric oxide (NO) mechanisms. Large-diameter low-threshold mechanoreceptive primary afferents (A fibers) respond maximally to innocuous tactile stimuli and normally produce tactile sensation. When central sensitization is present, A fibers become capable of activating central nervous system (CNS) pain-signaling neurons (+), leading to touch-evoked pain (allodynia). Modified from Fields HL et al. *Neurobiol Dis*, 1998.

neuron in the dorsal horn of the spinal cord where a new action potential heads toward higher brain structures (see Figures 2 and 3). It is at this point that repeated or intense C fiber activation facilitates and increases responsiveness in the second-order pain transmission neuron, enhancing synaptic transmission and depressing inhibition in the dorsal horn.²¹ This process further induces physiological, neurochemical, anatomical, and genetic changes.^{22,17} Excitatory amino acids such as glutamate stimulate the activation of the *N*-methyl-*D*-aspartate receptor (NMDAr), which is a major component of inflammatory and chronic neuropathic pain^{21,23,24} resulting in *central sensitization*.¹⁵ Long-term changes in the response of second-order pain transmission neurons to nonpainful and painful input are induced with intense or prolonged nociceptive stimuli.¹⁵ The response of these spinal cord dorsal horn neurons increases progressively and is enhanced with repeated

identical noxious cutaneous input from the periphery, a process called “wind-up.”^{25–27} In addition, the size of the receptive field of the second-order pain transmission neuron increases.²⁸ The subjective correlate of wind-up is “temporal summation,” for which a slowly repeated noxious stimulus is associated with a progressive increase in the intensity of perceived pain.^{15,29} In addition, with central sensitization, stimulation of Aβ fibers (large-diameter low-threshold mechanoreceptors that normally respond only to painless tactile stimuli) will also establish connections with second-order nociceptive dorsal horn neurons, producing what is called a “secondary mechanical hyperalgesia”^{15,30,31} (Figure 5). These plastic changes result in nonpainful stimuli causing pain. This can be observed in the hypersensitivity and allodynia present during a migraine headache or in the diffuse referred and aching pain in myofascial pain (MFP) disorders,^{22,32} as well as in the ongoing persistent aching

burning pain present in centralized trigeminal neuropathies such as atypical odontalgia.³³

Modulation refers to mechanisms by which the transmission of noxious information to the brain is reduced. Numerous *descending inhibitory* systems that originate supraspinally and strongly influence spinal nociceptive transmission exist.³⁴ In the past, only midline structures such as the periaqueductal gray, rostroventral medulla, and nucleus raphe magnus were known to be involved in descending nociceptive modulation (see Figure 2). Now many sites previously thought to be primarily involved in cardiovascular function and autonomic regulation (e.g., nucleus tractus solitarius; locus ceruleus/subceruleus, among others) have also been shown to play a role in pain modulation.³⁴ The ascending nociceptive signal that synapses in the midbrain area activates the release of norepinephrine and *serotonin*, two of the main neurotransmitters involved in the descending inhibitory pathways.^{34,35} Activity in the pain modulation system means that there is less activity in the pain transmission pathway in response to noxious stimulation.

An endogenous opioid system for pain modulation also exists.³⁶ *Endogenous opioid peptides* are naturally occurring pain-dampening neurotransmitters and neuromodulators that are *implicated in pain suppression* and modulation because they are present in large quantities in the areas of the brain associated with these activities (subnucleus caudalis and the substantia gelatinosa of the spinal cord).^{36–38} They reduce nociceptive transmission by preventing the release of the excitatory neurotransmitter substance P from the primary afferent nerve terminal. The presence of these natural opioid receptors for endogenous opiates permits morphine-like drugs to exert their analgesic effect. However, evidence suggests that exogenous opioids, when used extensively, can paradoxically induce hyperalgesia.³⁹

The final step in the subjective experience of pain is *perception*. How and where the brain perceives pain is still under investigation. Part of the difficulty lies in the fact that the pain experience has at least two components: the sensory-discriminatory dimension and the affective (emotional) dimension. The affective dimension of pain is made up of feelings of expectations, unpleasantness, and emotions associated with future implications related to the pain.^{40,41}

Neuroimaging studies have demonstrated the involvement of the thalamus and multiple cortical

areas (including the primary and secondary somatosensory cortices (S1,S2), the insular cortex (IC), the prefrontal cortex (PFC), and the anterior cingulate cortex (ACC)⁴² in the perception of pain. However, it is clear from intersubject variability in the activation of any one of these areas that affective reactions and possibly motor responses are also involved.⁴³

Of significance is the fact that, with high levels of modulation or with damage in the pain transmission system, it is possible to have nociception without pain perception. Conversely, with certain types of damage to the nervous system, there may be an overreaction to pain stimuli or pain perception without nociception.³

REFERRED PAIN

Pain arising from deep tissues, muscles, ligaments, joints, and viscera is often perceived at a site distant from the actual nociceptive source. Thus, the pain of angina pectoris is often felt in the left arm or the jaw, and diaphragmatic pain is often perceived in the shoulder or the neck. Whereas cutaneous pain is sharp, burning, and clearly localized, referred pain from musculoskeletal and visceral sources is usually deep, dull, aching, and more diffuse.

Referred pain presents a diagnostic dilemma. If left unrecognized, it may result in a clinician telling a patient that his pain is psychogenic in origin. Treatments directed at the site of the pain are ineffective and, if invasive, subject the patient to unnecessary risks, expense, and complications. However, referred pain is dependent on a primary pain source and will cease if this source is eliminated.

The mechanism of referred pain is still somewhat enigmatic. The two most popular theories are convergence-projection and convergence-facilitation.

1. *Convergence-projection theory*. This is the most popular theory. Primary afferent nociceptors from both visceral and cutaneous neurons often converge onto the same second-order pain transmission neuron in the spinal cord,⁴⁴ and convergence has been well documented in the trigeminal brainstem nuclear complex.^{23,45–47} The trigeminal spinal tract nucleus also receives converging input from cranial nerves VII, IX, and X, as well as the upper cervical nerves.^{48,49} The brain, having more awareness of cutaneous than of visceral structures through past experience, interprets

Figure 6 The convergence-projection hypothesis of referred pain. According to this hypothesis, visceral afferent nociceptors (S) converge on the same pain-projection neurons as the afferents from the somatic structures in which the pain is perceived. The brain has no way of knowing the actual source and mistakenly “projects” the sensation to the somatic structure. Reproduced with permission from Fields HL, McGraw-Hill; 1987.

the pain as coming from the regions subserved by the cutaneous afferent fibers (Figure 6).

2. *Convergence-facilitation theory.* This theory is similar to the convergence-projection theory, except that the nociceptive input from the deeper structures causes the resting activity of the second-order pain transmission neuron in the spinal cord to increase or be “facilitated.” The resting activity is normally created by impulses from the cutaneous afferents. “Facilitation” from the deeper nociceptive impulses causes the pain to be perceived in the area that creates the normal, resting background activity. This theory tries to incorporate the clinical observation that blocking sensory input from the reference area, with either a

local anesthetic or cold, can sometimes reduce the perceived pain. This is particularly true with referred pain from *myofascial trigger points (TrPs)*, for which application of a vapocoolant spray is actually a popular and effective modality used for pain control.

The mechanism of referred pain from myofascial TrPs is also under speculation. According to Mense,⁵⁰ the convergence-projection and convergence-facilitation models of referred pain do not directly apply to muscle pain because there is little convergence of neurons from *deep* tissues in the dorsal horn. Based on experimentally induced changes in the receptive field properties of dorsal horn neurons in the cat in response to a deep noxious stimulus,⁵¹ Mense proposed that convergent connections from other spinal cord segments are “unmasked” or opened by the nociceptive input from skeletal muscles and that referral to other myotomes is owing to the release and spread of substance P and CGRP to adjacent spinal segments.⁵⁰ Simons has expanded on this theory to specifically explain the referred pain from TrPs⁵² (Figure 7). MFP is discussed in more detail later in the chapter.

TRIGEMINAL SYSTEM

An appreciation of the arrangement of the trigeminal nociceptive system provides some insight into the interesting pain and referral patterns that are encountered in the head and neck region. The primary afferent nociceptors of the fifth cranial nerve synapse is the nucleus caudalis of the brainstem.⁵³ The nucleus caudalis is the caudal portion of the trigeminal spinal tract nucleus and corresponds to

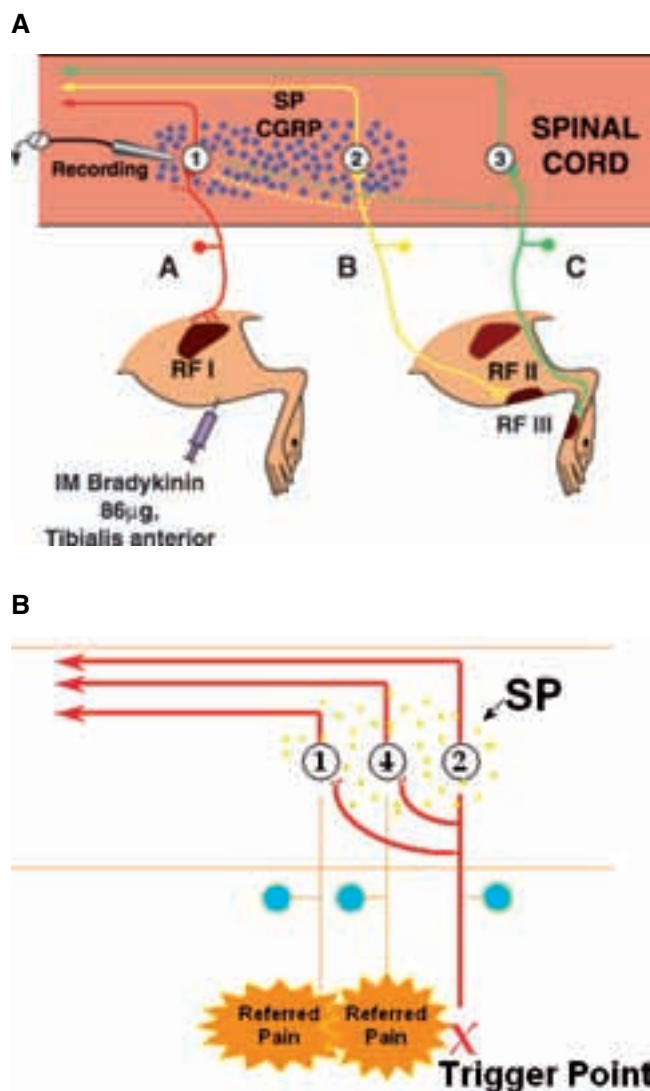

Figure 7 A, Neuroanatomic model explaining the appearance of new receptive fields (RF's) (see Figure 7A) by unmasking latent connections in the dorsal horn. The activity of neuron 1 was recorded with a microelectrode introduced into the spinal cord. The neuron is connected by pathway A to its original RF in the biceps femoris muscle (RF I). Synaptically effective connections are drawn as solid lines, ineffective (latent) connections as dashed lines. The injection of bradykinin was made outside RF I into the tibialis anterior (TA) muscle, which contains the RF of neuron 2 (RF II). The Bradykinin-induced excitation of nociceptive fibers of pathway B is assumed to release substance P (SP) and calcitonin gene-related peptide (CGRP) in the dorsal horn, which diffuse (stippling) to neuron 1 and increase the efficacy of latent connections from pathways B and C to this cell. Now neuron 1 can be activated also from RF II and RF III. **B**, Extension of the neuroanatomic model presented of Mense's model of deep referred pain. Although no direct experimental evidence substantiates this modification, it is compatible with the mechanisms described by Mense and helps to explain some trigger point characteristics not accounted for by his model. Neurons 1 and 2 correspond to neurons 1 and 2 in the Mense model. Neurons 1 and 4 are connected by solid lines to their respective receptive fields. These fields are the areas that would be identified as the source of nociception when neurons 1 and 4 are activated. Nociceptive input from the trigger point would activate neuron 2 and could account for the initial localized pain in response to pressure applied to the trigger point. This activity is assumed to release substance P (SP) and calcitonin gene-related peptide (CGRP) in the dorsal horn that diffuses (stippling) to neurons 1 and 4. This increases the efficacy of latent connections (dashed lines) to these cells. Now neurons 1 and 4 can be activated by nociceptive activity originating in the trigger point and would be perceived as referred pain. **A**, reproduced with permission from Menses S, *Am Pain Soc J*; 1994; **B**, reproduced with permission from Simons DG, *Am Pain Soc J*; 1994.

the substantia gelatinosa of the rest of the spinal dorsal horn (Figure 8). From here the nociceptive input is transmitted to the higher centers via the

trigeminal lemniscus. Of significance is the arrangement of the trigeminal nerve fibers within this nucleus and the fact that the nucleus descends as

Figure 8 Primary afferent nociceptive fibers of the trigeminal nerve (cranial nerve V) synapse in the nucleus caudalis of the spinal trigeminal tract. The nucleus caudalis descends as low as C3–4 in the spinal cord. Many nociceptors from deep cervical structures synapse on the same second-order pain transmission neurons as the trigeminal nerve. This may explain why cervical pain disorders are often perceived as facial pain or headache.

low as the third and fourth cervical vertebrae (C3–4) in the spinal cord. Fibers from all three trigeminal branches are found at all levels of the nucleus, arranged with the mandibular division highest and the ophthalmic division lowest.⁵⁴ In addition, they are arranged in such a manner that fibers closest to the midline of the face synapse in the most cephalad portion of the tract. The more lateral the origin of the fibers on the face, the more caudal the synapse in the nucleus (Figure 9). Understanding this “laminated” arrangement helps to explain why a maxillary molar toothache may be perceived as pain in a mandibular molar on the same side (referred pain) but not in an incisor. Similarly, pain perceived in the ear may actually be owing to (or referred from) an infected third molar.

Because the trigeminal nucleus descends to the C3–4 level in the spinal cord, primary afferent nociceptors from deep cervical structures synapse on the same second-order pain transmission neurons that subserve the fifth cranial nerve.⁵⁵ This convergence

Figure 9 The arrangement of the trigeminal nociceptive fibers of the spinal trigeminal tract is significant. Fibers from all three trigeminal branches are found at all levels of the nucleus, arranged with the mandibular division highest and the ophthalmic division lowest. Fibers closest to the midline of the face synapse in the most cephalad portion of the tract. The more lateral the origin of the fibers on the face, the more caudal the synapse in the nucleus. Modified from Kunc Z, Georg Thieme Verlag, 1970.

of primary afferent nociceptors from the trigeminal region and the cervical region provides a basis for understanding why *cervical pain* disorders may be perceived as pain in the head and face, particularly in the *forehead and temple*—the lateral ophthalmic trigeminal fibers synapse the lowest (see Figure 9).

CHRONIC PAIN

Pain becomes complicated and difficult to manage when it is prolonged. Often the clinician is frustrated by the apparent discrepancy between the identifiable nociceptive source, which may seem very small, and the amount of suffering and disability seen. It becomes easy to label these patients as “crazy” or “malingering” (deliberately, fraudulently feigning an illness for the purpose of a consciously desired outcome).¹ Yet there are both physiological and psychological mechanisms that may increase pain perception—mechanisms that help to explain why there may be a discrepancy between actual nociception, perceived pain, and the apparent resultant suffering and disability.

PHYSIOLOGICAL MECHANISMS MODIFYING PAIN

Sensitization. As previously discussed, primary afferent nociceptors become sensitized through the release of endogenous substances caused by tissue injury. As a result, normally innocuous stimuli become painful¹⁴ For example, acute arthritis of the temporomandibular joint (TMJ) results in pain on joint movement or with increased pressure from chewing, normally innocuous events. Similarly, a minor burn on the tongue from hot tea makes it almost impossible to eat anything, even mildly spicy.

Spreading muscle spasm. Sustained muscle contraction (spasm) may arise as a result of primary noxious stimulus. This is a spinal reflex and a protective response to tissue injury (Figure 10). An example of this would be masticatory elevator muscle spasm (trismus) secondary to an infected third molar. The spasm may actually be the chief complaint, and yet, initially, it is dependent on the primary pain source. However, if the muscle spasm results in ischemia and accumulation of potassium ions, muscle nociceptors may be activated, resulting in the development of an independent, self-perpetuating primary pain source in the muscle (see Figure 10). Successful treatment of the infection or removal of the painful third molar will no longer correct the muscle pain problem since use of the muscle produces pain, causing more spasm, causing more pain. In addition, studies have shown that this type of deep musculoskeletal pain causes spasm

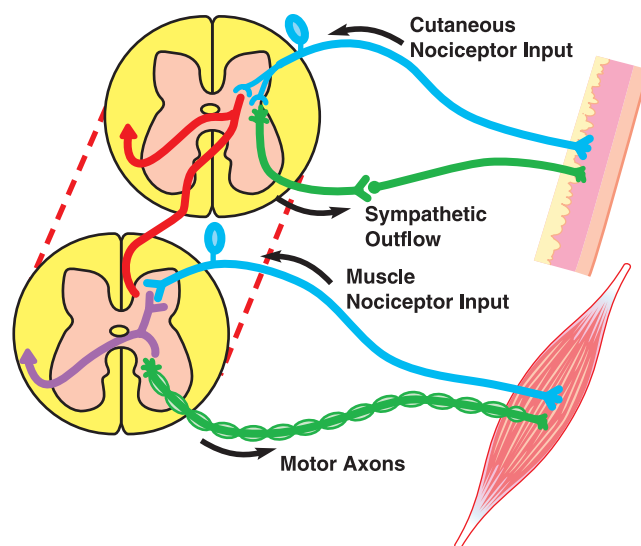

Figure 10 Reflex activation of nociceptors in self-sustaining pain. There are two important reflex pathways for pain. The top loop illustrates the sympathetic component. Nociceptor input activates sympathetic reflexes, which activate or sensitize nociceptor terminals. The bottom loop illustrates the muscle contraction loop. Nociceptors induce muscle contraction, which, in some patients, activates muscle nociceptors that feed back into the same reflex to sustain muscle contraction and pain. Modified from National Acad Sciences, 1987.

and pain in other muscles innervated by the same spinal segment.^{56,57} Long-standing conditions of this sort may result in the recruitment of more muscles and more pain, with the ultimate establishment of a vicious spreading pain cycle. This may partly explain the development and some of the characteristics of myofascial TrPs, to be discussed in detail later in the chapter.

Autonomic factors. Just as primary afferent nociceptive input may activate motoneurons, so may it also activate the sympathetic nervous system (see Figure 10). Efferent discharge from the sympathetic nervous system has been shown, in animals at least, to activate primary afferent nociceptors, especially when injured.⁵⁸ Thus, a peripheral injury may set up a positive feedback loop through activation of the sympathetic nervous system that will perpetuate the activation of the primary afferent nociceptors. The extreme result of this type of sympathetic hyperactivity is a condition known as “reflex sympathetic dystrophy” (RSD) included in the complex regional pain syndromes⁵⁹ (discussed in more detail later in this chapter). In this syndrome, the pain, even from a minor injury, does not subside and, in fact, develops into a progressive, excruciating burning pain with cutaneous hypersensitivity. The pain may occur in a

site larger than and different from that of the original injury; autonomic signs such as vasoconstriction or sweating of the painful area are usually present. The sympathetic nervous system is strongly implicated because sympathetic blockade abolishes the pain. Mild forms of this self-perpetuating loop of sympathetic activity and primary nociceptive response may explain why pain sometimes worsens, even when the injury has healed.

PSYCHOLOGICAL FACTORS MODIFYING PAIN

Psychological and social factors are inextricably linked with the perception of pain and illness.⁶⁰ The traditional dualistic view of mind and body as separate, independently functioning entities is wholly inadequate. As a result of the need for a new approach to illness and pain, the biopsychosocial model for disease and illness was developed. In this model, disease is defined as “definite pathologic process with a characteristic set of signs and symptoms.”⁶¹ Illness refers to the subjective experience of that disease or the belief that disease is present.⁶¹ An explosion of research in chronic pain over the last 10 years has documented the complex interrelationship between genetics, neurophysiology, pain, and emotion.⁶⁰ For example, emotional distress may predispose a person to experience pain, amplify or inhibit the intensity of the pain, perpetuate the pain, or be a result of the pain.⁶⁰ Anxiety and depression have long been studied with respect to their complexly intertwined relationship with chronic pain, but anger also plays an interesting role. These emotional concomitants to chronic pain are important to appreciate because they affect treatment motivation and compliance to treatment recommendations. For successful treatment, clinicians treating patients with pain, acute or chronic, must pay attention to their emotional/psychological states, as well as the somatically identified nociceptive cause.

Cognitive and affective factors. Sensory factors refer to the detection, localization, quantification, and identification of the quality of a particular stimulus. However, the reaction to the stimulus and the intensity of desire to terminate the stimulus are determined by cognitive and affective variables. *Cognitive variables* include such things as an individual’s *past experience* with similar stimuli, their *psychological makeup*, and *societal* and *cultural* factors. *Affective variables* relate to emotions and feelings and determine how unpleasant the stimulus is to the individual. *Affective descriptors* of a sensory experience might include words such as “nagging,” “uncomfortable,” “intense,” or “killing,”

in contrast to sensory features such as “mild burning,” “localized to the palate,” or “aching over the TMJ.”

Affective variables may be accompanied by *anxiety* or *depression* and are influenced by expectation and suggestion. Interestingly, the meaning that a person ascribes to their pain, threatening, benign or irrelevant, and their perception of the control they have over their pain, affects that individual’s affective and behavioral response to the pain. For example, most people are not particularly distressed about having a headache since the vast majority of headaches are not pathological. Yet someone whose sibling recently died of a brain tumor might be much more worried and anxious about this same symptom, even if it is very mild. Similarly, recurrence of pain owing to cancer carries with it the knowledge that the disease may be progressing and may remind the individual of his mortality. This type of pain will have many more emotional components and may be perceived as much more severe.⁶²

Another good example is the anxious dental patient who jumps in agony at the first touch of the cheek. Even though the sensation of touch is well below his experimental pain threshold, the patient perceives it and reacts to it as painful. Conversely, a person experiencing analgesia through hypnosis may perceive no sensations or only nonpainful sensations while undergoing normally painful procedures such as tooth extraction or pulp extirpation.^{63,64}

BEHAVIORAL FACTORS

Suffering and pain are communicated through actions such as moaning, limping, grimacing, guarding, pill taking, or visiting the doctor. These actions are termed *pain behaviors*. Pain behaviors follow basic learning principles and tend to increase unconsciously if they are rewarded by positive consequences. Positive consequences may include attention from loved ones and/or the medical/dental system and avoidance of various aversive tasks and responsibilities. Since chronic pain conditions, by definition, last a long time, they provide an opportunity for unconscious learning to occur. The pain behaviors observed in a patient with chronic pain may be the cumulative result of intermittent *positive reinforcement* over months or years. In addition, *well behaviors* are often totally ignored and nonreinforced, causing them to decrease. Just as positive reinforcement causes an increase in particular behaviors, so will nonreinforcement cause a decrease. Thus, even when the nociceptive source has diminished or healed, pain perception and attendant

disability may be maintained through *learned pain behaviors* along with physical, cognitive, and affective factors.⁶⁵

Pain Assessment Tools

Pain is a subjective experience that is communicated to us only through words and behaviors. Unlike measuring blood pressure, temperature, or erythrocyte sedimentation rate, measuring pain intensity is extremely difficult. As discussed above, there are several physiological and psychological factors that will influence the intensity of pain perceived. Other cognitive, affective, behavioral, and learning factors affect how this pain is communicated.

Nonetheless, measuring pain is important, not just for studying pain mechanisms in a laboratory but also to *assess treatment outcome*. To this end, a number of instruments have been developed and tested for their reliability and validity in measuring different aspects of the pain experience.

Quantifying the Pain Experience

VISUAL ANALOG SCALES

A visual analog scale is a line that represents a continuum of a particular experience, such as pain. The most common form used for pain is a 10-cm line, whether horizontal or vertical, with perpendicular stops at the ends. The ends are anchored by “no pain” and “worst pain imaginable” (Figure 11). Numbers should not be used along the line to ensure a better, less biased distribution of pain ratings. Otherwise, a

disproportionately high frequency of 5 and 10 seconds will be chosen.⁶⁵ Patients are asked to place a slash mark somewhere along the line to indicate the intensity of their current pain complaint. For scoring purposes, a millimeter ruler is used to measure along the line and obtain a numeric score for the pain ratings. Most people understand this scale quickly and can easily rate their pain. Children as young as 5 years are able to use this scale.⁶⁶ Its reliability and validity for measuring pain relief have been demonstrated^{67,68} Caution is advised with photocopying because this process usually lengthens the line and introduces error.

The use of the scale should be clearly explained to the patient. For measuring treatment outcome, relief scales (a line anchored with “no pain relief” and “complete pain relief”) may be superior to asking absolute pain intensities.⁶⁹ Similarly, if a pain intensity visual analog scale was used, patients may be more accurate if they are allowed to see their previous scores.⁷⁰

Numeric rating scales, where “0” is no pain and “10” is the worst pain imaginable, are also very useful and preferred by adults without cognitive impairment.⁷¹ Children and older adults, either minority or cognitively impaired, may do better with colored analog scales or faces pain scales.^{72–74} Colored analog scales use a 0 to 10 scale and verbal markers on a scale that is colored from green to yellow to red depicting increasing levels of pain. Faces pain scales use faces depicting various expressions from smiling to crying along a continuum with verbal descriptors underneath. Studies have shown that pain ratings are lower if the scale starts with a nonsmiling face.⁷⁵

Figure 11 Visual analog pain scale used to indicate patient’s level of daily pain. The patient places a mark at the perceived level of discomfort. The scale is 10 cm, so direct measurement can subsequently be made.

MCGILL PAIN QUESTIONNAIRE

The McGill Pain Questionnaire (Table 1) is a verbal pain scale that uses a vast array of words commonly used to describe a pain experience. Different types of pain and different diseases and disorders have different qualities of pain. These qualitative sensory descriptors are invaluable in providing key clues to possible diagnoses. Similarly, patients use different words to describe the affective component of their pain.

To facilitate the use of these words in a systematic way, Melzack and Torgerson set about categorizing many of these verbal descriptors into classes and subclasses designed to describe these different aspects of the pain experience. In addition to words describing the sensory qualities of pain, affective descriptors including such things as fear and anxiety and evaluative words describing the overall intensity of the pain experience were included.⁷⁶

The words are listed in 20 different categories (see Table 1). They are arranged in order of magnitude from least intense to most intense and are grouped according to distinctly different qualities of pain. The

patients are asked to circle only one word in each category that applies to them. Patients are usually happy to select from this list of pain-describing adjectives, often saying, “Now I can tell exactly how it feels. Before I couldn’t think of just the right words.”

The first 10 categories represent different sensory descriptors covering various temporal, spatial, pressure, and thermal qualities of pain. The next five categories are affective or emotional descriptors, category 16 is evaluative (i.e., how intense is the pain experience), and the last four categories are grouped as miscellaneous.

To score the questionnaire, the words in each category are given a numeric value. The first word in each category ranks as 1, the second as 2, and so on. The scores for each category are added up separately for the sensory, affective, evaluative, and miscellaneous groupings. Then the total number of words chosen is also noted. Using this questionnaire, it is possible to obtain a sense of the quality of a patient’s pain complaint (categories 1 through 10), its intensity (category 16), and the amount of emotional or psychological overlay accompanying the pain (categories 11 through

Table 1 Sample of Classic McGill Pain Questionnaire

Terms Describing Pain				
Sensory				
1	2	3	4	5

Annoying	Spreading	Tight	Cool	Nagging
Troublesome	Radiating	Numb	Cold	Nauseating
Miserable	Penetrating	Drawing	Freezing	Agonizing
Intense	Piercing	Squeezing		Dreadful
Unbearable		Tearing		Torturing

15). Changes in a patient's pain experience can be monitored by administering the questionnaire at various time points during treatment and follow-up.

Melzack used this master list of words to derive quantitative measures of clinical pain that can be treated statistically; if used correctly, it can also detect changes in pain with different treatment modalities.⁷²

PSYCHOLOGICAL ASSESSMENT

Chronic pain is the most complicated pain experience and the most perplexing and frustrating problem in medicine and dentistry today. Because chronic pain syndromes have such a complex network of psychological and somatic interrelationships, it is critical to view the patient as an integrated whole and not as a sum of individual parts. Determining the emotional, behavioral, and environmental factors that perpetuate chronic pain is as essential as establishing the correct physical diagnosis or, in many chronic cases, multiple diagnoses.

Almost all patients with chronic head and neck pain have physical findings contributing to their complaint. Similarly, almost all patients with chronic head and neck pain have psychological components to their pain as well. Contributing to the complex neurobehavioral aspects of pain is the fact that chronic pain is not self-limiting, seems as though it will never resolve, and has little apparent cause or purpose. As such, multiple psychological problems arise that confuse the patient and perpetuate the pain. Patients feel helpless, hopeless, and desperate in their inability to receive relief. They may become hypochondriacal and obsessed about any symptom or sensation they perceive. Vegetative symptoms and overt depression may set in, with sleep and appetite disturbances. Irritability and great mood fluctuations are common. Loss of self-esteem, libido, and interest in life activities add to the patient's misery. All of this may erode personal relationships with family, friends, and health professionals. Patients focus all of their energy on analyzing their pain and believe it to be the cause of all of their problems. They shop from doctor to doctor, desperately searching for an organic cure. They can become belligerent, hostile, and manipulative in seeking care. Many clinicians make gallant attempts with multiple drug regimens or multiple surgeries, but failure frustrates the clinician and adds to the patient's ongoing depression.

Near the end of this progression, in addition to their continuing pain, many of these patients have multiple drug dependencies and addictions or high stress levels; they may have lost their jobs, be on permanent disability, or be involved in litigation.

Herein lies the importance of proper *psychological diagnosis* as well as accurate physical diagnosis. An appropriate evaluation should include consideration of all factors that reinforce and perpetuate the pain complaints. Examining factors contributing to pain aggravation can include a look at stress (current and cumulative), interpersonal relationships, any secondary gain the patient may be receiving for having the pain, perceptual distortion of the pain, and poor lifestyle habits such as inadequate diet, poor posture, and lack of exercise. This information may well point to the reasons why patients have been unsuccessfully treated in the past. Obtaining baseline measures of pain levels, drug intake, functional impairment, and emotional state is important and will help monitor a patient's progress through rehabilitation. Additionally, systematic assessment of psychosocial difficulties that interfere with work and interpersonal activities is important but often neglected. The dentist should include questions to elicit information about oral habits, depression, anxiety, stressful life events, lifestyle changes, and secondary gain (operant pain) in the clinical interview.

To decide whether a patient should be referred for a full psychological assessment, the clinician evaluating the patient with chronic pain may choose to use simple questionnaires that are easy to administer, do not take long to fill out, and are reliable and adequate psychological screening tools. The Brief Battery for Health Improvement (BBHI-2) is a basic screening device that has been normed with a range of pain/orofacial pain/TMD patients.^{77,78} It is short and gives three main dimensions of pain that practitioners should screen for: (1) mood (with suicide ideation); (2) functional limitations; and (3) somatization. A brief tutorial on the use and interpretation of the BBHI-2 can be found on the web at <http://www.pearsonassessments.com/medical/bbhi2-tutorial.htm>.

Another extremely useful screening tool is the Beck Depression Inventory (BDI/BDI-II),^{*79,80} Patients who score high on any of these inventories should be sent to a psychologist or a psychiatrist familiar with chronic pain for a more complete workup. Psychologists or psychiatrists may use the Minnesota Multiphasic Personality Inventory (MMPI/MMPI-II),⁸¹ in addition to the BDI-II and other psychological instruments, as part of their comprehensive assessment.

*The BDI and BDI-II can be obtained by contacting the Psychological Corporation, 555 Academic court, San Antonio, TX 78204.

Making a Diagnosis

Diagnosing orofacial disease and headaches follows the same principles as any medical diagnosis. Of primary importance is a careful and exhaustive history. This alone will often point directly to a specific diagnosis or at least reveal a diagnostic category. The history is followed by a physical examination that should help to confirm or rule out the initial diagnostic impression. If necessary, further diagnostic studies such as pulp testing, nerve blocks, radiographs, or blood tests may be carried out or ordered at this time. These may help rule out serious disorders and provide information complementing the history and physical examination. Finally, if doubt concerning the diagnosis persists, or pathosis out of one's area of expertise exists, other medical specialists and health care providers may provide valuable consultation.

Begin by pondering the scenario of the following case:

Case history. A 33-year-old woman presents herself for evaluation of intense left-sided facial pain. The pain is described as a constant burning sensation that radiates from the left preauricular area to the orbit, zygoma, mandible, and, occasionally, shoulder. Her pain is exacerbated by cold air, cold liquids, chewing, smiling, and light touch over certain areas of her face. She also reports a constant "pinching" sensation over her left eyebrow and mandible and photophobia in the left eye. She is currently taking high doses of narcotics with little relief. The pain began 1 year previously, after the extraction of a left maxillary molar. The extraction site apparently developed a "dry socket" (localized osteomyelitis of the alveolar crypt). This was treated appropriately but without relief of the patient's symptoms. Subsequently, two mandibular molars on the same side were extracted in an attempt to relieve the pain. These extraction sites likewise developed "dry sockets" and were treated, again without pain relief. Local anesthetic

injections twice daily for many months and a 4-week course of cephalosporin, given empirically for possible periodontal infection or osteomyelitis of the mandible were also unsuccessful in relieving the pain.

To properly evaluate these rather confusing signs and symptoms, additional information is necessary.

CLASSIFICATION

In evaluating orofacial pains and headaches, an easy-to-use, practical, and clinical classification of these pains will facilitate diagnosis (Table 2). In developing such a classification, it is important to remember that local pathosis of the extracranial or intracranial structures and referred pain from pathema of more distant organs such as the heart must be ruled out first. This covers a wide variety of infectious, inflammatory, degenerative, neoplastic, or obstructive processes that can affect any organ in the head, neck, and thorax, including the brain (see Tables 7–9). Most dentists and physicians are well trained to evaluate a patient for such pathosis.

There are other disorders, however, causing pain in the head and neck region that cannot be attributed to any obvious diseases of the craniofacial, craniocervical, thoracic, or intracranial organs. These disorders are less well appreciated and, for ease of clinical use, are best classified according to the apparent tissue origin of the pain (see Table 2). For an exhaustive classification of headaches and facial pain that includes very specific diagnostic criteria, the reader is referred to the International Headache Society's publication.⁸²

The primary distinguishing feature of these diagnostic categories is the quality of the pain. For example, vascular pain, such as migraine, generally has a throbbing, pulsing, or pounding quality; neuropathic pain, for example, trigeminal neuralgia, is usually described as sharp, shooting, or burning and is restricted to the peripheral distribution of the affected nerve branch; muscle pain is usually deep, steady, and aching or produces a sensation of tightness or pressure.

Table 2 Practical Clinical Classification of Craniofacial Pain

General Classification	Origin of Pain	Basic Quality of Pain
Local pathosis of extracranial structures	Craniofacial organs	Any
Referred pain from remote pathologic sites	Distant organs and structures	Aching, pressing
Intracranial pathosis	Brain and related structures	Any
Neurovascular	Blood vessels	Throbbing
Neuropathic	Sensory nervous system	Shooting, sharp, burning
Causalgic	Sympathetic nervous system	Burning
Muscular	Muscles	Deep aching, tight
Unclassifiable	Etiology as yet unknown	Any

In contrast, *extracranial* or *intracranial* pathema may present with any quality of pain. An inflamed tooth pulp may throb with each heartbeat. A tumor pressing on a nerve may cause sharp, lancinating, neuralgic-like pain. A sinus infection may be dull and aching. *Referred pain* tends to be deep and poorly localized and has an aching or pressing quality.

Once organic pathosis has been ruled out, a preliminary diagnostic category can be chosen based on the location and the quality of the pain. Therefore, when taking a pain history, the first questions to ask are “*Where, exactly, do you feel your pain?*” “*How, exactly, does your pain feel to you?*” “Please mark on this line how severe you consider your pain to be at its worst, usual, and lowest.” This will help guide further questioning to confirm or rule out a specific diagnosis within that group. For example, a patient may complain of a constant dull ache in front of the ear and a paroxysmal lancinating pain that shoots from the ear to the chin and tongue. In this situation, two patterns of pain are described. One points to a possibly myofascial or rheumatic diagnosis for the ear pain and the other to a paroxysmal neuralgia for the shooting pain. Further history, examination, and diagnostic tests will help establish more definitive physical diagnoses. This systematic approach is particularly helpful in chronic pain, in which there are often multiple diagnoses, and psychological distress and pain behavior may confuse the diagnostic process.

If the patient in the case outlined above does not have any ongoing pathological lesions of the extracranial or intracranial structures, which categories of pain would fit her description best? Based on the limited information given, namely, a *constant burning quality*, the most likely preliminary diagnostic categories are neuropathic and sympathetic. To make a specific diagnosis within a category, more specific information regarding the pain, its temporal pattern (timing of occurrence), associated symptoms, and aggravating and alleviating factors is needed.

HISTORY

The key elements of taking a history for a pain complaint are delineated in Table 3. Establishing the patient’s chief complaint requires listening carefully as the patient describes each type of pain or complaint present, including the *location, quality, and severity* of each symptom. Chronic pain patients often have multiple pain complaints with different descriptions that may indicate that multiple diagnoses are involved. When this is the case, obtaining complete information

Table 3 History of Pain

Chief complaint
Characteristics of pain
Location
Quality
Temporal patterns
Constant or intermittent
Duration of each attack if intermittent
Diurnal or nocturnal variation in intensity if constant
Seasonal variation of symptoms if any
Associated symptoms
Precipitating factors if intermittent
Aggravating factors
Alleviating factors
Symptoms severity range (lowest, usual, and highest pain intensities)
Onset and history
Past and present medications or other treatments for pain
Past medical and dental history
Family history
Social history
Review of systems

on each pain complaint separately simplifies the diagnostic process.

The patient in this case scenario complains of only one pain. The location is over the left side of the face, radiating from the preauricular area. The quality of the pain is described primarily as burning. Her usual pain intensity on a 0 to 10 scale is 8, 5 being the lowest, and 9 being the highest.

Different pains also have different *temporal patterns* or patterns of occurrence. For example, a patient may complain of an intermittent, unilateral throbbing head pain. This would be the hallmark of a diagnosis in the vascular category. The exact pattern of the pain will help determine which vascular headache the patient is suffering. For example, *migraines* last from 4 to 48 hours and occur once or twice a year up to several times per month. *Cluster headaches* last less than 90 minutes each but occur several times a day, for several months, before going into remission. Similar distinctions can be made with neuropathic pains. The pain of trigeminal neuralgia is seconds in duration and may be triggered frequently throughout the day. The pain of a posttraumatic neuropathy or postherpetic neuralgia (PHN) is constant.

The temporal pattern for this patient’s burning pain is constant, with little daily variation.

Often there are associated symptoms such as nausea, vomiting, ptosis, nasal congestion, tingling, numbness,

blurred vision, or visual changes that may precede or accompany the pain. These symptoms may point to a specific diagnosis. For example, visual changes may precede a migraine with aura. Nausea and vomiting often accompany severe headaches, especially migraine. Generalized malaise may accompany a temporal arteritis. Autonomic changes, such as ptosis, nasal congestion, or conjunctival injection, almost always accompany cluster headaches or chronic paroxysmal hemicrania (CPH). Tingling and numbness may occur with deafferentation (nerve damage) pains such as postherpetic or posttraumatic neuralgias.

Unexplained neurological symptoms, however, such as cognitive or memory changes, transient sensory or motor loss of the face or extremities, tinnitus, vertigo, loss of consciousness, or any of the above symptoms not fitting an appropriate pain picture, must alert the health professional to the possibility of an intracranial lesion, requiring further workup. Some of these symptoms may be normal bodily sensations enhanced through distorted perceptions. Similarly, others, such as tinnitus, vertigo, or sensory tingling, may be associated with the referred symptoms of *myofascial TrP pain*.⁸³ Further diagnostic tests or consultations may be needed to rule out more serious pathosis.

Associated symptoms of this patient include a constant “pinching” sensation over her left eyebrow and mandible and photophobia of the left eye. She also describes occasional “electric” attacks that radiate out from the left TMJ. The “electric” attacks she describes last anywhere from 30 minutes to 24 hours.

Precipitating, aggravating, and alleviating factors also add clues to the origin of pain. Withdrawal from alcohol or caffeine may trigger a migraine attack.^{84,85} Light touch, shaving, or brushing teeth may precipitate an attack of trigeminal neuralgia. Cold weather, maintaining any one body position for a prolonged period of time, or overexercise will aggravate MFP. A dark room and rest will alleviate migraine but aggravate cluster headache. Heat and massage will alleviate muscular pain and MFP but may aggravate an inflamed joint.

The burning pain is constant, without precipitating factors. Aggravating factors include cold air, cold liquids, chewing, smiling, and light touch. The “electric” attacks are precipitated by light touch over the preauricular area. At this stage, nothing alleviates the pain. High doses of narcotics barely serve to “take the edge off.”

Gathering information about the onset and history of the problem will provide further clues as to the etiology of the complaint. Of interest are the events surrounding the initiation of the pain, how the pain

has changed since onset, and what evaluations and treatments have been tried in the past. For example, a history of skin lesions and malaise (herpes zoster) typically precedes PHN. Acute trauma may precede a myofascial TrP pain complaint. In contrast, psychological stress can trigger almost any type of pain complaint.

Knowing which specialists the patient has seen, which tests and radiographs have already been completed, what the previous diagnostic impressions have been, and which treatments have been tried, helps the practitioner in several ways. First, which workups are still needed? Did the past workups adequately rule out organic or life-threatening pathema? How long ago were these workups completed? Have the symptoms changed since then? Do any of these workups need to be repeated? Second, what diagnoses were considered in the past? Were appropriate medications or treatments tried, in adequate doses and for long enough periods of time? With acute pain, the history is usually quite short, but with chronic pain, the history may take hours to obtain, the patient having seen many different health care providers in the past. With chronic pain, the effect of past medications, surgeries, and other treatments may provide insight not only into the etiology of the pain but also into the psychological or behavioral status of the patient.

The pain began 1 year previously, after the extraction of a left maxillary molar. The extraction site apparently developed a “dry socket.” This was treated appropriately but without relief of the patient’s symptoms. Subsequently, two left mandibular molars were extracted in an attempt to relieve the pain. These extraction sites likewise developed “dry sockets” and were treated, again without pain relief. Local anesthetic injections twice daily for many months and a 4-week course of cephalosporin given empirically for a possible periodontal infection or osteomyelitis of the mandible were also unsuccessful.

This history tells us that, initially, local tooth pathosis was suspected as the etiology of the pain. However, extraction of teeth provided no relief. Osteomyelitis and possibly periodontal disease had also been suspected, but high-dose antibiotic treatment for osteomyelitis also failed to provide pain relief. Are there other extracranial or intracranial pathemas that may need to be ruled out?

A family history should include information regarding the patient’s parents and siblings. Are they alive and well? If not, why not? Does anyone in the immediate family suffer from a similar pain problem? For example, 70% of migraine patients have a relative who also has or had migraine. Does anyone in the

family have a chronic illness? This person may provide a model for pain behavior and coping.

The patient's parents and siblings are alive and well. There is no history of similar illness or chronic illness in her family.

A social history should not only cover demographic information, marital status, household situation, and occupation but also seek to uncover any potential perpetuating factors to the pain. Look for potential stressors at work and at home and ask about postural habits, body mechanics, dietary habits, environmental factors, and drug and alcohol use.

This patient lives in a rural farm area, has been married to the same man for 15 years, and has three children. She used to work on the farm but has been unable to do so for the last 6 months because of the pain. The patient has smoked one pack a day for 18 years. She does not drink alcohol. Currently she spends most of her day in bed because of the pain.

Since the patient lives in a rural area, the possibility of a coccal infection must be considered and ruled out.

The past medical history may reveal some underlying illnesses such as lupus erythematosus or hypothyroidism that may predispose the patient to developing pain. Past surgeries and medications for other purposes, any psychiatric history, allergies, hospitalizations, and other illnesses must be included and may reveal health care abuse.

The patient states that she is otherwise in good health. She had the usual childhood diseases, has no known allergies, and had been hospitalized only for the birth of her children. There is no history of trauma other than the tooth extractions previously mentioned.

A review of systems screens the person's present state of health. It includes asking about any recent symptoms related to the head and neck; the skin; and the cardiovascular, respiratory, gastrointestinal, genitourinary, endocrine, neurological, obstetric-gynecologic, and musculoskeletal systems.

The patient complains of decreased energy and sleep disturbance secondary to the pain. She has no other complaints.

In acute pain problems, a firm diagnosis may be established almost immediately from the history. In contrast, diagnosis of a chronic pain complaint may take months of tests or trials despite an exhaustive history. The next step in diagnosis is a thorough physical examination.

PHYSICAL EXAMINATION

The physical examination for craniofacial pain may vary slightly, depending on its location and the

apparent cause. Pathosis of extracranial structures, particularly the oral cavity, must be sought and ruled out first. This usually involves inspection, palpation, percussion, transillumination, and auscultation of the tissues and structures suspected of causing pain. Intraoral examination that must include inspection of all intraoral tissues, teeth, and periodontium is discussed in detail in Chapters 14 and 15. Once acute pathoma has been ruled out, the physical examination must be augmented to include evaluation of the cranial nerves, TMJ, cervical spine, and head and neck muscles. In specific cases, a more comprehensive neurological examination may be indicated. The basic components of a physical examination are listed in Table 4.

General inspection can reveal a great deal about a patient to the alert clinician. A slouching posture can point to depression. Rigidity in posture or clenching is an indication of excess muscle tension in the neck, shoulders, or jaws. Asymmetry, swelling, redness, and other signs may indicate a neoplastic or infectious process. Closer inspection of the head and neck may reveal scars of past surgeries, trophic skin changes associated with RSD, or color changes from local infection, systemic anemia, or jaundice.

The examination of the TMJs involves testing the range and quality of motion of the mandible, palpating and listening to joint noises, and palpating the lateral and dorsal joint capsules for tenderness. The normal range of jaw opening is 40 to 60 mm. Laterotrusive and protrusive movements should be 8 to 10 mm. The path of opening and laterotrusive and protrusive movements should be straight, without deflections or deviations. Joint capsule palpation anterior to the tragus of the ear for the lateral capsule and from the external auditory meatus for the dorsal capsule may be "uncomfortable" but should not be painful.

As discussed later in the chapter, the cervical spine is often the source of persistent referred pain to the orofacial and TMJ regions. Similarly, poor posture is one of the most important contributing factors to TMJ dysfunction and myofascial TrP pain. For these reasons, the cervical spine and the posture must be evaluated in any chronic head and neck or facial pain

Table 4 Physical Examination

General inspection
Head and neck inspection
Stomatognathic examination
Cervical spine examination
Myofascial examination
Cranial nerve examination

problem. The examination of the cervical spine includes testing its range and quality of motion as a whole, as well as testing the range and quality of motion of the first two cervical joints individually.^{86–88} Posture, especially anterior head positioning, must also be systematically evaluated. For details on how and why this is important, the reader is referred to Travell and Simons' *Trigger Point Manual*.⁸³

Myofascial TrP examination requires a thorough, systematic palpation of all of the masticatory and cervical muscles, looking for tight muscle bands and the focal tenderness associated with myofascial TrPs. Myofascial TrP is the most prevalent cause of chronic pain, both in the head and neck region and in general.^{89–93} Also, it is frequently an accompanying diagnosis to other chronic pain conditions.

A *cranial nerve examination* (Table 5) is indicated when the history points to a neuropathic type of pain; if disturbances in touch, taste, smell, sight, hearing, motor function, balance, or coordination are suspected; or if there are any subjective complaints or objective signs of cranial nerve involvement. Lesions of the cranial nerve nuclei or their efferent or afferent pathways will result in an abnormal examination. For example, meningitis may cause double vision; an acoustic neuroma may cause hearing loss. Symptoms of numbness or tingling may accompany nasopharyn-

geal carcinoma or other intracranial pathema. Sensory deficits can be verified using accurate two-point discrimination testing, pinprick tests, and light touch tests. Complaints of transient or persistent paralysis, weakness, or spasticity of any of the head and neck muscles dictate the need for evaluation of the nerves that control their motor function.

The motor function of the head and neck is mediated through several cranial nerves. The *trigeminal nerve, cranial nerve V*, controls the masticatory muscles. The *facial nerve, cranial nerve VII*, controls the muscles of facial expression. The *hypoglossal nerve, cranial nerve XII*, controls the tongue. The *spinal accessory nerve, cranial nerve XI*, controls the trapezius and sternocleidomastoid muscles. Detailed information on how to perform a cranial nerve examination is available in Bates's textbook on physical examination and history taking.⁹⁴ If intracranial pathosis is suspected, a complete *neurological examination*, including mental status; cerebellar, motor, and sensory function; and reflexes, is indicated. This requires referral to a competent neurologist.

General inspection of the patient reveals an obese female in moderate distress. Closer inspection of the head and neck reveals slight swelling of the left cheek with a distinct increase in skin temperature over this site. On intraoral examination, the intraoral tissues are firm, pink,

Table 5 Cranial Nerve Examination

I	Olfactory test: sense of smell of each nostril separately by using soap, tobacco, or coffee with patient's eyes closed
II	Optic test visual acuity Examining fundi ophthalmoscopically Test visual fields
III, IV, VI	Oculomotor, trochlear, abducens Test pupillary reactions to light and accommodation Test extraocular movements Check for ptosis or nystagmus
V	Trigeminal Motor—palpate masseter and temporalis during contraction Sensory—Test discrimination of pinprick, V1, V2, V3 temperature, V1, V2, V3, and light touch, V1, V2, V3 Test corneal reflex
VII	Facial Observe patient's face during rest and conversation Check for symmetry, tics Examine for symmetric smile, ability to wrinkle forehead, hold air in cheeks, and tense the platysma muscle
VIII	Acoustic Whisper, rub fingers, or hold watch next to ear, use tuning fork for Rinne and Weber tests
IX, X	Glossopharyngeal, vagus Check for symmetric movement of the soft palate and the uvula when patient says "Ah" Check gag reflex by touching back of throat. Note any hoarseness
XI	Spinal accessory Have patient shrug shoulders against resistance (trapezius) (partially innervated by C4) Have patient turn head against resistance (SCM)
XII	Hypoglossal. Observe tongue in mouth: check for atrophy or asymmetry Check for deviation by having patient stick tongue out

and stippled without lesions. The patient is missing the maxillary left third molar and all three mandibular left molars. TMJ examination reveals an active oral opening of only 33 mm with little translation of the left condyle (the jaw deflects to the left with opening). Definitive intraoral or extraoral palpation is impossible because the patient complains of pain at the slightest touch.

The patient has full range of motion of the cervical spine. The first two cervical joints similarly show good range and quality of motion. Her posture is slightly abnormal, with elevation of the left shoulder and a forward head position.

Myofascial TrP examination is restricted to the cervical muscles and unaffected side owing to the extreme sensitivity of the left side of the face. Even so, active myofascial TrPs are found in the left upper trapezius that intensifies the patient's pain over the left temple and angle of the jaw.

Cranial nerve examination is normal except for the extreme cutaneous sensitivity on the left side of the face. Neurological examination is similarly unremarkable.

At this stage, one must still rule out acute pathological changes. Pathosis of the various organs and structures of the head and neck should always be suspected first in any orofacial pain. The teeth, pulp and periodontium, TMJs, eyes, ears, nose, throat, sinuses, and salivary glands should be thoroughly evaluated (see Table 6). As mentioned previously, the quality of pain from this group varies depending on the etiology. Equally important are many referred pain problems (see Table 7). These are very often difficult to diagnose and include pathological conditions such as the tight, pressing pain of coronary artery disease that may be felt in the sternum and the jaws.

This patient demonstrates swelling and temperature change as well as cutaneous hyperesthesia over the painful area. She could still have a chronic osteomyelitis despite the previous course of antibiotics. She could have a retropharyngeal abscess or a neoplastic disease affecting or surrounding the fifth cranial nerve, either intracranially

Table 6 Local Pathosis of Extracranial Structures

or extracranially. She could also have a localized coccal infection since she lives in a rural area. The limited range of motion of the left TMJ and the fact that much of her pain seems to emanate from there bring up the possibility of severe degenerative joint disease or neoplastic disease involving the joint. The myofascial TrPs in the left trapezius have probably developed in response to the chronic pain problem. It is unlikely that myofascial TrP pain is the primary cause of this patient's pain.

The next step involves choosing appropriate diagnostic studies to help rule out the pathoma suspected.

DIAGNOSTIC STUDIES

Table 8 is a list of some of the more common diagnostic studies available to help facilitate diagnosis.

Panoramic and periradicular radiographs reveal an area of bony sclerosis in the mandibular extraction sites, consistent with the history of curettage of dry sockets and not at all typical of osteomyelitis. TMJ tomograms reveal flattening of the left condyle consistent with mild to moderate degenerative joint disease. Computed tomographic (CT) scans of the brain, mandible, and retropharyngeal area are normal. A gallium scan, which is used to identify soft tissue inflammation, is also normal. Skin tests for coccal infection are negative. Complete

blood count and erythrocyte sedimentation rate also fail to show any signs of infection or inflammation. No pathosis of the extracranial and intracranial structures can be identified.

What, then, could be causing this patient's pain? At this point in the workup of a pain patient, practitioners are often tempted to ascribe the pain to some "psychogenic" problem. Clearly, if there is no obvious pathological process, and the patient is in severe distress or does not respond well to treatments, then she must be suffering from a "psychogenic" pain. Do not be too sure!

PSYCHOGENIC PAIN

Many clinicians use the term "psychogenic" to refer to patients with a chronic pain problem that has a strong emotional component or to patients who do not respond well to somatic treatment. It must be re-emphasized, however, that psychological factors are intimately involved in the expression of all pain, regardless of etiology or time course.

By definition, chronic pain has been present for a protracted period (at least 6 months), and the patient has usually received multiple treatments with little or no results. This creates an emotional strain for the patient and frustration for the clinician, sometimes resulting in the inappropriate label of "psychogenic pain." Patients with chronic pain invariably have a somatic diagnosis. What frustrates the clinician is often the discrepancy between the identifiable somatic cause and the disproportionate amount of perceived pain and disability that accompanies this cause.

"Psychogenic pain" or "somatoform disorders" are described in the DSM-IV, the Diagnostic and Statistical Manual of Mental Disorders,⁹⁵ and include physical complaints that, after appropriate medical workup and testing, either cannot be explained by a medical condition or substance (ab)use or, if due to an identifiable medical condition, cause physical, social or occupational impairment greater than what would be expected given the objective findings. In addition, they have been present for over 6 months and cannot be explained by other psychological disorders such as depression or anxiety. Despite their inclusion in the Diagnostic and Statistical Manual of Mental Disorders, somatoform disorders have been the subject of continuing criticism by both professionals and patients⁹⁶ mostly because no empirical evidence exists to support these psychodynamic diagnoses and to date no psychodynamic treatment has been shown to be effective in treating these disorders. Thus the validity of these diagnoses is under debate.⁹⁷

Myofascial TrP pain is frequently overlooked as an organic finding and is thus often mislabeled as psychogenic pain.⁹⁸ Occasionally, there are patients in whom no etiology for their pain can be identified and who have no psychological findings consistent with a psychological disorder. This situation simply speaks to the limitations of our current medical knowledge and the complexity of the human nervous system and is not an indication of the mental state of the patient.

OPERANT PAIN (PAIN BEHAVIOR)

Although pain behaviors (the behavioral manifestations of pain, distress, and suffering) likely result from a complex interaction of various psychological and physical factors,⁶⁵ understanding the basic concepts of learning and "operant" conditioning is essential to understanding the chronic pain patient.

In combination with cognitive and affective factors, learned behavior and "operant conditioning" are powerful psychological or "psychogenic" factors that play an important role in any patient with a chronic or persistent pain problem. Fordyce and Steger^{99,100} described operant pain and conditioning as follows:

...in chronic pain, the normal responses to a noxious stimulus, such as moaning, complaining, grimacing, limping, asking for medication, or staying in bed, are present for a long enough period of time to allow learning to occur. By using the above set of actions, termed operants, the patient either purposely or unintentionally communicates to those around him that he has pain. The significance of these operants is that they can be influenced by certain consequences. For example, if a certain behavior or action is consistently followed by a favorable consequence (a positive reinforcer), then the probability that the behavior or action will be repeated again in response to a similar stimulus is increased (as in Pavlov's dog). If, however, a certain behavior or action is not consistently followed by a favorable consequence, the behavior will diminish in frequency and disappear. This is known as "extinction."

It is generally accepted that all chronic pain begins at some point with a true pathological or nociceptive stimulus. This stimulus elicits a pain response or "pain behavior." Most people live in an environment that systematically and positively reinforces pain behaviors while ignoring or punishing healthy behaviors.⁹² In acute pain, these behaviors and their rewards subside quickly, but in chronic or persistent

pain, pain behaviors become more prominent and may persist even after the noxious stimulus is gone: “The degree of pain behavior has little or no direct relationship to pathogenic [or nociceptive] factors.”⁹⁰

It is easy to label the behavioral manifestations of pain, distress, and suffering as pain of psychogenic origin. Unfortunately, this term usually implies some kind of personality disorder such as *hypochondriasis* (excessive concern with one’s health and bodily functions) or *hysteria* (also known as conversion reaction), and often this is not present, or, if it is, it generally has little or nothing to do with the pain. As Fordyce said,¹⁰⁰ “It is not necessary to have personality problems to learn a pain habit, because learning occurs automatically if the conditions are favorable.” Therefore, other psychological labels, such as *somatization* (conversion of mental states into bodily symptoms similar to hysteria but with more elaborate complaints), *malingering* (conscious exhibition of pain or illness for secondary gain), and *Munchausen syndrome* (a type of malingering characterized by habitual presentation for hospital treatment of an apparent acute illness with a plausible and dramatic but fictitious history),¹ are also usually inappropriate. The astute clinician will try to ascertain which environmental factors are acting to maintain and reinforce a particular behavior instead of assuming that the patient has a character disorder.

It is important to realize that, whether or not the pain has an ongoing identifiable organic basis, it is still very real to the patient and can be as intense as any somatic pain. Management typically requires a multidisciplinary approach that includes identification and elimination of any positive reinforcers to the pain behaviors. All treatment and follow-up visits, medications, exercises, rest, and so on must be scheduled on a time-contingent and not on a pain-contingent basis, regardless of the somatic diagnosis. The family must also be educated to reinforce well behaviors and ignore sick behaviors. Then activity levels must be increased and medications gradually decreased and eliminated. The help of a behaviorally oriented psychologist or psychiatrist familiar with chronic pain patients is highly recommended.

Occasionally, situational insight, supportive therapy, guidance, or counseling is sufficient to resolve the problem. Other cases may require more long-term outpatient psychotherapy. Sometimes medications such as antidepressants, antipsychotics, hypnotics, or tranquilizers will help alleviate the pain. Inpatient psychiatric care is indicated for anyone at risk of committing suicide or inflicting bodily injury on themselves or others.

An interview with a psychologist and the MMPI did not reveal a psychopathological state in this particular patient. So, clearly, there must be other factors that have not been considered that are causing this patient’s pain.

Instead of falling into the trap of calling unidentified pain “psychogenic,” one should go back to the classification of pain (see Table 2) to answer this question. Based on the burning quality of pain, it is clear that neuropathic or sympathetic pains would be the categories most likely to carry a diagnosis that accounts for this patient’s pain. These pains and specific diagnoses within each category are described in more detail later in the chapter.

Specifics for Each Broad Category of Pain Origin

The remainder of the chapter will be devoted to discussing many of the specific diagnoses that fall into each broad diagnostic category. This classification is by no means exhaustive. The disorders discussed are those with which dentists should be familiar. An exhaustive treatise of orofacial pains has been published by Bell¹⁰¹ and an official classification with diagnostic criteria by the International Headache Society.⁸²

Extracranial Pathosis

LOCAL PATHOSIS OF EXTRACRANIAL STRUCTURES

Local pathosis of extracranial structures and referred pain from remote pathologic *sites* are listed in Tables 7 and 8. Acute pain arising from pathosis of the extracranial structures is commonly seen in dental practice. Some extracranial acute pain is well localized, easily identifiable, and straightforward to treat. However, some pains from local pathema are more elusive because they are referred to other head and neck structures. Similarly, pathosis of some distant structures such as the heart and thyroid may refer pain into the head, neck, or jaws. These more unusual pains will be discussed.

Tooth Pulp, Periodontium, Periradicular Structures, Gingiva, and Mucosa

Diseases of the intraoral structures, including referred pain from pulpalgia, are fully discussed in Chapter 10,

“Mechanisms of Odontogenic and Non-Odontogenic Pain” and will not be covered here.

Salivary Gland Disorders

The salivary glands can be affected by many diseases, including ductal obstruction, infection, inflammation, cystic degeneration, and tumor growth. Pain and tenderness are typically found in association with ductal obstruction, inflammation, or infection.

The salivary glands are also affected by various medications, especially those with anticholinergic activity against the M3 muscarinic receptor including some sympathomimetic drugs, antidepressants, amphetamines, protease inhibitors, and cytokines.¹⁰² Medication use is the most common cause of reduced salivary flow and, while not painful, may result in subjective complaints of dry mouth and occasionally true xerostomia.

Etiology. The most common causes of salivary gland pain are mumps and acute parotitis in children and blockage of salivary flow by a mucus plug or a sialolith in adults. The latter results in pressure from salivary retention and may cause ascending infection. Sjögren’s syndrome, a disease of unknown etiology typically seen in older women, is characterized by dry eyes, dry oropharyngeal mucosa, and enlargement of the parotid glands.¹⁰³ This disorder may also cause salivary gland pain if the glands become inflamed. The use of various medications may contribute to or aggravate symptoms or signs of dry mouth or xerostomia in susceptible individuals.

Symptoms. Salivary gland pain is typically localized to the gland itself, and the gland is tender to palpation. Precipitating and aggravating factors to the pain are salivary production prior to meals, eating, and swallowing. Mouth opening may aggravate the pain because of pressure on the gland from the posterior border of the mandible during this movement. This, and increased pain with chewing, may lead the clinician to mistake the pain as being from the masticatory system. Associated symptoms include salivary gland swelling and, occasionally, fever and malaise. Salivary flow from the affected gland may be minimal or nonexistent. Cancer of the parotid gland should not be ruled out. It may be characterized by persistent Bell’s palsy.

Symptoms of dry mouth may include symptoms such as a painful tongue, the tongue sticks to the palate, lipstick sticks to the teeth, dentures are painful, hoarseness, difficulty in swallowing food, needing to sip water a lot, and taste changes.¹⁰⁴

Examination. The pain can be localized fairly well by palpation. Other signs of inflammation may be

present. With parotid gland disorders, to determine diminished or absent flow, the gland can be manually milked while observing salivary flow from the parotid duct.

Screening tests for dry mouth include visual inspection of the lips, gingiva, and mucosa looking for evidence of dryness, visual inspection for the presence or the absence of salivary pooling, and placing a tongue blade against the buccal mucosa to see if it sticks (sticking indicates dryness).¹⁰⁴

Diagnostic tests. Radiographs of the gland and ducts may reveal a calcific mass in the region of the gland. Sialography (radiographic examination of a gland using a radiopaque dye injected into the ductal system) may also show obstruction or abnormal ductal patterns.

Salivary flow testing is useful to verify salivary gland hypofunction, and the saliva can also be tested for pH and buffering capacity.¹⁰⁵ The standard procedure for evaluating dry mouth is to have the patient expectorate into a graduated measuring cup for 5 minutes (the unstimulated test) and the volume of the saliva is recorded. The patient is then given a piece of paraffin (the stimulated test) to chew while expectorating into the graduated cup for another 5 minutes, and the unstimulated and stimulated volumes are compared. If the volume of the unstimulated test is within the range of normal, the patient does not have dry mouth or xerostomia. If the volume of the unstimulated test is below normal but the volume of the stimulated test comes up to the normal range, the patient has dry mouth, not xerostomia. If, however, the volume of the stimulated test continues to be in the low range, the patient has xerostomia.

Treatment. The mucus plug or sialolith should be removed in the case of obstruction. Antibiotics may be needed if infection accompanies the pain.

Management of dry mouth or xerostomia can range from simple home care including frequent brushing and flossing, using fluoridated toothpaste, rinsing and wiping the oral cavity immediately after meals, drinking more water, avoiding liquids and foods with high sugar content, overly salty foods, citrus juices and mouthwash containing alcohol, and using lip balm regularly, use of prescription mouthwash, toothpaste, and fluoride as well as sialogogues. Depending on the severity of the salivary gland hypofunction, increased frequency of regular dental cleanings and periodontal maintenance may be required.¹⁰⁵

Patients with otitis externa (inflammation of the external auditory canal) may present themselves to the dentist first because this pain is aggravated by

swallowing. Otitis externa may be misdiagnosed as arthralgia of the TMJ if the condyle is palpated through the external auditory canal without first evaluating the ear. Glossopharyngeal neuralgia, also aggravated by swallowing, may need to be considered if ear and dental pathosis are absent.

Examination. The dentist must carefully examine the dentition for pulpal disease and the oropharyngeal mucosa for inflammation to rule out referred ear pain from oral or dental sources. Myofascial TrPs in the lateral and medial pterygoid muscles frequently refer pain to the ear as well. Deep masseter and SCM TrPs may cause tinnitus.⁵⁴

If primary ear pain is suspected, referral to a competent ENT specialist should be made. However, screening examination should include visual inspection of the ear and ear canal. The use of an otoscope facilitates this examination. Wiggling the auricle itself or tugging on the earlobe will aggravate otitis externa and will help distinguish an ear lesion from a TMJ problem. Pumping on the ear with the palm of the hand will exacerbate pain from otitis media. Hearing can be grossly evaluated by rubbing the fingers together in front of each ear or using a watch tick or coin click. The practitioner can use his own hearing as a control.

Treatment. Primary ear pain should be diagnosed and managed by an ENT specialist. Dental sources of ear pain are treated by treating the oral pathema. Of importance is the fact that primary ear pain may also induce *secondary myospasm*, and development of *myofascial TrPs* may persist beyond the course of primary ear disease. These TrPs and the resulting masticatory dysfunction are self-perpetuating, even after the acute ear problem resolves. Appropriate treatment of this secondary masticatory dysfunction will be required for resolution of the complaint.

Case history. A good example of this phenomenon is a 27-year-old woman who presented with an 18-month history of right-sided facial pain that started after a middle ear infection. During the initial illness, she experienced dizziness, and a spinal tap was performed to rule out viral meningitis. This was negative, and a diagnosis of a viral syndrome was made. Several months later, persistent pain led the patient to seek a further ENT consultation. A cyst discovered in the right maxillary sinus was removed through a Caldwell-Luc procedure, with only transient relief of symptoms.

On evaluation, the patient complained of intermittent, deep, dull, aching pain in the right side of her face, including her eye, ear, and neck. The pain was associated with blurred vision, ptosis, and redness of both eyes. She also complained of unilateral hearing loss and

nasal congestion on the symptomatic side. The pain occurred one or two times per week and lasted 24 to 48 hours.

Examination revealed multiple active myofascial TrPs in the right masseter, temporalis, medial pterygoid, sternocleidomastoid, and suboccipital muscles that reproduced all of her symptoms, including blurred vision. In contrast, there were essentially no TrPs in any of the muscles on the asymptomatic side. Treatment directed at rehabilitation of the involved muscles provided significant reduction in the intensity and frequency of her pain.

Ear Pain

Most patients who have a primary complaint of ear pain will seek the help of their primary care physician or an ear, nose, and throat (ENT) specialist. Ear pain is typically seen with disorders such as otitis media, otitis externa, and mastoiditis and may be associated with headache. When a medical workup is negative, patients may be referred to the dentist for evaluation of ear pain. Astute physicians will want to know whether the TMJ or pulpalgia is referring the symptoms. Patients may also present themselves to the dentist with another primary pain complaint such as toothache or headache, whereupon when taking a careful history, ear pain is found to be an associated symptom. The dentist needs to rule out dental disease or temporomandibular disorders (TMDs) as a cause of ear pain. Additionally, the dentist must decide when a referral for a medical workup of ear pain is indicated.

Etiology. The ear is innervated by cranial nerves V, VII, VIII, IX, X, and XI and also branches of the upper cervical roots that supply the immediate adjacent scalp and muscles. Therefore, pain can be referred to the ear from inflammatory or neoplastic disease of the teeth, tonsils, larynx, nasopharynx, thyroid, TMJ, and cervical spine, as well as from inflammation or tumors in the posterior fossa of the brain.¹⁰⁶ Ear pains are also associated with neuralgias such as herpes zoster of the cranial nerve V or VII, glossopharyngeal neuralgia, and nervus intermedius neuralgia. These will be discussed later.

Symptoms. Primary ear pains are usually described as a constant aching pressure. Their onset is usually recent. Inflammatory or infectious disorders may be associated with fever and malaise. These complaints should be diagnosed and managed by an ENT specialist.

Sinus and Paranasal Pain

The most common extraoral source of dental pain arises from the maxillary sinus and associated pain-sensitive

nasal mucosa. Many teeth have been mistakenly extracted because of an incorrect diagnosis of this syndrome.

Etiology. The sinuses themselves are relatively pain-insensitive structures. Reynolds and Hutchins¹⁰⁸ demonstrated that most so-called “sinus” pain actually arises from the nasal mucosa or from the stimulation of the nasal ostia. Minor disease in critical locations within the nasal ostia and meata may give rise to greater symptomatology than diffuse disease in the sinuses.¹⁰⁹ Conversely, various intranasal and sinus abnormalities, anatomic variations or subclinical inflammation, may present as primary headache disorders.¹¹⁰

Allergies may also cause boggy, edematous nasal mucosa. This may cause swelling of the turbinates, that may, in turn, block off the ostia of the maxillary sinuses. This has been implicated in causing referred symptoms to the teeth (Figure 12) Sicher¹¹¹ pointed

Figure 12 Inflammation of nasal mucosa causes swelling of the turbinate and blocks off the ostium of the maxillary sinus. Pain referred to maxillary teeth may then develop. Reproduced with permission from Ballenger JJ, Lea & Febiger; 1969.

out that the superior alveolar nerves, supplying the maxillary molar and premolar teeth, pass along the thin wall of the sinuses. The canaliculi of the teeth often open toward the sinus, and pulpal nerves may be in direct contact with the inflamed mucoperiosteum of the sinus lining. Their direct irritation may cause dental symptoms. The reverse is also true. Inflammation or infection from the root of a tooth in contact with the sinus floor may cause sinusitis. This, in turn, will not resolve until the dental problem is corrected.

Symptoms. Contrary to popular belief, infection and inflammation of the sinuses rarely cause facial pain or headache. Many headache patients with autonomic features will probably have tension-type headaches or migraines. Most authors feel that acute or chronic headache processes are not a result of overt paranasal sinus disease.¹⁰⁷

Chronic sinusitis may cause symptoms of fullness or pressure but rarely pain. The location of these symptoms may vary from the maxilla and maxillary teeth in maxillary sinusitis to the upper orbit and frontal process in frontal sinusitis, between and behind the eyes in ethmoid sinusitis, and at the junction of the hard and soft palate, occiput, and mastoid process in sphenoid sinusitis.

The sinusitis patient who reports to the dentist does so with a chief complaint of “toothache.” In this case, constant but rather mild pain in a number of posterior maxillary teeth on one side is almost pathognomonic. All of the teeth on this side, the roots of which are related to the floor of the sinus, may be aching mildly.

The teeth feel elongated, as if they “touch first” when the patient closes. The teeth are also tender, and the patient clenches against them, saying it “hurts good” to do so. These same maxillary teeth are hypersensitive to cold fluids. Occasionally, all of the maxillary teeth on the involved side, to the midline, feel uncomfortable and elongated. The pain, mild but deep and nonpulsating, radiates out of this area onto the face, upward toward the temple and forward toward the nose. A referred frontal headache and cutaneous hyperalgesia along the side of the face and the scalp may also be present. The patient frequently reports that the pain begins in the early afternoon or may give a history of increased pain at altitude when crossing a high mountain pass or when making a plane flight. Patients may also complain of a “stuffy nose,” blood- or pus-tinged mucus, postnasal drip, fever, and malaise.

Examination. The dentist’s contribution will be to rule out dental disease as the cause of the pain and

correctly refer the patient for complete diagnosis and treatment.

The extraoral examination should include palpation of the maxillary sinuses under the zygomatic process bilaterally. If maxillary sinusitis is present and unilateral, the cheek on the involved side, from the canine fossa back to the base of the zygomatic process, will be tender to heavy palpation. The patient may say it feels as if he has been hit in the area, or “frostbitten” is another term used in northern climes. It may also hurt to smile.

If the patient complains of frontal headache, the dentist should check the frontal sinuses for tenderness by pressing up against the inferior surface of the supraorbital ridge on each side of the nose. All of the anterior sinuses, maxillary, frontal, and anterior ethmoidal, may be involved at one time. Such pansinusitis may follow an upper respiratory infection.

The intraoral examination should include mobility, percussion, thermal and electric pulp tests, and radiographs. The teeth adjacent to the affected maxillary sinus often are mobile when moved between the two index fingers. Furthermore, the teeth are painful and sound “mushy” when percussed and may be hypersensitive to cold or when pulp tested electrically compared to the uninvolved side. Illuminating the sinuses with a fiber optic in a darkened room may reveal changes in the affected sinus. Direct inspection of the nasal passages with a speculum may reveal engorged nasal mucosa and turbinates.

Radiographically, the involved teeth are likely to be normal, reconfirming that nothing is wrong orally. The roots of the teeth, however, may be found extending well up into or against the sinus floor, which would account for their involvement. On the other hand, the radiograph and the pulp test may show a pulpless tooth with a periapical lesion. Periapical infections may extend into the sinus.¹¹² As stated previously, this could be the cause of a unilateral sinus inflammation. Nenzen and Welander¹¹³ found “local hyperplasia of the maxillary sinus mucosa” in 58% (14 of 24) of the patients who had pulpless teeth with periradicular lesions associated with the floor of the sinus.

Persistent pain in this area may be caused by a cyst or neoplasm of the maxillary sinus. In these cases, the pain syndrome is the same as for sinusitis but more long-standing. A radiographic study of the area may reveal the lesion.

The diagnosis of maxillary sinusitis may be confirmed by spraying 4% lidocaine anesthetic from a spray bottle into the nostril on the affected side. This will anesthetize the sensitive area around the ostium. The pain from the congested nasal mucosa and accompanying maxillary sinusitis should be substantially reduced within a minute or two.

Treatment. Complete diagnosis and treatment of maxillary sinusitis are left to the ENT specialist. Treatment usually consists of the use of decongestants and analgesics. If there is persistent purulent discharge, cultures should be taken and appropriate antibiotics prescribed. For a more complete discussion of “Rhinosinusitis and Endodontic Disease” refer to Chapter 17, “Rhinosinusitis and Endodontic Disease.”

Temporomandibular Joint Articular Disorders

Before discussing TMJ disorders, a distinction must be made between pain and dysfunction arising from the TMJ itself, TMD, and MFP owing to TrPs. TMD is an umbrella term that refers to various painful and nonpainful conditions involving the TMJ and the associated masticatory musculature. MFP is a distinct muscle pain disorder that produces various local and referred symptoms from TrPs in taut bands of skeletal muscle, and may or may not be associated with a TMJ disorder. MFP is reviewed in detail later in this chapter.

Historically, there has been much confusion around TMD and the differential contribution of pain from the joint versus the muscles and MFP. In a study conducted at the University of Minnesota TMJ and Facial Pain Clinic, doctors evaluated 296 consecutive patients with chronic head and neck pain complaints.⁸⁹ Only 21% of these patients had a TMJ disorder as the primary cause of pain. In all 21%, the joint disorder included an inflammation of the TMJ capsule or the retrodiscal tissues. MFP owing to TrPs was the primary diagnosis in 55.4% of the patients in the Minnesota study, almost three times the incidence of primary joint pain. Nonpainful internal derangements of the TMJs were felt to be a perpetuating factor to the myofascial TrPs in 30.4%.⁸⁹

Considering these data, it is important to make a distinction between true TMJ pain, MFP owing to TrPs alone, and MFP owing to TrPs that is being perpetuated by a noninflammatory or intermittently inflammatory joint condition. Treatment priorities will be affected accordingly.

Table 9 provides a simple breakdown of TMJ disorders, the vast majority of which are nonpainful. Included in this category are inflammatory disorders, disk derangement disorders, and osteoarthritis. It is possible to have several of these diagnoses affecting one joint. It is also very common to find myofascial TrP pain associated with TMJ pathosis.

The term *internal derangement* applies to all joints and encompasses those disorders causing mechanical interference to normal joint functions. In the TMJs, this primarily involves displacement and distortion of the articular disk, as well as remodeling of the articular surfaces, and joint hypermobility.¹¹⁴ Many of the articular disorders affecting the TMJs involve an abnormal or restricted range of motion and noise but are relatively painless. These include the congenital or developmental disorders, disk derangement disorders, osteoarthritis, and ankylosis listed in Table 9. Any pain associated with these disorders is usually momentary and associated with pulling or stretching of ligaments. In the case of *ankylosis*, pain ensues if the mandible is forcibly opened beyond adhesive restrictions. Forcible opening can cause acute inflammation. Primary or secondary *osteoarthritis*, unless accompanied by synovitis, is also associated with

minimal pain or dysfunction,⁹⁰ although crepitus and limited range of motion may be present.

As far as the incidence of TMJ pain in the general population is concerned, the National Institute of Dental Research, reporting on the National Center for Health Statistics' 1989 survey of 45,711 US households over 6 months, has estimated that 9,945,000 Americans were suffering from what they termed "jaw joint pain." They further estimated that 5.3% of the US population was experiencing this condition at any one time. Twice as many women as men complained of jaw pain.¹⁰⁴

Inflammatory Disorders Of The Joint. It is the inflammatory joint disorders that cause pain. Included in this group are *capsulitis and synovitis* and *polyarthritides* (see Table 9).¹¹⁵⁻¹¹⁷

Symptoms. Capsulitis and synovitis present with similar signs and symptoms and are difficult to differentiate. The chief symptom is continuous pain over the joint, aggravated by function. Swelling may be evident, and the patient may complain of an acute malocclusion ("back teeth on the same side don't touch"), restricted jaw opening, and ear pain. There is usually a history of trauma, infection, polyarthralgia, or chronic, nonpainful degenerative arthritis that is now in an acute stage.^{90,116} Because the pain is fairly constant, the clinical picture is often complicated by referred pain, masticatory muscle spasm, or myofascial TrP pain.¹¹⁶ The pain tends to wax and wane with the course of the inflammation. Inflammatory disorders of the joint may occur alone or in combination with an internal derangement.

Polyarthritides are relatively uncommon and occur with other rheumatological diseases, such as rheumatoid arthritis. Symptoms may include pain at rest and with mandibular function, crepitus, and a limited range of motion.

Etiology. *Inflammation of the capsule or synovium* may occur secondary to localized trauma or infection, through overuse of the joint, or secondary to other joint disorders. Synovitis may also occur secondary to primary osteoarthritis. The inflammatory conditions occur most commonly in young people with a history of trauma, clenching, bruxism, or internal derangement.¹¹⁸

Inflammation and degenerative changes in the TMJ caused by systemic rheumatological illnesses that affect multiple joints are called polyarthritides. They

most commonly include rheumatoid arthritis, juvenile rheumatoid arthritis (Figure 13A,B), psoriatic arthritis, and gout. The autoimmune disorders and mixed connective tissue diseases such as scleroderma, Sjögren's syndrome, and lupus erythematosus may also affect the TMJ.⁹⁰

Examination. For capsulitis and synovitis, palpation over the joint itself is painful. Posterior or superior joint loading and any movement that stretches the capsule may also increase the pain. Range of motion

is not usually restricted except owing to pain. Initiation of mandibular movement after a period of rest may be slow and "sticky." Inflammatory effusion in the joint may cause acute malocclusion with slight disclusion of the homolateral posterior teeth. Although clenching may be painful, biting on a tongue depressor may reduce the pain by preventing intercuspation and full closure.

In the polyarthritides, palpation of the joint is also painful. Range of motion is not affected except owing to

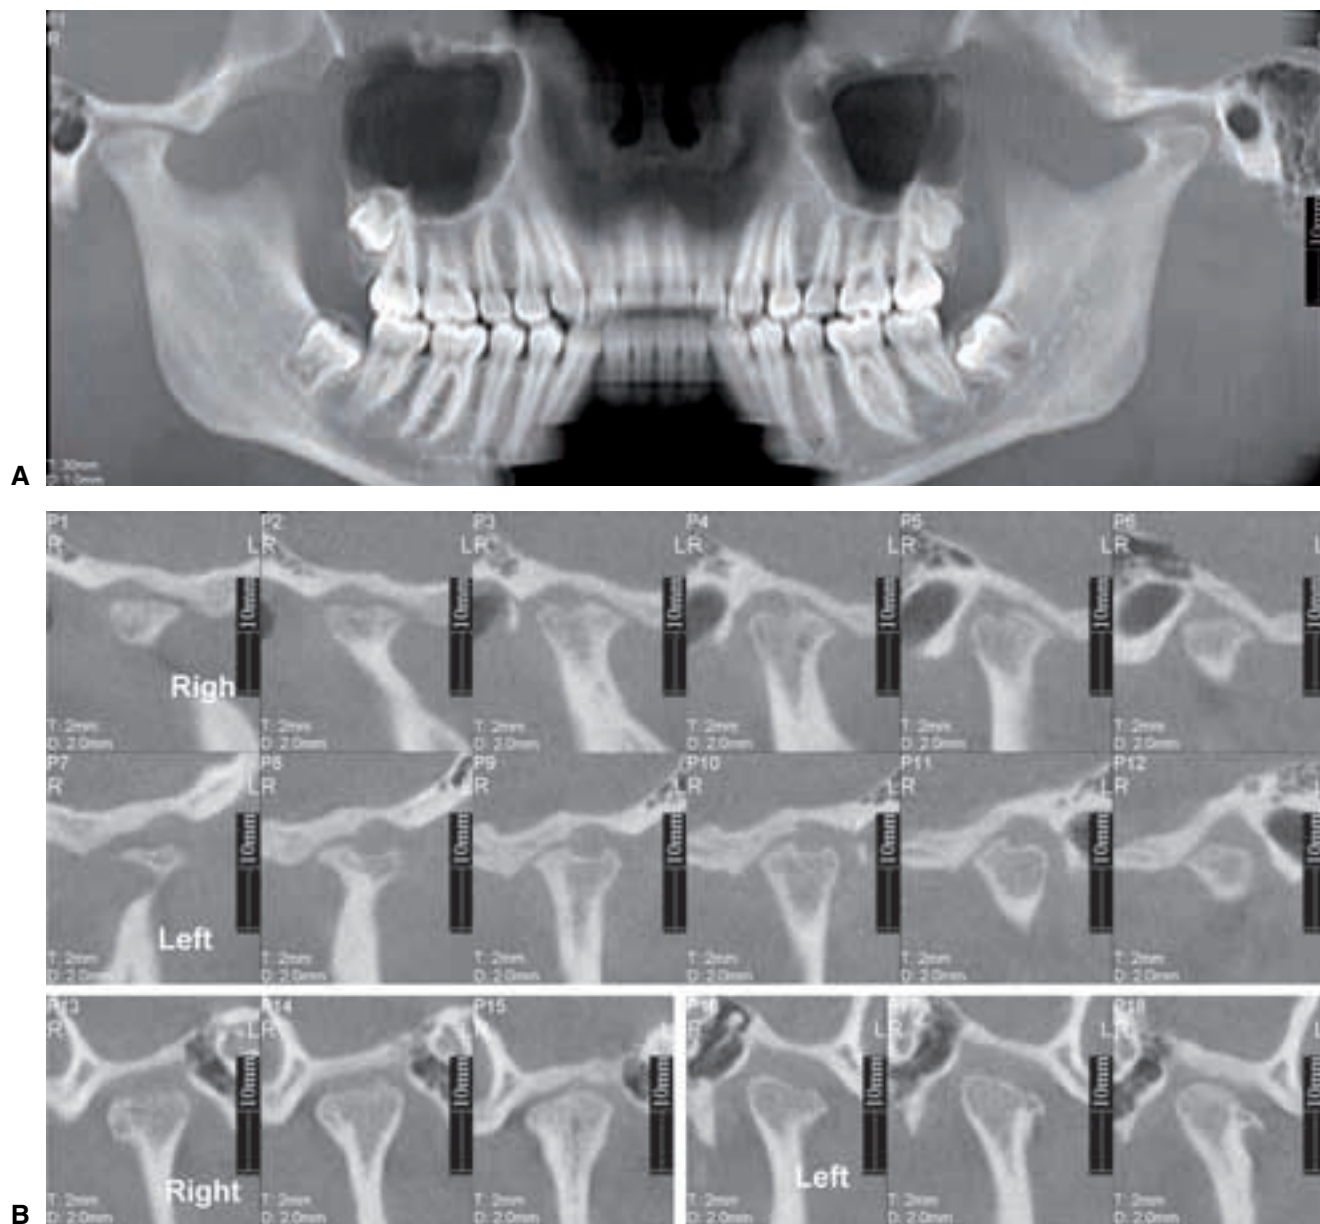

Figure 13 Tomography of a juvenile rheumatoid arthritic temporomandibular joint (TMJ). **A**, Observe the flattened surface of both TMJ condyles. **B**, Note the resorption of both articular surfaces of the TMJ and in particular, the important resorption of the left condyle. Courtesy, Dr. Marcela Romero.

pain and may be accompanied by crepitus; malocclusion is related to inflammatory effusion or lateral pterygoid muscle spasm secondary to the primary pain.⁸⁷ In severe cases of rheumatoid arthritis, rapid resorption of the condyles causes an acute anterior open bite.⁹⁰ Ankylosis may also occur.

Diagnostic tests. Plain radiographs and tomography will show a few, if any, bony changes in the joint with capsulitis or synovitis unless these are secondary to osteoarthritis. Magnetic resonance imaging, on the other hand, will show a bright T₂-weighted signal secondary to the presence of fluid.

The polyarthritides will show extensive TMJ changes on radiographic examination. Radiographic changes include more gross deformities than are seen in osteoarthritis, including erosions, marginal proliferations, and flattening. Of particular diagnostic value in the polyarthritides are various serologic tests screening for evidence of rheumatoid disease such as antinuclear antibodies, elevated erythrocyte sedimentation rate, rheumatoid factor, or anemia, although not all rheumatologic diseases are seropositive. Definitive diagnosis and management of the polyarthritides are left to the rheumatologist. The dentist's role is to manage concomitant TMJ symptoms should they occur.

Treatment. In treating inflammatory TMJ disorders, palliative care is an appropriate first step. This includes jaw rest, a soft diet, and *nonsteroidal anti-inflammatory drugs* (NSAIDs). Intermittent application of ice or moist heat may also be helpful. Office physical therapy, including ultrasonography, may be indicated in some patients. Single supracapsular or intra-articular injections of steroids may be effective in reducing inflammation and pain if simpler methods prove ineffective. Pain relief from steroid injection can be expected to last 1 1/2 to 2 years provided that the patient limits joint use appropriately. It is generally accepted that steroid injections into the TMJ should be limited: no more than two in 12 months, and two or three in a lifetime. This is because of concern about inducing joint deterioration owing to the steroid.¹¹⁹ More recent data suggest that these injections may be better tolerated than previously thought.¹²⁰

Definitive therapy is aimed at reducing the causative or contributing factors. This must involve the patient who alone controls the functional demands placed on the joint. The dentist must enlist his help and compliance. This is best achieved through reassurance and education. The patient must be motivated to reduce joint use and eliminate abusive habits. Home exercises,

application of heat and ice, and massage are also important. In addition to the self-help program, construction of a *stabilization splint* may help reduce *bruxism* and decrease intra-articular pressure on the joint. If necessary, a psychological approach to decrease bruxism or clenching may also be instituted. Surgery is seldom, if ever, indicated.

If the condition is owing to polyarthritis, management is similar to treating the systemic disease itself. It includes analgesics and anti-inflammatory agents such as aspirin, indomethacin, and ibuprofen, corticosteroids such as prednisone, gold salts, and penicillamine. Physical therapy, home exercises, appropriate jaw use, reduction of abusive habits, occlusal stabilization, and periodic intra-articular steroid injections are other supportive measures. Surgical intervention is limited to severe cases with marked dysfunction.

Disk Derangement Disorders. The disk derangement disorders include disk displacement with and without reduction.

Symptoms. Both of these disorders are typically painless. With *disk displacement with reduction*, pain, when present, is intermittent and related to interference or "jamming" of the disk and function of the condyle against ligaments. Patients may complain of difficulty in opening the jaws, particularly in the morning. Sometimes they have to manipulate their jaws, with a resultant loud crack, before they can function normally for the rest of the day.

Patients who present with *disk displacement without reduction* usually relate a history of TMJ clicking that stopped when the joint "locked." In addition to the limited range of motion, they may also complain of mild hyperocclusion on the affected side. Acutely, there may be pain that is usually secondary to attempts to open the mouth. Over time, the mandibular range of motion gradually improves and the pain subsides, often being replaced with a feeling of stiffness.

Etiology. The development of a disk displacement disorder is often attributed to external trauma, such as a blow, or to chronic microtrauma, such as *habitual parafunction* (especially *bruxism*) in the TMJ in which structural or functional incompatibilities exist. Occlusal disharmony, such as loss of posterior teeth or occlusal interferences in retruded and lateral movements, may contribute to the problem but is rarely causative.

Discrete clicks and pops are the result of the rapid reduction of an anteriorly displaced disk on opening

Figure 14 Internal temporomandibular joint (TMJ) derangement—the early click. Notice in the closed position **A**, that the disk (stippled) is situated completely anterior to the articulating surface of the condyle. As the condyle begins to translate anteriorly, it passes beneath the thickened rim of the disk at the same time the patient notices a “click” within the joint. At one fingerbreadth opening **B**, and throughout the remaining opening sequence **C**, and **D**, the relationship between the disk and the bony structure is normal and not painful. Reproduced with permission from Wilkes CH, *Minn Med*; 1978.

(Figure 14). Locking results when the disk is so severely displaced or deformed that it can no longer relocate itself on top of the condyle during normal opening movements (Figure 15).

Examination. With disk displacement with reduction, there is a normal mandibular range of movement. Palpation of the joint on opening and closing will reveal a fairly distinct click or pop that is often accompanied by a slight deviation of mandibular movement. These clicks and pops are usually found at approximately 25 to 30 mm of opening, the point at which the condyle shifts from rotation to translation in the opening cycle. Often these joint noises are reciprocal. That is, there is another, very soft click just at the end of the closing path. It is at this time that the disk once again slips off the condyle and into its anterior position.

With disk displacement without reduction, there is clear restriction of jaw range of motion to approximately 25 to 30 mm. If only one joint is locking, the midline will deviate toward the affected joint. Forced opening results in pain. Laterotrusive movement is restricted to the unaffected side; bilateral restriction exists if the disorder affects both joints.

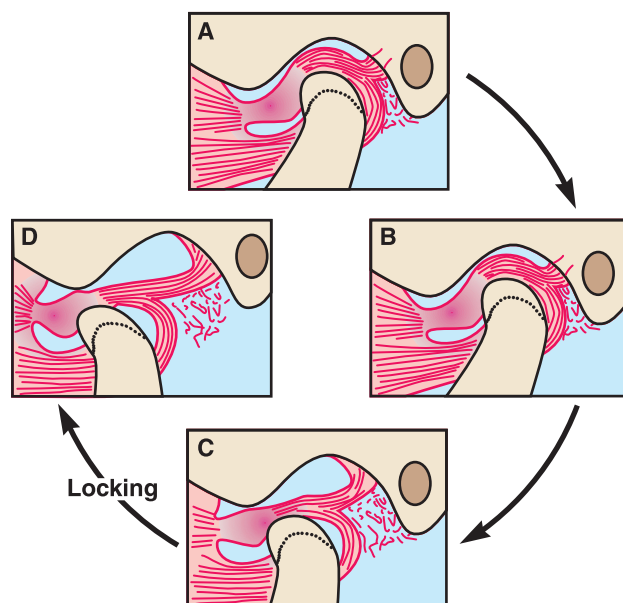

Figure 15 Severe disk derangement—the closed lock situation. In the closed projection **A**, notice that the stippled disk has been deformed from a normal biconcave wafer to an amorphous mass. The disk is situated entirely anterior to the condylar articulating surface. During jaw opening **B**, and **C**, the condyle progressively forces the disk mass anteriorly, causing greater deformation. At no point in the sequence does the condyle negotiate its way past the thickened posterior aspect of the disk to acquire a normal relationship. Locking **D**, and discomfort ensue. Reproduced with permission from Wilkes CH, *Minn Med*; 1978.

Diagnostic tests. For both disk displacement with and without reduction, tomograms of the joints may reveal a mild posterior displacement of the condyle in the glenoid fossa, although this is not a consistent finding and should not be used alone to make a diagnosis. Bony contour of the condyle will usually show only mild degenerative changes. Arthrography or magnetic resonance imaging (MRI) reveals anterior displacement of the articular disk in both conditions. In disk displacement with reduction, the anterior displacement typically normalizes during jaw function.

Treatment. Because most disk displacement disorders are nonpainful, many patients only require an explanation for their symptoms and reassurance. There is no clear evidence that all disk displacement disorders are progressive¹²¹ or that intervention prevents progression. In fact, most TMDs are self-limiting.^{122–124}

Specific treatment, when indicated, will depend on the specific nature of the derangement. Conservative, reversible treatments such as patient education and self-care, physical therapy, behavior modification, orthopedic appliances, and medications are

appropriate. Since most TMDs are self-limiting and resolve without serious long-term effects,^{125,124} extensive occlusal rehabilitation or surgery should be avoided except in carefully selected cases.¹²⁶

Osteoarthritis (noninflammatory). Osteoarthritis (noninflammatory) is found in many of the joints of the body and is classified according to the perceived etiology. *Primary osteoarthritis* is so-called because its etiology is unrelated to any other currently identifiable local or systemic disorders.¹²⁷ It may affect the TMJ alone or may include other joints of the body.^{124,128,129} When other joints are involved, any of the weight-bearing joints in the body may be affected. Heberden's nodes of the terminal phalangeal joints are a clinical feature.

Secondary osteoarthritis, on the other hand, is considered to be the result of a specific precipitating event (such as trauma or infection) or other disease or disorder (such as rheumatoid arthritis, endocrine disturbance or gout, or a TMJ disk derangement disorder).

Symptoms. Despite their classification as noninflammatory disorders, *primary and secondary osteoarthritis* may be associated with a secondary synovitis. As a result, the patient may complain of pain with function and tenderness over the joint. In the absence of synovitis, crepitus and limited range of motion are the most likely complaints.

Etiology. Osteoarthritis is a degenerative joint condition characterized by joint breakdown involving erosion and attrition of the articular tissue along with remodeling of the underlying subchondral bone¹³⁰ (Figure 16). Degenerative change is thought to be induced when the

Figure 16 Degenerative joint changes that occur to the disk and condylar surfaces. Disk perforation (arrow), allowing bone-to-bone contact, may cause crepitus and pain on opening and closing. Reproduced with permission from Dr. Samuel Higdon.

joint's natural physiological remodeling capabilities are exceeded owing to factors that overload and stress the joint.^{130,131}

Examination. The distinguishing clinical feature of osteoarthritis is crepitus: grating or multiple cracking noises within the joint during opening and closing. There may also be limitation of the movement of the condyle and deviation to the affected side with opening. When accompanied by synovitis, there is pain with function and point tenderness over the joint on palpation.

Diagnostic tests. Radiographic examination of the condyle may reveal decreased joint space, subchondral sclerosis, cystic formation, surface erosions, osteophytes, or marginal lipping. The articular eminence may be flattened or eroded or may contain osteophytes (see Figure 16). All clinical laboratory findings are usually within normal limits.

Treatment. Since most osteoarthritis is nonpainful and dysfunction is minimal, patients often do well with appropriate explanation of their symptoms and reassurance without specific treatment. When accompanied by synovitis and pain, treatment strategies for the acute inflammatory disorders are appropriate. In *secondary osteoarthritis*, identification of a precipitating disease or event may simplify treatment since correction of the underlying cause may facilitate the resolution of any symptoms associated with the osteoarthritis.

Congenital or developmental disorders. Congenital or developmental disorders such as *aplasia*, *hypoplasia*, and *hyperplasia* tend to cause esthetic and functional problems and are rarely accompanied by pain.

Temporomandibular joint dislocation. TMJ dislocation refers to that situation when a patient is unable to close his mouth because the condyle is trapped either anterior to the articular eminence or anterior to a posteriorly dislocated disk.¹³² Elevator muscle spasm usually aggravates the situation by forcing the condyle superiorly and opposing attempts to relocate the condyle in the glenoid fossa or on the articular disk. There is usually a history of nonpainful hypermobility and sometimes of previous dislocations that the patient was able to reduce himself.

Symptoms. The patient is distressed because of the inability to close the mouth and sometimes associated pain. There is acute malocclusion.

Examination. This reveals an anterior open bite with only the posterior teeth in contact. Visual inspection or palpation of the articular fossa may reveal a depression where the condyle would normally be.¹³³

Diagnostic tests. Radiographic examination shows the condyles anterior to the articular eminence or anteriorly displaced within the fossa.

Treatment. Reduction of the mandibular displacement is the goal and usually requires some kind of manual manipulation of the mandible. Initial steps include reassurance followed by gentle jaw opening against resistance to relax the elevator muscles. Manipulation procedures to reduce the mandible range from simple downward and posterior pressure on the chin during voluntary yawning, to downward and backward pressure on the mandibular molar teeth during yawning, to the administration of muscle relaxants or local anesthetics or even intravenous sedation followed by manual manipulation. Patients can expect some mild residual pain for one to several days following reduction.

Ankylosis in the TMJ refers to a fibrous or bony union between the condyle, disk, and fossa causing restricted mandibular range of motion with deflection of the mandible to the affected side but no pain. Ankylosis may follow joint inflammation caused by direct trauma, mandibular fracture, surgery, or a systemic disease such as arthritis. Treatment depends on the degree of dysfunction: arthroscopy and physical therapy may improve function for fibrous ankylosis (most common); open joint surgery is needed to create a new articulating surface in bony ankylosis (relatively rare). Elevator muscle shortening must be addressed as part of the management protocol for both conditions.

REFERRED PAIN FROM REMOTE PATHOLOGICAL SITES

Angina Pectoris

Severe pain of cardiac origin can be referred to the mandible and the maxillary region. The opposite pain reference has also been reported—pain from pulpalgia referring down the homolateral neck, shoulder, and arms.¹³⁴ That cardiac pain can be referred as far away as the jaws is fascinating. Yet remembering that dorsal root ganglion cells have been shown to branch in the periphery^{135,136} and that, in the rat at least, the dorsal root ganglion cell supplying the heart also supplies the arm¹³⁵ helps to provide a probable explanation to this referred pain phenomenon (Figure 17). Potential convergence of nerve fibers from different sensory dermatomes in the dorsal horn of the spinal cord provides a basis for a “convergence-projection” phenomenon for the pain referral (see Figure 6). The thoracic dermatomes, innervating the chest and arms, overlap with the cervical dermatomes, some of which innervate the arm and shoulder, as well as part of the lower face. The second cervical dermatome, in turn, slightly overlaps with the fifth cranial nerve that innervates the entire oral complex.

Symptoms. *Angina pectoris* is typically characterized by heaviness, tightness, or aching pain in the mid or the upper sternum. These symptoms may radiate upward from the epigastrium to the mandible—the left more frequently than the right. In addition, the inner aspects of the arms may ache, again the left

Figure 17 Branched primary afferent hypothesis of referred pain. According to this theory, a single primary afferent branches to supply both the deep structure stimulated and the structure(s) in which the pain is perceived. Reproduced with permission from Fields HL, McGraw-Hill; 1987.

Figure 18 **A**, Pattern of pain and referred pain emanating from myocardial infarction. Central necktie pattern and greater left jaw and arm pain than on the right side are typical. **B**, Harmless noncardiac pain in the left chest. Reproduced with permission from Turner GO, Med World News; 1973.

more frequently and extensively than the right. This pattern is similar to that seen with myocardial infarction (Figure 18A). Precipitating factors include exertion and emotional excitement or ingestion of food.¹³⁷ Angina attacks are usually short-lasting, rarely longer than 15 minutes. A number of patients with recurrent angina pectoris, who know they have the disease and who use nitroglycerine to control the attacks, have reported left mandibular pain with each spasm. Anginal pain referred to the teeth may be experienced with or without concomitant chest pain.¹³⁸

Myocardial Infarction

Myocardial infarction is characterized by a symptom complex that includes a sudden, gradually increasing precordial pain, with an overwhelming feeling of suffocation. The squeezing pain radiates in a pattern similar to that described for angina pectoris (see Figure 18A). Accompanying these symptoms may be a sense of impending doom, nausea, and the attendant signs of shock: sweating, cold clammy skin, and a gray complexion. In advanced stages, the patient becomes unconscious and cyanotic. If conscious, the patient generally complains of severe pain and rubs the chest, jaw, and arms. Thus myocardial infarct pain is similar to angina but is more pronounced, long-lasting, and does not resolve with rest. Severe pain in the left maxilla and mandible related to angina pectoris or myocardial infarction may occur without any other symptoms. Bonica reported an incidence as high as 18% for the presentation of cardiac pain as jaw or tooth pain alone.¹³⁹ The distribution of this cardiac pain may vary. One patient had the unusual symptoms of referred pain in the left maxilla and right arm but no chest pain. Matson reported a case of coronary

thrombosis during which the patient experienced “pain in both sides of the mandible and neck that radiated to the lateral aspects of the zygoma and temporal areas. She specifically denied having chest, shoulder, or arm pains...”¹⁴⁰ Norman¹⁴¹ discussed four unusual cases of myocardial infarction with pain referred to the right and left jaws. The left maxilla is also a common site. Batchelder and her colleagues¹³⁷ also reported a case in which mandibular pain was the sole clinical manifestation of coronary insufficiency. Krant¹³⁹ reported referred pain in the left mandibular molars that proved to be a manifestation of a malignant mediastinal lymphoma.¹⁴² It is these patients with jaw pain in the absence of other symptoms of heart disease who report to the dental office for diagnosis.¹³⁸

Etiology. *Angina pectoris* refers to pain in the thoracic region and surrounding areas owing to transient and reversible myocardial ischemia.¹⁴³ Coronary atherosclerosis with or without coronary artery spasm is the most common cause of myocardial ischemia. Any other cause of reduced myocardial blood flow may also cause angina, such as in aortic stenosis or isolated coronary artery spasm

Myocardial infarction refers to necrosis of the cardiac muscle secondary to a severe reduction in coronary blood supply.¹⁴³ Coronary artery occlusion is usually an abrupt event related to unstable atherosclerotic plaques. Predisposing factors include heredity, obesity, tobacco use, lack of physical exercise, diets high in saturated fats, emotional stress, and hostility and anger.

Examination. A careful history is important in diagnosing the referred oral pain of cardiac origin. Usually, the patient has a rather unusual story to tell, with a fairly severe pain that began rather suddenly in the left jaw and grew in intensity. The symptoms may sound very much like a pulpitis. The pain might even have moved from the mandible to the maxilla. The dentist must rule out dental pathosis quickly and efficiently.

Diagnostic tests. Radiographs and pulp testing of all of the teeth in the site of pain or rinsing with ice water will be equivocal. Analgesic block of the involved tooth or teeth will fail to relieve the pain.

After localized dental or TMJ origins have been ruled out, referred pain from the chest must be considered.

Treatment. If previously undiagnosed cardiac pain is suspected, the patient must be referred to an emergency room immediately. The patient should be transported by paramedic or emergency services personnel and not allowed to drive. It is wise to call the hospital and have them ready to receive the patient.

If the patient loses consciousness, basic cardiopulmonary resuscitation should be applied until help arrives. This may be lifesaving. Every dental office should be equipped with a defibrillator.

Thyroid

The thyroid is a butterfly-shaped gland situated in the neck superficial to the trachea at or below the cricoid cartilage. Thyroid hormone regulates the metabolic state of the body. Disorders of the thyroid gland are prevalent in medical practice, second only to diabetes as an endocrine disorder.¹⁴⁴ *Subacute thyroiditis* (viral inflammation of the thyroid gland) is of interest to the dentist because it may refer pain to the jaws and ears.

Symptoms. The typical symptom picture includes a sore throat with pain over at least one lobe of the thyroid gland or pain radiating up the sides of the neck and into the lower jaws, ears, or occiput. Swallowing may aggravate the symptoms. This is usually associated with a feeling of pressure or fullness in the throat. There may be mild fever, asthenia, and malaise.¹⁴⁴ Symptoms may wax and wane over a period of months and then finally resolve with return of normal thyroid function.

Etiology. Subacute thyroiditis is reported to occur 2 to 3 weeks after an upper respiratory infection and is viral in origin.¹⁴⁴

Examination. The thyroid gland may be visibly enlarged and will be exquisitely tender to palpation with nodularity (Figure 19). If thyroiditis or other thyroid disease is suspected, referral to the patient's physician should be made for a complete medical workup.

Diagnostic tests. A complete blood count may show an elevated leukocyte count. The erythrocyte sedimen-

Figure 19 Benign thyroid tumor that recurred following thyroidectomy is referring pain into the mandibular first molar on the homolateral side.

tation rate will be substantially elevated. Further workup and treatment are in the realm of the physician and will likely include various thyroid function tests.

Treatment. Subacute thyroiditis may resolve spontaneously. Large doses of aspirin and occasionally steroids are used to control the pain and inflammation. Thyroid supplements are sometimes indicated.¹⁴⁴

Carotid Artery

Carotidynia is a symptom of unilateral vascular neck pain which was first described by Temple Fay in 1927.¹⁴⁵ Stimulation of various parts of the carotid artery in the region of the bifurcation was shown to cause pain in the *ipsilateral jaw, maxilla, teeth, gums, scalp, eyes, or nose.*¹⁴⁶ Long thought to be a benign complaint, frequently associated with migraine, and often responding to migraine therapy,¹⁴⁷ carotidynia was removed from International Headache Society (IHS) classification in 2004 due to an apparent lack of radiological or pathological findings.¹⁴⁸ More recently, various systematic MRI and ultrasonic studies have found evidence of abnormal soft tissue infiltration surrounding the symptomatic carotid arteries, renewing the interest in carotidynia as a distinct disease entity.⁵⁰

Symptoms. The patient with *carotidynia* will most likely complain of constant or intermittent dull aching, rarely pulsing jaw and neck pain, with intermittent sore throat or swollen glands. The pain may also involve the *temple and TMJ region* and radiate forward into the *masseter muscle* with occasional concomitant tenderness and fullness. Aggravating factors may include *chewing, swallowing, bending over, or straining.* Females outnumber males in the ratio of approximately 4:1.¹⁴⁷ A history of migraine may be present. Precipitating factors may include an inflammatory response secondary to physical trauma or bacterial or viral infection, drugs, or alcohol.

Etiology. The nerves innervating the adventitial and intimal walls of the carotid artery are considered part of the visceral nervous system. The convergence-projection theory of referred visceral pain discussed earlier in this chapter may explain why pain is referred from the carotid artery to the skin and muscles of the head and neck region.

Recent studies support the idea that there is inflammation and abnormal soft tissue infiltration surrounding the symptomatic tender carotid bulb.¹⁴⁹

Examination. The examination may reveal tenderness and swelling over the ipsilateral carotid artery along with pronounced throbbing of the carotid pulse. Palpation may aggravate the pain. The thyroid is nontender. All other tests and examinations are

normal. Carotidynia has an extensive *differential diagnosis*, including such conditions as pharyngitis, otitis, bruxism, TMJ syndrome, neuralgia, myalgia, and temporal arteritis,¹⁵⁰ and these should be ruled out with appropriate history and examination prior to making a diagnosis of carotidynia.

Treatment. Medications used in the treatment and prevention of migraine headaches have been shown to be effective in controlling the symptoms of carotidynia.¹⁵¹ Some authors advocate the use of steroids and NSAIDs.¹⁵¹ Concomitant treatment of any myofascial TrPs will ameliorate the symptoms to some extent as well.

Cervical Spine

Disorders of the cervical spine and neck area may refer pain into the *facial region* owing to the convergence of cervical and trigeminal primary afferent nociceptors in the nucleus caudalis of the spinal trigeminal tract. The normal cervical spine has 37 individual joints, making it the most complicated articular system in the body.¹⁵² Most of the structures in the neck have been shown to produce pain when stimulated.¹⁵³ Pain may be elicited through several different pathological processes including trauma; inflammation or misalignment of the vertebral bodies; inflammation or herniation of the intervertebral disks; trauma or strain in the spinal ligaments; and strains, spasms, or tears of the cervical muscles.

Nonmusculoskeletal pain-producing structures of the neck include the cervical nerve roots and nerves and the vertebral arteries.¹⁵³ Trauma, inflammation, and compression are implicated in the etiology of pain from these structures as well.

Acute trauma and primary pathological processes of the neck are obviously not in the realm of the dentist to diagnose and treat; therefore, these will not be discussed. However, the cervical spine must be recognized as a potential source of dermatomal and referred pain into the head and the *orofacial region*. Chronic subclinical dysfunction of the cervical spine may produce complaints that first appear in the dental office. This dysfunction may serve as a powerful perpetuating factor in temporomandibular and facial pain disorders and must be screened for and appropriately managed for successful treatment outcome.

Cervical Joint Dysfunction. Cervical joint dysfunction refers to a lack of normal anatomical relationship and/or restricted functional movement of individual cervical vertebral joint segments.

Etiology. In the craniocervical region, cervical joint dysfunction may occur as the result of trauma (e.g., a

whiplash injury), degenerative osteoarthritis, or chronic poor postural habits that result in sustained muscular contraction and immobility. As the cervical spine loses mobility and adapts to abnormal positions, nerve compression, nerve root irritation, neurovascular compression, posterior vertebral joint irritation, and peripheral entrapment neuropathies may result.^{88,151,152} Entrapment or chronic irritation of the nerve roots in the C4 to C7 area generally produces pain in the respective dermatomes in the shoulder and arm regions (see Figure 10). Although C1, C2, and C3 nerve roots are not thought to be involved in compression or peripheral entrapment-type problems,¹⁵⁶ they do become inflamed through mechanical irritation by other neighboring structures such as the vertebral processes, muscles, or connective tissue capsules. When this occurs, pain may be experienced in the craniofacial, orofacial, mandibular, and temporomandibular regions (the C2–C3 dermatomes) (see Figures 10 and 20). Pain impulses from the first four upper cervical roots are thought to be referred to the trigeminal region (mainly V1 and V2) as a result of the proximity of the nucleus caudalis in the spinal trigeminal tract.⁵⁵ The nucleus caudalis descends into the spinal cord as far as C3–C4. These dermatomal and referred pain syndromes are particularly important to the dentist.

Symptoms. Local symptoms of cervical dysfunction may include stiffness, pain, and a limited range of motion of the head and neck.¹⁵³ The patient may also complain of throat tightness and difficulty in swallowing.¹⁵⁴

Figure 20 A study by Poletti revealed a slightly different distribution of C2–C3 dermatomes for pain than those previously defined by using tactile criteria. The upper figure **A**, depicts the C2 and C3 tactile dermatomes previously defined by Foerster. **B**, depicts C2 and C3 pain dermatomes as defined by Poletti. Reproduced with permission from Poletti CE, Cephalgia; 1991.

Dermatomal pains may have an aching or neuritic quality and typically follow the distribution of the cervical nerve root involved. *Referred pains* are usually deep and aching and may present as a unilateral headache, as in a headache syndrome known as “cervicogenic headache.”^{55,157,158} This headache has a clinical picture similar to migraine except the pain is strictly or predominantly unilateral and always on the same side. The patient may note that cervical movement or pressure on certain spots in the neck will precipitate a headache.

Examination. Postural evaluation is essential for all facial pain patients. Of particular importance is anterior head position. The examination of the cervical spine should include range of motion in flexion, extension, lateral flexion, and rotation. Additionally, the movement of the individual upper cervical segments (occiput—C1 and C1—C2) should be evaluated.^{86,88} Range of motion is often restricted with cervical dysfunction. Upper cervical dysfunction may be unilateral or bilateral.

Radiographic evaluation may reveal osteoarthritis or show a decreased cervical lordosis, evidence of soft tissue spasm, or muscular shortening. Most commonly, however, no pathological radiographic findings are present. More sophisticated radiographic techniques can pick up decreased cervical mobility.¹⁵⁹

Treatment. Physical therapy, including cervical joint mobilization along with a comprehensive home exercise program and postural retraining, is required to treat pain of cervical origin.

Local treatment of referred symptoms does not provide long-lasting, if any, relief. If the patient has a true dental or temporomandibular disorder and dysfunction of the cervical spine, both problems must be addressed. Very often craniofacial pain will resolve once the cervical problem is corrected. If pain exists in both regions, it is likely that the cervical problem is perpetuating the facial pain. It is extremely rare for pain to be referred in a caudal direction.¹⁰¹ Thus, facial pain only rarely causes neck pain.

Case history. The following is a classic example of misdiagnosis of a referred cervical pain problem. A 38-year-old woman presented herself to the Pain Management Center at the University of California at Los Angeles (UCLA) with a 14-year history of severe left hemicranial headaches that had forced her to give up working. Because of the unilateral distribution, they had previously been misdiagnosed and unsuccessfully treated as migraine. However, the pain was strictly unilateral and was present on a continuous daily basis (unlike migraine), with intermittent exacerbations. The quality of the pain was described as dull and aching, progressing to throbbing only when severe. The patient also had an endodontic history

involving the upper left second premolar, reportedly still sensitive. The dental examination revealed slight hyperocclusion of the involved premolar that was corrected. Thorough musculoskeletal range of motion examination of the TMJ and cervical spine revealed a very prominent Cervical spine dysfunction of atlas on axis on the left. There was no evidence of any internal derangement of the TMJ. Myofascial examination revealed several active TrPs that reproduced her pain complaint.

Physical therapy, including cervical joint mobilization along with a comprehensive home exercise program and postural retraining, was instituted. As treatment progressed, the painful area began to decrease in size until all that remained was the left TMJ and left lower-border mandible pain—the precise distribution of the C2 tactile dermatome (see Figure 20A) and C3 pain dermatome (see Figure 20B).

Myofascial TrP injections into the left splenius capitis muscle in conjunction with further physical therapy and a continued home program completely resolved the C1—C2 dysfunction and the associated dermatomal pain. The patient has now been pain free for 18 years.

The case of this patient illustrates how easy it would be to search in the TMJ and dental area for a cause for the pain when the true culprit is actually the neck. The role of cervical dysfunction and myofascial TrPs in this type of pain presentation has been thoroughly discussed.¹³⁴

A TMJ disorder is unlikely to be causing all of our initial patient's pain. However, on examination, a restricted mandibular range of motion was found, as well as radiographic evidence of degenerative joint disease. Perhaps these are incidental findings. Alternatively, if the internal derangement is painful or the joint is inflamed, it may also be a contributing factor.

Muscles

Myofascial TrP pain is discussed under section “Muscular pains” in this chapter.

Intracranial Pathosis

Although rare, intracranial lesions can cause pain referral to all areas of the head, face, and neck, including the oral cavity. Neurological or neurosurgical evaluation is critical to rule out space-occupying lesions, intracranial infections, or neurological syndromes.

Intracranial causes of head and neck pain can be classified into two groups: those caused by *traction on pain-sensitive structures* (which include the venous sinuses, dural and cerebral arteries, pia and dura mater, and cranial nerves) and those caused by *specific*

Table 10 Intracranial Causes of Pain

Neoplasm	Neurofibromatosis
Aneurysm	Meningitis
Hematoma/hemorrhage	Thalamic pain
Edema	
Abscess	Cerebrovascular accidents
Angioma	Venous thrombosis

CNS syndromes, such as neurofibromatosis, meningitis, or thalamic pain¹⁵⁹ (Table 10). Different types of cerebrovascular accidents and venous thrombosis may also cause painful CNS lesions. Most of these problems will, however, not be seen in the dental office and therefore will not be discussed in detail.

Intracranial lesions are rarely painful, but when they are, the pain is severe and difficult to treat.¹⁶¹ The quality of pain may vary from a generalized throbbing or aching to a more specific paroxysmal sharp pain. *Neurofibromatosis*, a condition in which there are numerous pedunculated tumors of the neurolemmal tissue all over the body, is not painful unless the tumors press on nerves. Intracranial lesions are usually associated with different focal neurological signs or deficits such as weakness, dizziness, difficulty in speaking or swallowing, ptosis, areas of numbness, memory loss, or mental confusion. If such neurological signs or deficits appear with a pain complaint, pain from intracranial sources must be ruled out. This will require referral to a competent neurologist or neurosurgeon. Treatment will depend on the diagnosis and may range from antibiotic or antiviral therapy for infective processes to surgical intervention for aneurysms and tumors to palliative pain management for inoperable cases.

In our patient, presented earlier, extensive examinations and sophisticated imaging techniques have already ruled out extracranial and intracranial pathosis as causes for her pain, although she does have active myofascial TrPs in the trapezius muscle referring pain into the angle of the jaw. This, however, does not account for her entire pain presentation. The other sources of pain must still be sought.

Neurovascular Pains

This category of pain encompasses several of the primary headache disorders (headaches not of

pathological origin) such as migraines, trigeminal autonomic cephalalgias (Iwata, Imai et al.), and simple intracranial vasodilation, as well as some headaches associated with pathological vascular disorders, such as temporal arteritis (Table 11). The list includes only those headaches that have a higher likelihood of presenting in the dental office.

In general, these headache types share the following features. They all have primarily a deep, throbbing, pulsing, or pounding quality, occasionally sharp, and occasionally with an aching or burning background. The pain is exclusively or *predominantly unilateral* with pain-free or almost pain-free periods between attacks. The main difference between the different headache types lies

Figure 21 Comparison of temporal pattern of three main “vascular” head ache types.

in their temporal patterns (Figure 21) and their associated symptoms.

MIGRAINE

Migraine is a debilitating, inherited, episodic disorder and a form of sensory processing disturbance in the CNS.¹⁶²

Symptoms. Migraine with aura, commonly known as “classic” migraine, is distinguished by the occurrence of transient focal neurological symptoms (the aura), 10 to 30 minutes prior to the onset of headache pain.

Visual auras are most common and may present as flashing lights, halos, or loss of part of the visual field. Somatosensory auras are also common and consist of dysesthesias that start in one hand and spread up to involve the ipsilateral side of the face, nose, and mouth.¹⁶³ The headache itself is predominantly unilateral in the frontal, temporal, or retrobulbar areas, although it may occur in the face or in a single tooth. The pain may begin as an ache but usually develops into a pain of throbbing, pulsating, or beating nature. Associated symptoms may include nausea, vomiting, photo- and phonophobia, cold extremities, water retention, and sweating. The headaches are episodic and can last anywhere from several hours to 3 days, with variable pain-free periods (days to years).

Migraine without aura or “common” migraine is similar to migraine with aura except that the headache occurs without a preceding aura. Migraine headaches

are more common in females and may begin in early childhood. The usual onset is between the ages of 20 and 40 years, with 70% of these patients reporting a *family history* of migraine. Some factors that may precipitate the headache include stress and fatigue, foods rich in tyramine (ripe cheese) or nitrates, red wines and alcohol, histamines, and vasodilators. Often patients with migraine, especially migraine without aura, have *overlying MFP*, causing additional dull, aching headache pain. The prevalence of TMDs and various orofacial pain (OF) disorders in relation to headaches has been reported.^{164–167}

Case history. The following is an example of an unusual presentation of a migraine headache of particular interest to the dentist. The patient was a 52-year-old woman who had a 7-year history of pain in the upper right quadrant, second premolar area, radiating to the right temple. The quality of pain was described as pulsing, sharp, and penetrating. The temporal pattern was intermittent, with 2 to 3 days of pain followed by 1 to 2 weeks without pain. The symptoms occurred without any identifiable precipitating factor, although loud noise seemed to make the pain worse. Associated autonomic symptoms were absent. Previous unsuccessful treatments included endodontic treatment of the right maxillary second premolar and an exploratory open flap in the same area, looking for fractures or external resorption. Topical anesthetics over the gingiva surrounding tooth #4 were similarly ineffective in relieving the symptoms. A diagnosis of migraine without aura was made based on the quality

Figure 22 Potential binding sites of the action of triptans in the trigeminovascular complex. Modified from Burstein et al.¹⁷⁴

and temporal pattern of the pain and the absence of dental pathema to explain the symptoms. Treatment with abortive migraine medications proved quite successful.

Etiology. The exact etiology and pathogenesis of migraine with aura headaches remain controversial. Evidence suggests that migraine is a disorder of cortical brain excitability,¹⁶⁸ which may be due to an increase or a disturbance of excitatory neurotransmitters and as a result enhancing the probability of cortical spreading depression (CSD). CSD is the experimental correlate of the aura.¹⁶⁹ The pain is thought to be referred to the more superficial cranial structures through convergence of vascular and somatic nerve fibers on single second-order pain transmission neurons in the trigeminal nucleus caudalis.¹⁷⁰ In addition, a sterile neurogenic inflammation caused by the release of vasoactive neuropeptides from nerves surrounding the affected intracranial vasculature is thought to be the nociceptive source. While the mechanism of pain generation in migraine is still controversial, evidence suggests that central sensitization in the trigeminocervical complex (the trigeminal nucleus caudalis and the dorsal horns of C1 and C2), together with the reflex connections of the trigeminal system with the cranial parasympathetic neuronal flow mediated through the pterigopalatine, otic and carotid ganglia, results in headache and cutaneous allodynia.^{168,171–174} It has been proposed that vasodilatation of the dural blood vessels activates the trigeminal sensory afferents that surround them. They then transmit the input to the trigeminocervical complex,

cervicomedullary junction, and C1–C2 levels of the dorsal horn. From there the signals are transmitted to the higher centers.^{168,175} The activation of the trigeminal sensory afferents around the dural blood vessels induces the release of SP, CGRP, glutamate, serotonin (5-HT), and nitric oxide (NO) from the trigeminal afferents exacerbating the vasodilation and neurogenic inflammation.^{169,173,174} The efficacy of the ergot alkaloids and a family of tryptamine-based drugs called “triptans” appears to be due to the ability of these drugs to cause a vasoconstriction in the cranial blood vessels.^{169,175} They do this through their binding action to serotonin 5-HT_{1B} and 5-HT_{1D} receptors (Figure 22). Furthermore, experimental pharmacological evidence suggests that triptans also act on the second-order neurons of the trigeminocervical complex reducing cell activity¹⁷⁸ and repressing the CGRP promoter,^{180,181} thereby inhibiting the transcription of this neuropeptide.

Many headache researchers and clinicians feel that migraine without aura is the same as migraine with aura, except that the aura is absent or not dramatic enough to be noted. Thus, the mechanism is thought to be similar. The cortical blood flow changes resemble closely those observed in migraine with aura.¹⁸² In addition, data indicate the possibility of a clinically silent CSD in migraine without aura not only in the cortex but also in the cerebellum.^{182,183}

There is, however, fairly good evidence that the pain of migraine without aura may actually be due to muscle tenderness and referred pain from myofascial TrPs

rather than cerebral vascular changes.^{167,184–187} This indicates that the nociceptive input to the CNS may be increased as a result of sensitization of peripheral sensory afferents.¹⁸⁸

Examination. The diagnosis of migraine can usually be made by history. Nonetheless, examination of the patient complaining of undiagnosed intermittent toothache or facial pain should include a thorough dental, TMJ, and muscle evaluation. Once obvious dental and joint pathology has been ruled out, and the qualitative and temporal pattern of the pain raises the possibility of dental or facial migraine, referral to an orofacial pain dentist should be made. Dental heroics should be avoided—*Diagnostic Tests.*

There are no diagnostic tests that will confirm the diagnosis of migraine headache. If the headache is of recent onset, a neurological evaluation including a CT scan or an MRI may be indicated. Thermography during an acute attack of migraine does show areas of increased blood flow on the side of the headache.^{189,190}

Treatment. Long-term management of migraine headache typically requires identification and control of any obvious precipitating factors. Restriction of alcohol intake and elimination of tyramine-containing foods¹⁹¹ are simple yet sometimes effective means of decreasing the frequency of migraine attacks. Regular meals and good sleep hygiene also help prevent the onset of migraine. If myofascial TrPs or musculoskeletal dysfunction is present, competent treatment of these will significantly reduce the frequency of vascular headache symptoms and reduce the need for migraine medications. For those patients in whom stress, depression, or anxiety play a role, psychological interventions such as stress management and relaxation training, biofeedback, or cognitive behavioral therapy may be indicated.

Medications used in the treatment of migraine include abortive and prophylactic drugs, the choice of which depends on the frequency of migraine attacks. Individuals who suffer less than three or four migraines per month may do well with abortive drugs that are taken during the onset of the headache or migrainous facial pain. Abortive drugs are particularly useful in migraine with aura for which the aura warns the patient that a headache is pending. The serotonin 5-HT(1B/1D) agonists or “triptans” are highly effective. They improve headache as well as nausea, photo- and phonophobia. Prophylactic medications are used when headache frequency exceeds three or four per month since the triptans may cause coronary vasospasm or ischemia. Prophylactic medications include β -blockers,

tricyclic antidepressants, calcium channel blockers, 5-HT antagonists, and antiepileptic drugs such as valproic acid, Gabapentin, and topiramate. The use of botulinum toxin is under investigation.¹⁹²

TRIGEMINAL AUTONOMIC CEPHALAGIAS

Cluster headaches and chronic paroxysmal hemicrania belong to the trigeminal autonomic cephalalgias. They share several clinical characteristics and may have similar etiological mechanisms. Nonetheless, they are easily distinguishable clinically and clearly differ from migraine.

Symptoms. *Cluster headaches* are probably one of the most painful conditions known by humankind and derive their name from their temporal pattern. They tend to occur in “clusters,” a series of one to eight 20- to 180-minute attacks per day lasting for several weeks or months, followed by remissions of months or years^{82,193,194} (see Figure 21). These headaches are found five to eight times more frequently in men than in women, particularly in *men* aged 20 to 50 years *who smoke*. The pain is a severe, unilateral, continuous, intense ache or burning that often occurs at night. Movements that increase the blood flow to the head may result in throbbing. The most common sites are either around or behind the eye radiating to the forehead and temple or around and behind the eye radiating infraorbitally *into the maxilla and occasionally into the teeth*, rarely to the lower jaw and neck. Because of the oral symptoms, serious diagnostic errors are committed by dentists. Researchers from UCLA reported that 42% of 33 patients suffering cluster headache had been seen by dentists and that 50% of these patients *received inappropriate dental treatment.*¹⁹⁵

Prodromal auras are absent with cluster headaches, but nasal stuffiness, lacrimation, rhinorrhea, conjunctival injection, perspiration of the forehead and face, and Horner’s syndrome (ptosis of upper lid and miosis) are characteristics. Precipitating factors may include alcohol or other vasodilating substances, such as nitroglycerine. Cluster headache patients typically pace the floor during their headaches owing to the intensity of pain. This is in contrast to the migraine patient who retreats to a dark room to sleep.

Cluster headaches may progress from the more classic episodic form, occurring in periods lasting 1 week to 1 year, with at least 2-week pain-free periods between, to a chronic form in which remissions are absent or last less than 2 weeks.⁸² Rarely is the chronic form present from the onset.

Case History. *The following history was obtained from a 42-year-old man who had suffered from cluster*

headaches for 27 years. The pain, located retro-orbitally on the right side, was described as intermittent, sharp, excruciating, and knife-like. Associated symptoms included tearing of the right eye, stuffiness of the right nostril, numbness on the right side of the face, and right conjunctival injection. The pain occurred one or two times per year in “cluster periods” of 1 to 5 weeks duration. The headaches typically lasted 60 to 75 minutes and could occur multiple times per day. During an attack, the patient would pace the floor and hit his head against doors and walls. He noted that red wine could precipitate an attack and avoided alcohol during headache periods. Past trials of various migraine medications were all without benefit. Oxygen inhalation at the onset of a headache attack, however, immediately relieved the pain. Of importance was a past medical history of myocardial infarction at age 35 and poorly controlled hypertension. These factors impacted treatment and will be discussed.

Chronic Paroxysmal Hemicrania (CPH)

As the name implies, it is typically an unremitting, unilateral headache disorder, although episodic versions have been identified.¹⁹⁶ CPH is characterized by short-lasting (2 to 30 to 45 minutes), frequently occurring attacks of pain (five per day for more than half of the time).^{82,197,198} The quality of pain is throbbing or pounding, with an intensity that parallels that of cluster headaches, the patient often choosing to pace the floor during an attack. Pain location is predominantly oculotemporal and frontal, always on the same side, and can spread to involve the entire side of the head and the neck, shoulder, and arm.¹⁹⁸ Cases involving CPH presenting as *intermittent toothache* have been reported.¹⁹⁹ Turning or bending the head forward may precipitate an attack in some cases.²⁰⁰ Associated symptoms include unilateral lacrimation, nasal stuffiness, and conjunctival injection. Nausea and vomiting are usually absent, as are visual or somatosensory auras. In contrast to cluster headache, CPH is seen *predominantly in women*.²⁰¹ Age at onset appears to be 20 years, although a variable pre-CPH period may exist.²⁰¹

Case history. A 21-year-old woman presented with a 3-year history of right-sided supraorbital headaches. These headaches had a full, tight, aching quality with shooting, stabbing exacerbations brought on by rapid head movement, sneezing, or running. Associated symptoms included ptosis and tearing of the right eye. The pain lasted approximately 1 hour and occurred three to four times per day. The longest the patient had ever been without pain since the onset of the headaches was less than 5 days. The headache was

completely responsive to indomethacin (NSAID), which is typical of CPH. Of interest was a family history of cluster headaches in her father and a cousin of her mother.

Etiology of trigeminal autonomic cephalalgias. The exact etiology or pathophysiology of *cluster headaches*, and CPH for that matter, is as yet unknown; however, involvement of the posterior hypothalamus is suspected.^{202,203} Over the years, many theories have been advanced to try to explain the pronounced sympathetic and parasympathetic symptomatology, the trigeminal distribution of the pain, and the periodicity. To date, no consensus has been reached. Vasodilation, once considered an important element in the pathogenesis of cluster, is now thought to be secondary to trigeminal activation.¹⁹⁴ This is because the pain of cluster headache typically precedes any extracranial blood flow changes, and intracranial blood flow studies have shown inconsistent results.¹⁹⁴ The unusual temporal pattern of cluster headaches implicates the hypothalamus that regulates autonomic functions and also largely controls circadian rhythms, as possibly triggering the primary neuronal discharge resulting in cluster headache pain.^{190,201} Studies of circadian changes in various hormone levels in cluster patients versus controls do support activation of the hypothalamic gray matter region during cluster headache.^{191,205,206} Others propose a complex neuroimmunological mechanism.²⁰⁷

The pathophysiology of Chronic Paroxysmal Hemicrania (CPH) is also unknown. Because of the autonomic and temporal similarities of CPH with cluster headache, similar mechanisms are implicated, yet studies of the cardiovascular and sweat responses as well as cognitive processing in the two headaches suggest that they are different.^{208,209}

Examination: Cluster headaches. The diagnosis is based on signs and symptoms. There are no diagnostic tests to confirm a diagnosis of cluster headache. Either the patient presents with a typical history and no abnormalities on physical and neurological examination or the examination may cause suspicion of organic lesions with an ultimately normal neuroimaging scan.⁸² Mild ptosis and miosis with or without periorbital swelling and conjunctival congestion may be present on the side of the headache if the patient is seen during or shortly after an attack.¹⁸⁹

As with cluster headaches, a careful history is the primary basis for diagnosis. Organic lesions should always be ruled out with any new headache disorder.

Treatment. Definitive treatment of cluster headaches and CPH is best left to the orofacial pain dentist or other health care providers with a specific interest in headache management.

Cluster Headaches

Many of the treatments used for migraine therapy are also useful in cluster headaches, including symptomatic use of subcutaneous or intranasal triptans.^{210–212} In general, however, prophylactic medications are more appropriate in cluster headache because of the frequency of attacks and because prodromal warning symptoms are rare. Cluster headache patients are often awakened from sleep, and the pain reaches its high intensity very quickly. Once the cluster period subsides, patients are weaned from their prophylactic medications until the headaches recur.

Oxygen inhalation (100% 7 to 8 L/min with a non-rebreathing mask), given at the very beginning of an attack for 15 minutes, may be successful in aborting an attack. Oxygen and subcutaneous sumatriptan or intranasal zolmitriptan are also useful as abortive options for the patient taking prophylactic medications who is experiencing breakthrough headaches. In rare cases of resistant chronic cluster headache, trigeminal ganglion lysis or gamma knife treatment may be considered.^{213–216}

Chronic Paroxysmal Hemicrania

Indomethacin is the medication of choice for CPH. If the pain does not resolve with this medication, it is unlikely to be CPH. Aspirin and naproxen have a partial effect, but the relief is not as dramatic as with indomethacin.¹⁹⁸

MISCELLANEOUS HEADACHES UNASSOCIATED WITH STRUCTURAL LESION

Symptoms. These headaches that include external compression headache, cold stimulus headache, benign cough headache, benign exertional headache, and headache associated with sexual activity⁸² are usually bilateral, short-lasting, and clearly related to a well-defined precipitating factor. For example, cold stimulus headache may result from exposure of the head to cold or from ingestion of cold substances.

The latter headache, also known as “ice cream headache,” typically occurs in the middle of the forehead after cold food or drink passes over the teeth and the palate and lasts less than 5 minutes. *Benign cough headache* is a bilateral headache of extremely short duration (1 minute) that is precipitated by coughing. Physical exertion may also result in bilateral throbbing headaches that may last anywhere from 5 minutes to 24 hours. In some individuals, *sexual excitement* precipitates bilateral headache. This headache intensifies with increasing sexual arousal and may become “explosive” at orgasm.

Etiology. *External compression headache* is precipitated by prolonged stimulation of the cutaneous nerves through pressure from a tight band, hat, swim goggles, or sunglasses. *Cold stimulus headaches* are caused by exposure of the head to cold or from sudden stimulation of the nasopalatine or posterior palatine nerves with cold foods such as ice cream.⁸² *Benign cough* and *exertional headaches*, as well as headaches associated with sexual activity, seem to occur more commonly in people with a history of migraine. The exact mechanism underlying these headaches is unknown but may be related to increased venous pressure in the head, transient hypertension, muscle contraction, increased sympathetic tone, or possibly the release of vasoactive substances.²¹⁷

Treatment. Most of these headaches can be prevented by avoiding the precipitating cause (e.g., pressure from swim goggles, exposure of the head to cold, rapid ingestion of cold substances, exertion). If necessary, frequent exertional headaches can be treated with prophylactic medications such as propranolol or NSAIDs.²⁰⁷

HEADACHES ASSOCIATED WITH VASCULAR DISORDERS

This category includes headaches that are attributable to demonstrable pathosis, such as *giant cell arteritis* or *acute hypertension*. Other pathological vascular causes of headache include vertebral or carotid artery dissection and intracranial ischemia owing to intracranial hematoma, subarachnoid hemorrhage, arteriovenous malformations, or venous thrombosis (see Table 11). Headaches owing to such intracranial pathosis are unlikely to appear in the dental office and are therefore not further described. Giant cell arteritis, however, which does, on occasion, present with dental symptoms, may produce serious, irreversible consequences if left unrecognized and untreated.

Giant Cell Arteritis (Temporal Arteritis)

Headache or facial pain from giant cell arteritis is relatively rare, but the dentist must know about this disorder and be able to recognize it because blindness is a serious potential complication.

Symptoms. The patient with giant cell arteritis is usually over 50 years old and may have other rheumatic symptoms, such as polymyalgia rheumatica. Involvement of the temporal artery may bring the patient in to see the dentist first because pain with mastication (“jaw claudication”) may be the first or only symptom. Friedlander and Runyon²¹⁸ reported patients with a *burning tongue and claudication of the muscles of mastication*. Guttenberg et al.²¹⁶ reported a

case mimicking dental pain that led to *inappropriate, ineffective endodontic surgery*.²¹⁹

The pain is usually unilateral and in the anatomic area of the artery and may also radiate down to the ear, *teeth*, and occiput with generalized scalp tenderness. Temporal arteritis may resemble a migraine attack because it, too, has a persistent throbbing quality that may last hours to days and the location is unilateral, over the temple area.²¹⁰ *Temporal arteritis*, however, has an *additional burning, ache-like quality*. The pain increases with lowering of the head, *mastication*, and movements that create increased blood flow to that artery. The patient may present with complaints of malaise, fatigue, anorexia, and weight loss if the arteritis occurs as a febrile illness. In advanced cases, patients may complain of transient visual loss on the side of the headache. This is a particularly severe symptom and requires immediate, aggressive treatment since thrombosis of the ophthalmic artery may result in partial or complete blindness.

Etiology. Arterial inflammation, which may often be associated with immunological disorders, is the causative factor in this headache. Arterial biopsy often reveals frayed elastic tissues and giant cells in the vessel walls on histological examination.²²⁰

Examination. Dental examination is negative. The temporal artery may be tender to palpation, thickened, and enlarged and may lack a normal pulse. Digital pressure with occlusion of the common carotid artery on the same side will frequently alleviate the symptoms. Ophthalmological examination or evaluation of optic ischemia is mandatory. Occasionally patients will have signs and symptoms that mimic other disorders.²²¹

Diagnostic tests. In giant cell arteritis, erythrocyte sedimentation rate, although a nonspecific test, will be significantly elevated above 60 mm/h Westergren. Definitive diagnosis is based on arterial biopsy. The entire temporal artery is typically removed to ensure sampling of diseased sections; skip lesions are common. Biopsy of the artery is essential because treatment involves high doses of steroids, but treatment is never delayed if visual disturbance is present.

Treatment. The dentist who suspects temporal arteritis should immediately refer the patient to a rheumatologist or an internist for complete workup. If optic symptoms are present, emergency ophthalmological examination is essential without delay.

Treatment of the condition consists of emergency dosages of steroids. When the elevated sedimentation rate has been reduced, maintenance doses of *prednisone* are administered as clinically determined.

Carotid Or Vertebral Artery Pain. The dissection of the carotid or vertebral arteries causes headache and cervical pain on the same side as the dissection. This serious, life-threatening condition is typically acute and accompanied by symptoms of transient ischemic attack or stroke. Since patients with this problem are unlikely to appear in the dental office, there need be no further discussion of this type of syndrome. *Idiopathic carotid-dynia* is discussed under the category of “Referred Pain From Remote Pathosis.”

Hypertension

Symptoms. Generalized throbbing headache may be a symptom of acute hypertension, especially if the diastolic pressure rises 25%.⁸²

Etiology. Usually, abrupt increases in blood pressure are associated with ingestion of a substance that causes vasoconstriction or a systemic disorder such as pheochromocytoma, preeclampsia, or eclampsia in pregnancy, or malignant hypertension. Chronic arterial hypertension is not reported to cause headache.²²¹

Examination. A routine blood pressure check is useful to rule out hypertension as a medical problem requiring treatment.

Treatment. Patients with acute or chronic hypertension should be referred to their family practitioner for management. Associated headaches resolve within 24 hours to 7 days after the resolution of the hypertension.

HEADACHE ASSOCIATED WITH ABUSE SUBSTANCES OR THEIR WITHDRAWAL AND HEADACHE ASSOCIATED WITH METABOLIC DISORDERS

These headache types are unlikely to present as a primary complaint in the dental office and thus will not be discussed further here.

Our patient's pain had none of the characteristics described in this category of pain. Therefore, vascular headaches can be excluded in the differential diagnosis.

Neuropathic Pains

Neuropathic pains are caused by some form of structural abnormality or pathosis affecting the peripheral nerves themselves. This is in contrast to the normal transmission of noxious stimulation along these nerves from organic disease or trauma. The structural abnormality or pathosis affecting the nerve(s) may have many different etiologies, including genetic disorders such as porphyria; mechanical damage from compression, trauma, entrapment,

traction, or scarring; metabolic disorders such as diabetes, alcoholism, nutritional deficiencies, or multiple myeloma; toxic reactions to drugs, metals, or certain organic substances; or infectious or inflammatory processes such as herpes, hepatitis, leprosy, or multiple sclerosis.

Not all neuropathies are painful. When they are, they may be dramatically so. The distinguishing feature of peripheral neuropathic pains in the head and neck region is the quality of pain, which is burning, sharp, shooting, lancinating, or electric-like. The distribution of the pain is limited to the anatomical pathways of the nerve involved and is almost always unilateral. Sensory abnormalities may include diminished pain sensation in the presence of hypersensitivity to typically nonpainful stimuli.

In general, *neuropathic pains* in the head and neck can be divided into two main groups, *paroxysmal* or *continuous*, based on their temporal pattern (Table 12).

PAROXYSMAL NEURALGIAS

Symptoms. Paroxysmal, lancinating, sharp, unilateral pain that follows a distinct dermatomal pattern is common to all paroxysmal neuralgias. The pain is often described as electric-like, shooting, cutting, or stabbing. The attacks may last only a few seconds to minutes, with virtually no discomfort between attacks. Sometimes patients notice vague prodromata of tingling and occasionally ache or burn after an attack. The attacks may occur intermittently, with days to months between a series of attacks. Usually, patients complain of “trigger areas” that, when stimulated, precipitate an attack. These are frequently located within the distribution of the nerve affected, usually on the skin or the oral mucosa. Neural blockade of the trigger area almost always relieves the pain for the duration of action of the local anesthetic. Should neural blockade fail to relieve the symptoms, either the diagnosis or the nerve block technique must be

questioned. Each type of paroxysmal neuralgia has its own distinct characteristics.

Trigeminal Neuralgia and Pretrigeminal Neuralgia

Trigeminal neuralgia or tic douloureux usually affects one or at most two divisions of the fifth cranial nerve.⁸² The *mandibular and maxillary* divisions are most commonly involved together, causing pain to shoot down the mandible and across the cheek into the teeth or the tongue. The maxillary or mandibular divisions alone are the next most frequently affected, with ophthalmic division neuralgias being the least common. The pain is unilateral 96% of the time. Touching and washing the face, tooth brushing, shaving, chewing, talking, or even cold wind against the face may set off the trigger and result in pain. Deep pressure or painful stimuli are usually tolerated without a painful episode. Patients go to extraordinary lengths, such as not shaving, washing, or brushing their teeth, to avoid stimulating the trigger area. Between attacks, patients are completely pain-free. Long remissions for months or years are not uncommon but tend to decrease with increasing age.

Trigeminal neuralgia is almost twice as common in women as in men and usually starts after the age of 50.²²³ Anyone under the age of 40 with this disorder should be referred to a neurologist to be worked up for a structural lesion or multiple sclerosis.

A syndrome of pain preceding the onset of true paroxysmal trigeminal neuralgia, known as *pretrigeminal neuralgia*, has been described.^{224–226} Patients may present themselves up to 2 years before developing trigeminal neuralgia, with pain usually *localized to one alveolar quadrant* and sometimes a sinus. They may describe this pain as dull, aching, and/or burning, or as a sharp (burning) toothache, not unlike pain arising from the dental pulp. Some patients may also report a “pins and needles” sensation. The duration of PTN pain may be 2 hours to several months, with variable periods of remission. Movement, usually opening of the mouth, may trigger the pain.

Dental pathosis may be minimal or absent. Retained root tips are the most common finding, and their removal has been associated with remission of pain. Obvious dental pathosis should be treated, but dental heroics in the absence of clinical or radiographic findings should be avoided. A UCLA group reported that 61% of the cases with PTN or trigeminal neuralgia were incorrectly diagnosed and treated for dental conditions.²²⁶ Onset of classic trigeminal neuralgia may be quite sudden and occurs in the same division affected by the PTN symptoms. The onset may follow remission produced by previous dental treatment.

Case history. A 67-year-old man underwent extensive dental treatment, including endodontic therapy and hemisection of tooth #30, followed by the placement of two different intraoral stabilization appliances, for a pain complaint that turned out to be trigeminal neuralgia. He had also seen a general medical practitioner and a neurologist, who were unable to identify a cause for his pain. A diagnosis of psychogenic pain was made. The reason the true diagnosis was not obvious was because the patient described the pain as constant and related to tooth #30, worsened by eating and talking. Careful questioning, however, revealed that the pain was not constant. Indeed, if he sat very still without talking or moving his mouth, he was pain-free. Movement of the tongue, touching the lower lip, and biting anywhere in the mouth seemed to be precipitating factors. Observation of an attack during the history and physical examination confirmed the diagnosis: the patient became very quiet, his lips began to tremble, and tears came to his eyes because the pain was so intense. The whole episode lasted less than a minute, after which the patient resumed normal conversation.

Glossopharyngeal neuralgia

Glossopharyngeal neuralgia is 70 to 100 times less common than trigeminal neuralgia.²²⁷ The symptoms include unilateral and rarely nonconcurrent bilateral stabbing pain in the lateral posterior pharyngeal and tonsillar areas, the base of the tongue, down into the throat, the eustachian tube or ear, and down the neck.²²⁸ Sometimes pain radiates into the vagal region and may be associated with salivation, flushing, sweating, tinnitus, cardiac arrhythmias, hypertension, vertigo, or syncope. Throat movements, pressure on the tragus of the ear, yawning, or swallowing may trigger the pain. Again, local anesthesia of the trigger area temporarily prevents precipitation of attacks. This can be accomplished by spraying the posterior pharynx with a topical anesthetic.

Eagle's syndrome may be the cause of symptoms similar to those of glossopharyngeal neuralgia,^{229–231} although some believe that this syndrome is not sufficiently validated.⁸² The symptoms that include a “sore throat” and *posterior tongue and pharyngeal pain* are thought to be related to the compression of the area of the glossopharyngeal nerve by a calcified elongation of the *stylohyoid process* of the temporal bone. Precipitating factors include fast rotation of the head, swallowing, and pharyngeal motion from talking and chewing. Blurring of vision and vertigo are rarely seen.

Nervus intermedius neuralgia

Nervus intermedius neuralgia is extremely rare.²³² The pain is described as a lancinating “hot poker” in the ear.²²⁸ It can occur anterior to, posterior to, or on the

pinna; in the auditory canal; or, occasionally, in the soft palate. A duller background pain may persist between attacks. Attacks may be accompanied by *salivation, tinnitus, vertigo, or dysgeusia*.²³³ The trigger area is usually in the external auditory canal. This neuralgia has also been termed *Ramsay Hunt syndrome, geniculate neuralgia, or Wrisberg's neuralgia* and is often associated with *herpes zoster* (or shingles).

Superior laryngeal neuralgia

Superior laryngeal neuralgia is also a rare neuralgia with paroxysmal neuralgic pains of varying duration, minutes to hours, located in the throat, in the submandibular region, or under the ear. Triggering factors include swallowing, turning the head, loud vocalizations, or stimulating the site overlying the hypothyroid membrane where the nerve enters the laryngeal structures.

Occipital neuralgia

Occipital neuralgia occurs in the distribution of the greater or lesser occipital nerves to the back of the head and mastoid process. The *ear and the underside of the mandible* may be involved because of the dermatomal patterns of C2 and C3 (see Figure 20). The pain often radiates into the *frontal and temporal regions*, occasionally with the same sharp, electric-like character of the other neuralgias, but may last hours instead of seconds. Sometimes the pain takes on a more continuous burning, aching nature. A case of maxillary right posterior quadrant dental pain owing to occipital neuralgia has been reported.²³⁴ Trauma, especially rotational injuries to the neck, may precede the onset. Trigger zones, such as those seen with trigeminal neuralgia, are rare. The pain may be associated with neck and back pain, and emotional stress is a common aggravating factor.

Etiology. The paroxysmal neuralgias are considered *symptomatic* if a specific pathological process affecting the involved nerve can be identified and *idiopathic* if not. Paroxysmal neuralgias rarely occur in young people unless there is a distinct compression of the nerve by a tumor or other structural lesion. Compression of the nerve either peripherally or centrally by bone, scar tissue, tumors, aberrant arteries, or arteriovenous malformations causes *focal demyelination*, which is postulated to result in ectopic firing and reduced segmental inhibition of the low-threshold mechanoreceptors and wide-dynamic-range relay neurons.²³⁵ The net effect is a *lowered threshold* of neuronal firing for which ordinary orofacial maneuvers such as chewing, swallowing, talking, or smiling may precipitate a neuralgic attack.

Trigeminal neuralgia, along with other paroxysmal cranial neuralgias, is typically considered idiopathic,

although nerve compression by intracranial arteries that have become slack and tortuous with age is thought to be the likely culprit.²³⁶ The *demyelinating* lesions associated with *multiple sclerosis* may also precipitate trigeminal neuralgia in younger individuals. The symptoms of trigeminal neuralgia associated with diabetic polyradiculopathy have also been reported.²³⁷

Glossopharyngeal neuralgia is more commonly, secondary to another pathologic disorder. For example tumors are found in 25% of cases. Local infection, neck trauma, elongation of the styloid process (Eagle's syndrome), and compression of the nerve root by a tortuous vertebral or posterior inferior cerebellar artery²³⁸ are other symptomatic causes of this ninth-nerve neuralgia. Unlike trigeminal neuralgia, glossopharyngeal neuralgia is almost never associated with multiple sclerosis,²²⁴ and has been reported to be associated with an anomaly of the nerve itself.²³⁹

Occipital neuralgia may be secondary to hypertrophic fibrosis of subcutaneous tissue around the occipital nerve following trauma, irritation of the nerve by the atlantoaxial ligament, spondylosis of the upper cervical spine, spinal cord tumors, or tubercular granulomas.²⁴⁰ Myofascial TrPs in the semispinalis capitis and splenius cervicis muscles may mimic this type of pain or may cause neuralgia-like symptoms owing to the entrapment of the greater occipital nerve as it passes through the tense semispinalis muscle fibers.⁸³ Since treatment of myofascial TrPs is noninvasive, with very low morbidity and no mortality, they must be carefully ruled out before neurectomy or other neuroablative techniques are considered.²⁴¹

Examination. A patient presenting with symptoms of *trigeminal neuralgia* must be worked up for dental disorders, sinus disease, and head and neck infections or neoplasms.^{90,242,243} Since nerve compressions from intracranial tumors, aneurysms or vascular malformations, or central lesions from multiple sclerosis may also cause symptomatic trigeminal neuralgia,^{244,245} all patients with trigeminal neuralgia-like symptoms should be worked up with an *imaging study* of the head, either contrast-enhanced CT or MRI, in addition to routine films.

Diagnosis of *pretrigeminal neuralgia* is based on the clinical presentation of constant *dull toothache pain* in the absence of dental or neurological findings and normal radiographic, CT, or MRI examinations.

Since *glossopharyngeal neuralgia* is more often associated with nasopharyngeal, tonsillar, or posterior fossa tumors or other pathosis than is trigeminal neuralgia, imaging studies including skull films, panoramic films, and MRI are essential.

In *Eagle's syndrome*, the diagnosis is usually established on the basis of radiographs, as well as intraoral finger palpation of the posterior pharyngeal area. Panoramic films should reveal a *stylohyoid process that is so long* that its image projects beyond the ramus of the mandible. Anything shorter is not significant, and other causes for the patient's pain should be sought. Pain is alleviated temporarily by neural block of the suspected compressive area. Treatment is primarily surgical shortening of the styloid process either through an intraoral or an extraoral approach.²²⁹

Occipital neuralgia requires a thorough musculoskeletal evaluation in addition to a cervical spine radiographic series to rule out neoplasms or other local destructive lesions. Digital palpation of the greater occipital nerve along the nuchal line may be painful. Caudal pressure to the vertex of the head while it is flexed and rotated toward the side of the pain may reproduce cervical compression symptoms.²⁴⁶ Sensory loss is rare. Because myofascial TrPs may mimic or accompany this disorder, careful palpation of the posterior cervical muscles for the tight bands and focal tenderness with referred pain, characteristic of myofascial TrPs, is essential.²⁴²

Treatment. Obviously, if a neuralgia is "symptomatic" or the result of identifiable pathema or structural lesion, treatment is directed at correction of the cause. For example, stylohyoid resection may be indicated if this is the cause of glossopharyngeal neuralgia. However, for idiopathic paroxysmal neuralgias, the first treatment of choice is the drug *carbamazepine (Tegretol)*. Carbamazepine is most efficacious in trigeminal neuralgia but has some success in glossopharyngeal or nervus intermedius neuralgias as well. Baclofen (Lioresal), gabapentin (Neurontin), pregabalin (Lyrica) and diphenylhydantoin (Dilantin) are also used, alone or in combination. All of these medications may cause varying degrees of dizziness, drowsiness, and mental confusion. In addition, carbamazepine may cause hematopoietic changes and baclofen may affect liver enzymes. Although such side effects are not as common as once thought and are less common with gabapentin and diphenylhydantoin; patients taking any of these medications must be monitored very closely initially. Patients on Dilantin must be very careful to not develop gingivitis that can lead to gingival hypertrophy.

In those infrequent instances for which these medications or combinations thereof are ineffective, or the patient becomes refractory to the medications or cannot tolerate them, either owing to severe drowsiness or frank allergy, neurosurgical intervention remains an

option. In *trigeminal neuralgia*, gamma knife radiosurgery is the newest alternative for treatment. *Gamma knife radiosurgery* is a neurosurgical technique using a single-fraction high-dose ionizing radiation focused on a small (4 mm), stereotactically defined intracranial target.²⁴⁷ The targeted cells necrotize without apparent harm to adjacent tissues. In *trigeminal neuralgia*, the beam is focused on the trigeminal sensory root adjacent to the pons. The results have been so good^{248,249} that some authors advocate gamma knife radiosurgery as the “safest and most effective form of treatment currently available for trigeminal neuralgia.”²⁴⁸ The procedure carries with it low morbidity (infrequent reports of delayed onset of facial tactile hypesthesia or paresthesias) and no mortality.²⁴⁷ Nonetheless, the long-term effects of this form of treatment have yet to be evaluated, and more traditional approaches to the surgical treatment of trigeminal neuralgia are still used, especially in younger patients.

Younger, healthier patients may choose to undergo *suboccipital craniotomy with microvascular decompression*.²⁵⁰ In this major neurosurgical procedure, which in some centers is now performed endoscopically, an attempt is made to relieve any pressure on the trigeminal sensory root from blood vessels or other proximal structures. The superior cerebellar artery is the most common offender because it tends to kink under the ganglion itself. Muscle or sponge may be used to hold the vessel away from the nerve root. In this way, pain relief may be obtained with no or minimal loss of sensation or damage to the fifth cranial nerve.^{250–253}

For older or medically infirm patients, alternatives to gamma knife radiosurgery include injection of glycerol into the arachnoid cistern of the gasserian ganglion or radiofrequency neuroablation of the trigeminal sensory root to destroy A δ and C pain fibers.^{253,254} Both of these procedures involve the percutaneous insertion of a needle through the cheek into Meckel’s cave. They are usually carried out by a neurosurgeon under local anesthesia with fluoroscopic control and take less than 45 minutes. The patient is conscious for both of these percutaneous procedures. Because they are relatively simple procedures, with low morbidity and mortality, they can be easily repeated should the symptoms return. Rare complications include corneal anesthesia, anesthesia dolorosa, injury to the carotid artery, and sixth cranial nerve palsy.²⁵⁵

Therapies, especially medications, used to treat true trigeminal neuralgia have been reported to work for *pretrigeminal neuralgia* as well.²⁵⁶

Idiopathic *glossopharyngeal neuralgia* can be managed with the same medications used for trigeminal

neuralgia. If these fail, microvascular decompression has been reported effective.^{257,258} Nerve section or radiofrequency rhizotomies have mixed results.^{258,259}

Because of its predominantly musculoskeletal etiology, *occipital neuralgia* lends itself best to nonpharmacological and nonsurgical treatments. Consequently, physical therapy, postural re-education, corrected ergonomics, home neck-stretching exercises, TrP injections, and even C2 nerve blocks, with or without corticosteroids, are the first line of approach.²⁴⁰ Surgical interventions, such as neurectomy,²⁶⁰ rarely provide long-term relief.²⁶¹

Surgical section of the nervus intermedius or the chorda tympani has been reported to relieve the pain of *nervus intermedius neuralgia*, as has neurectomy in the case of recalcitrant *superior laryngeal neuralgia*.^{262–264}

Neuromas

Neuromas are non-neoplastic, nonencapsulated, tangled masses of axons, Schwann cells, endoneurial cells, and perineurial cells in a dense collagenous matrix (Figure 23).

Etiology. Neuromas tend to develop when a nerve axon is transected, as might occur with a dental extraction, surgery, or trauma. The proximal stump of a transected nerve is still connected to its cell body and, in a few days postinjury, it will start to

Figure 23 Amputation neuroma revealed by biopsy. Strikingly clear-cut, tangled, and well-myelinated fibers, cut at various angles, are massed with irregular sheath and perineurial connective tissues into an abnormal aggregate of varying size and surrounded by well-vascularized fibrous tissue. Biopsy was occasioned by sharp, intermittent pricking “nerve pain,” 6 months in duration, becoming more diffuse and steady. Courtesy, Dr. Gordon Agnew.

sprout axons, in an attempt to re-establish continuity with its distal segment. Usually, this process is unsuccessful, especially in soft tissue; therefore, a tangled mass of tissue results.^{265,266} In the orofacial region, neuromas most commonly develop in the area of the mental foramen, followed by the lower lip, tongue, and buccal mucosa, all easily traumatized sites. Neuromas are least likely to occur in the inferior alveolar canal because the bone guides the tissue growth.

In a seminal research effort, Hansen²⁶⁴ found neuromas forming quite routinely in the extraction sockets of the rat alveolus. Four months after extraction, he noted axon and myelin sheath degeneration at the bottom of the alveolus. At 10 months, the appearance was that of a small traumatic neuroma. If this same phenomenon occurs as frequently in humans as in experimental animals, it might well account for persistent postextraction pain, for which the patient is finally classified as neurotic and the pain as psychogenic. Of 45 oral traumatic neuromas reviewed for clinicopathological features, 15 were painful, and 53% of these demonstrated inflammatory infiltrate under light microscopy.²⁶⁵ This was in contrast to only 17% of asymptomatic neuromas. Only 4 (9%) in this series were associated with extractions. Anoxia and local scar formation are thought to contribute to the production of pain.²⁶⁷

Symptoms. A neuroma may be completely asymptomatic, and, in fact, approximately 25% of them are. However, neuromas are capable of generating very prolonged electrical impulses in response to a variety of stimuli.²⁶⁵ They may even discharge spontaneously.

The diagnostic features of a neuroma include a history of prior surgery or a lacerating injury at the site of the pain, along with precipitation of the pain with local pressure or traction. The pain is short-lasting, with a burning, tingling, radiating quality. A drop of local anesthetic will abolish the response. If the neuroma has developed on the inferior alveolar nerve, it may be visible radiographically as a widening of the mandibular canal.

Neuromas may also occur in the *TMJ postsurgically* or post-lacerating trauma.¹⁰¹ Symptoms include restricted joint movement owing to adhesions and pain with neuropathic qualities (sharp, shooting, itching, burning) on stretching of the adhesions. The deep aching pain of musculoskeletal disorders is lacking.

Examination. In the oral cavity, neuromas may appear as nodules of normal surface color but usually are not visible or palpable. Of greater interest is the presence of a scar, indicating previous injury or surgery. In the TMJ, movement against adhesive

restrictions, as with jaw opening, should elicit short-lasting neuropathic pain.

Treatment. A one-time excision of a sensitive neuroma located in the accessible scar tissue is worth trying provided that the pain is localized and can be relieved by infiltration with a local anesthetic.⁶⁹ Unfortunately, neuroma excision and other peripheral neuroablative procedures provide significant relief in very few patients.²⁶⁸ *Neuromas often re-form*, and the pain may return. Medications such as carbamazepine (Tegretol) or amitriptyline (Elavil) may be helpful but should be used only if the patient feels that the pain is severe enough to warrant tolerating the side effects that may accompany these medications.

CONTINUOUS NEURALGIAS

Continuous neuralgias typically occur after some kind of peripheral nerve damage or “deafferentation.” This category includes postherpetic, post-traumatic, and postsurgical neuralgias, as well as anesthesia dolorosa. As with paroxysmal neuralgias, the continuous neuralgias follow the distribution of the damaged nerve but differ in that the pain is more or less continuous, with some fluctuation over time. Patients report altered sensations, dysesthesias, or pain in the distribution of the nerve that varies from tingling, numbness, and twitching to prickling or burning. They may also report “formication,” which is a sensation of worms under the skin or ants crawling over the skin. The dysesthesias are generally discomforting to the patient because they are continuous and exacerbated by movement or touching of the area. As with paroxysmal neuralgias, local anesthetic blocks of the nerve eliminate all paresthesias except numbness.

Postherpetic Neuralgia

Etiology. PHN follows an acute attack of *herpes zoster* (“shingles”). Herpes zoster is an acute viral infection produced by the deoxyribonucleic acid²⁶⁹ virus varicella zoster. Varicella zoster causes chickenpox in the young and afterward remains in the ganglia of sensory nerve endings in a dormant “provirus” form. Periodically, the virus reverts to its infectious state and is held in check by circulating antibodies. If an individual is immunocompromised or is older and has a low antibody titer, the infectious virus is able to retrace its path down the sensory nerve and escape into the skin, where it causes the typical skin eruptions and vesicles of zoster. Acute hemorrhagic inflammation with demyelination and axonal degeneration of dorsal root ganglion cells has been demonstrated in early and more recent pathological studies.²⁷⁰⁻²⁷⁴

Acute herpes zoster affects individuals over 70 years of age 12 times more frequently than persons under 10 presumably because their antibody titer decreases as their exposure to children with chickenpox diminishes. One or two of every 100 elderly people suffer an attack of shingles in a single year. They may have repeated attacks, often in the same distribution; 3.4 per 1,000 individuals develop PHN annually.²⁷⁵

Symptoms. Continuous pain in the distribution of the affected nerve and malaise commonly precedes the eruption of *acute herpes zoster*, sometimes along with paresthesia and shooting pains. Vesicles form, become infected, scab over, and heal. Small and sometimes severe scars are left behind. The scars are usually anesthetic, the skin between being hyperesthetic.

Ten to 15% of patients with herpes zoster develop lesions in the head and neck region, and 80% of these are in the ophthalmic division of the trigeminal nerve^{82,101} (Figure 24). C1–3 are also sometimes

Figure 24 Herpes zoster infection of the first division of the trigeminal cranial nerve. Courtesy of Faculty of Medicine, University of Toronto, Canada.

affected. When cranial nerve V1 is affected, vesicles may appear on the cornea, and the risk of impaired vision is high. If the infection affects the *maxillary division of the trigeminal nerve*, intraoral eruptions may develop concomitantly with those on the skin. Involvement of the oral mucosa without cutaneous involvement may occur and must be differentiated from aphthous stomatitis.¹⁰¹ Multiple devitalized teeth, isolated in a single quadrant, have been reported as a rare complication of herpes zoster infection.²⁷⁶ If the *facial nerve (cranial nerve VII)* is involved, facial palsy may occur owing to pressure on the nerve from inflammatory swelling in the bony canal. The pupil may become permanently paralyzed, and the upper eyelid may droop. Involvement of the geniculate ganglion causes lesions to erupt in the external auditory canal, may cause acoustic symptoms, and is known as Ramsey Hunt syndrome.¹⁰¹

PHN results when the pain of acute zoster does not subside as the acute eruption clears. The pain of PHN often has several distinct components.¹⁵ Patients complain of a steady, deep, aching pain along with superimposed sharp, stabbing pains similar to trigeminal neuralgia. In addition, many complain of *allodynia*, pain in response to light brushing of the skin, an innocuous event under normal circumstances. The pain is limited to the distribution of the affected nerve, and there is usually cutaneous scarring and sensory loss also.^{276,277} Complaints of *formication* are not infrequent. Since this pain is severe and unrelenting, it places a large emotional burden on the elderly patients who suffer from it. Interruption of sleep, drug reliance, depression, and even contemplation of suicide are common.

Examination. The history of acute zoster infection and the obvious scars it leaves behind make diagnosis relatively simple in most cases. PHN, on the other hand, may occur up to a month or two after the vesicular stage of herpes zoster has healed. If the patient knows he has had severe herpes zoster infection, the diagnosis may well be self-evident. The dentist, however, should carefully check the mouth to ascertain that a concomitant severe pulpitis is not superimposed on the condition.

Difficulty in diagnosis arises when the severe vesicular herpetic attack is not manifested but rather one or two small aphthous ulcers appear in the oral cavity or on the lips or face. This mild attack is often forgotten by the patient, and a careful history is essential.²⁷⁸

Treatment. In the future, new vaccines may reduce the overall incidence of chickenpox in the population or boost immunity to varicella-zoster virus in middle-

aged persons, thus preventing the emergence of the virus from its latent phase.²⁷⁹ Although age is the most important risk factor for the development of this painful chronic disorder, early treatment during the *acute phase of herpes zoster* with antiviral agents or certain tricyclics such as amitriptyline (antidepressants),²⁸⁰ combined with psychosocial support, may be effective in preventing the development of PHN.²⁸¹ Although sympathetic nerve blocks do tend to reduce acute herpetic pain, they have not been proven to be effective in preventing PHN.^{276,282,283} The treatment of PHN is often difficult and unrewarding. The longer the infection continues and the longer the patient has PHN, the more difficult pain management becomes. Tricyclic antidepressants, gabapentin, and opioids are the only medications that have shown efficacy in randomized clinical trials.²⁸⁰ Topical agents also work²⁸⁴ but are rarely effective alone.²⁸⁰ *Amelioration of the depression* that invariably accompanies this condition is as significant in therapy as reduction of the primary pain.

Posttraumatic Neuralgias

Traumatic injury to the peripheral nerves often results in persistent discomfort that is qualitatively different from PHN.

Symptoms. The pain is described as a continuous tingling, numb, twitching, or prickly sensation but without the intense, burning hyperesthesia usually seen with PHN or painful neuromas. The onset is following damage to the nerve by trauma or surgery. The discomfort can be self-limited, but total nerve regeneration is a slow, inaccurate process and can result in permanent dysesthesias or the formation of a neuroma.

Etiology. Peripheral degeneration or scarring of the nerve may be found on histopathological examination. Substance P has been implicated as a mediator of the pain, and depletion of this neurotransmitter has been shown to reduce the pain.

Treatment. Treatment of traumatic trigeminal dysesthesias may be met with varying success and can include any of the pharmacological therapies used for the other neuralgias as well as acupuncture, transcutaneous electrical nerve stimulation, and hypnosis. Capsaicin, a substance P depletor with significant long-term effects, has been used topically in the treatment of posttraumatic neuralgia with some success.²⁸⁵

All of the available therapies may be used individually or in combination with other interventions. In some cases of trigeminal neuropathy, in which peripheral nerve damage has resulted in continuous severe pain, electrical stimulation of the gasserian ganglion via an

implanted electrode has been shown to provide good pain relief.²⁸⁶

Anesthesia Dolorosa

This literally means “painful anesthesia” or pain in a numb area.

Etiology. Anesthesia dolorosa is considered a complication of deafferentation procedures such as trigeminal rhizotomy or thermocoagulation used to treat trigeminal neuralgia. It may also follow trauma or damage to the trigeminal nuclear complex or after vascular lesions of the central trigeminal pathways.⁸²

Symptoms. Patients complain of pain in an area that is otherwise numb or has decreased ability to detect tactile or thermal stimuli. Onset follows deafferentation of part or all of the trigeminal nerve, and the pain typically follows the distribution of the deafferented branches.

Examination. The painful area is numb or has diminished sensation to pinprick.

Treatment. Anesthesia dolorosa is a chronic intractable pain syndrome¹⁰¹ that is very difficult to treat. Centrally acting medications such as tricyclics or anticonvulsants may provide some relief.

Case history. *Our patient, described initially, has complaints that have characteristics of both the continuous and paroxysmal neuralgias. The constant burning pain could be a continuous neuralgia. Since there is no history of viral infection or herpes zoster outbreak, it is unlikely to be PHN. Since there is no history of deafferentation procedures, anesthesia dolorosa is also unlikely. However, multiple extractions and repeated dry sockets may have resulted in the development of deafferentation pain in V2 and V3. It does not explain the pain in V1, however.*

What about the sharp, shooting, electric-like pains the patient complained about? These are reminiscent of trigeminal neuralgia. However, the temporal pattern is inconsistent. Trigeminal neuralgia attacks are over in seconds to minutes; this patient complains of pains lasting 30 minutes to 24 hours. Also, the patient is too young for an idiopathic trigeminal neuralgia, and CT scans have failed to show any structural lesion that could account for such a pain. Thus, at this point, there is one possible diagnosis on our differential list, namely, post-traumatic deafferentation pain.

Causalgic Pains

Causalgia is a word derived from the Greek words *kausos*, meaning “heat,” and *algia*, meaning “pain.” Causalgia was first described by Mitchell in 1864 as a

pain that appears following damage to a major peripheral nerve by a high-velocity missile injury.²⁸⁷ Consequently, it is typically seen in the extremities. In 1947, Evans²⁸⁸ used the term RSD to describe the same burning pain. He noted that the pain had many features of sympathetic stimulation such as redness, swelling, sweating, and atrophic changes in the skin, muscles, and bones. He also found that minor injuries, such as fractures or sprains, could precipitate this pain, not just major nerve trauma. That same year, Bingham published the first report of RSD of the face.²⁸⁹

Today, RSD and in particular causalgia are considered the most dramatic forms of a class of pains called *sympathetically maintained pains* (SMPs), RSD occurring without and causalgia with a definable nerve lesion. Because the exact contribution of the sympathetic nervous system to RSD and causalgia is still under investigation, an effort was made in the mid-1990s to rename these types of pain disorders as “complex regional pain syndromes,” *type I and type II*, respectively.^{290,291} These terms eliminate the implied causal association of the sympathetic nervous system to these pain disorders. This terminology, along with clinical criteria, was included in the second edition of the IASP Classification of Chronic Pain Syndromes but has shown marginal reliability when tested clinically,^{291,292} and the terms SMP, RSD, and causalgia continue to be used.

Symptoms. The characteristic pain is a constant, hot, burning sensation with painful cutaneous hypersensitivity (hyperalgesia) and muscle tenderness.³ The pain is worse with light touch, heat, cold, or emotional stress.

Typically, RSD begins a few days to several weeks after an injury to or an inflammation of sensory afferent pathways.²⁹³ In the head and neck region, RSD has been reported to develop after maxillofacial surgery for cancer, head injury, *molar extraction*, and sinus surgery.²⁹⁴ If allowed to progress undiagnosed or untreated, RSD passes through an initial or “traumatic” stage characterized by a burning ache, edema, and hyperthermia to a second or “dystrophic” stage, with cool, cyanotic skin, spreading pain, and edema. The third or “atrophic” stage is evidenced by muscle atrophy; osteoporosis; smooth, glossy, mottled-appearing skin; and intractable pain. However, because of the abundant collateral blood circulation in the head and neck region, the bony, vascular, and trophic changes so typical in the extremities are less common in the face.²⁹⁴

Etiology. The exact pathophysiological mechanisms of RSD are unknown. What is known is that after experimental nerve injury, surviving primary afferent nociceptors develop noradrenergic receptors and become sensitive to noradrenalin,^{279,294,295} as do primary afferents that are experimentally cut and surgically repaired.²⁹⁶ Other experimental studies suggest that some regenerating primary afferents may anastomose with the regenerating postganglionic sympathetic axons that run with them.^{297,298} Posttraumatic sympathetic-afferent coupling also appears to occur in the dorsal root ganglion where sympathetic fibers that innervate the vasculature subserving the dorsal root ganglion begin to sprout around the primary afferent fibers^{299,300} (Figure 25).

Clinically, the sympathetic nervous system is implicated in these pains because sympathetic blockade provides profound relief, and electrical stimulation of

Figure 25 The influence of sympathetic activity and catecholamines on sensitized and damaged primary afferents. Normally, primary afferent neurons do not have catecholamine sensitivity, and their activity is unaffected by sympathetic outflow. After nerve lesion (1) or in the presence of inflammation, afferent terminals in the periphery or afferent somata in the dorsal root ganglion acquire sensitivity to noradrenalin (NA) by expressing α -receptors at their membrane. Activity in postganglionic sympathetic neurons is now capable of activating afferent neurons by the release of NA. In addition, sympathetic postganglionic neurons sprout around dorsal root ganglion cells (2). Reproduced with permission from Fields HL et al., *Neurobiol Dis*; 1998.

sympathetic outflow makes the pain worse.³⁰¹ Neither of these conditions exists in a normal individual. Changes in central pain pathways are also implicated in the RSD picture.³

Examination. The patient with causalgia/RSD complains of pain at the slightest touch and is difficult to examine. The skin may be flushed and dry or cold and sweaty, and a temperature difference may be discernible.

Diagnostic tests. Definitive diagnosis of the condition in the head and neck can be accomplished through immediate reduction of pain and hyperesthesia with a successful local anesthetic block of the stellate ganglion. This procedure requires a trained anesthesiologist since the stellate ganglion is located in close proximity to several vital structures, including the vertebral artery and the apex of the lung.

Treatment. Repeated sympathetic blocks are the treatment of choice for sympathetically maintained pains. Early intervention is best. For the upper extremities and the head and neck region, this involves repeated blocks of the stellate ganglion.²⁹⁴ Oral medications such as calcium channel blockers or low-dose tricyclic antidepressants with or without an anticonvulsant or systemic local anesthetic may be a useful adjunct.³⁰² Biofeedback and relaxation techniques may help reduce generalized sympathetic activity. Transcutaneous electrical nerve stimulation or acupuncture in combination with physical therapy may be helpful in providing relief and increasing function. Surgical removal of the upper sympathetic chain is the last resort procedure when all else has failed. If an inadequate sympathectomy is performed, the pain may return.

Case history. *Our patient complains of pain with many of the characteristics described for RSD and causalgic pain. The pain has a burning quality. The skin is hypersensitive. The affected side of the face is warmer to touch and slightly swollen. The pain is made worse with any type of stimulation. She has a history of tooth extraction with alveolar osteitis (dry socket). RSD of the face is definitely worth listing as a possible diagnosis.*

When dealing with any neuropathic or sympathetically maintained pain, referral to a neurologist should be considered if there are any subjective complaints or objective findings of cranial nerve deficits such as areas of facial hypesthesia, persistent motor weakness or paralysis, or a depressed corneal reflex.

Muscular Pains

Pain of muscular origin is generally described as a continuous, deep, dull ache or as tightness or pressure.

Table 13 Muscular Pains

Myospasm pain
Myositis pain
Local myalgia—unclassified
Myofascial pain
Tension-type headaches
Coexisting migraine and tension-type headaches

Adapted from Okeson.⁹⁰

It is undoubtedly the most prevalent cause of pain in the head and neck region.^{91,92,303} According to Bell,¹⁰¹ “a good rule to follow in diagnosing pains about the face and mouth is initially to assume that the pain is dental until proved otherwise, then muscular until proved otherwise.” Myospasm, myositis, and myofascial TrP pain will be discussed as part of this group (Table 13). “Local myalgia—unclassified” includes muscle splinting, which is grouped with other muscle disorders such as delayed-onset muscle soreness or pain owing to ischemia, bruxism, or fatigue. This is because there are a few clinical characteristics that differentiate these muscle disorders from each other.⁹⁰

Myospasm

Etiology. Myospasm, involuntary continuous contraction of a muscle or group of muscles, may occur owing to acute overuse, strain, or overstretching of muscle previously weakened through protective reflex contraction (see Figure 9). Commonly termed a “charley horse,” muscle spasm may occur, for example, after sustained opening of the patient’s mouth for dental treatment. Deep pain input from other sources such as joint inflammation, dental infection, or myofascial TrPs may also result in reflex spasm of associated muscles. In the absence of an obvious etiology, patients should be questioned regarding medication use. Medications such as Compazine (prochlorperazine) and Stelazine (trifluoperazine) or other major tranquilizers may cause muscle spasm. Prolonged use of this type of medication may also result in tardive dyskinesia, an irreversible condition consisting of involuntary movement of the tongue and/or lips.

Symptoms. An acutely shortened muscle with gross limitation of movement and constant pain is characteristic. The pain has a dull, aching quality with occasional sharp, lancinating pains in the ear, temple, or face. Depending on which muscles are involved, acute malocclusion may result. Patients may complain of increased pain on chewing or functioning of the spastic muscle. Headache may also result.

Examination. A normal jaw opening of 40 to 60 mm may be reduced to 10 to 20 mm with spasm. Malocclusion and abnormal jaw opening may be evident.

Diagnostic tests. Electromyography (EMG), surface, needle, or fine wire, will show substantially increased muscle activity even at rest.^{90,304} Injection of suspected muscles with plain 0.5% or 1% procaine or lidocaine should provide relief and confirm the diagnosis.

Treatment. If left untreated, the pain will subside. However, as a result of decreased function, there is a risk of developing contracture. Many episodes of “lock jaw” and torticollis (wry neck) are attributable to contracture. Therefore, patients should continue to use the jaw within pain-free limits. Heat may provide symptomatic relief. As the pain decreases, gradual active stretching of the muscle over a period of 3 to 7 days, with simultaneous application of counterstimulation or injection of the muscle with a weak solution of plain procaine or lidocaine, may facilitate restoration of normal function.

Myositis

Myositis is *inflammation* of muscles that, in the head and neck region, most frequently involves the masseter and medial pterygoid muscles. According to Bell,¹⁰¹ “*the familiar trismus* associated with dental sepsis, injury, surgery, or needle abscess typifies this condition.”

Etiology. Myositis is usually the result of external trauma (e.g., contact sports), excessive muscle overuse, or spreading infection (e.g., dental abscess).¹⁰¹ In fact, many of the same things that cause myospasm may cause myositis if prolonged or severe enough. The associated mandibular dysfunction is related to pain and to the presence of inflammatory exudate in the muscles. Myositis may progress to fibrous scarring or contracture.¹⁰¹

Symptoms. Characteristically, the patient complains of continuous pain over the muscle aggravated by jaw opening, limited jaw opening, and swelling over the involved muscle. There is usually a history of trauma or infection. If the cause is attributable to infection, the patient may also complain of malaise and fever.

Examination. Myositis can be distinguished from myospasm owing to the presence of swelling. The muscle is diffusely tender. Mandibular range of motion is severely restricted. *Regional lymphadenitis* is present if there is infection.

Treatment. Treatment of both myositis and contracture is similar to that used for myospasm, except that NSAIDs are also recommended. Exercises,

massage, and injections are contraindicated until acute symptoms have subsided.

Local Myalgia: Unclassified

Myospasm and myositis present with specific characteristics that allow a definite clinical distinction to be made. Other kinds of myalgias owing to ischemia, muscle overuse (fatigue and postexercise muscle soreness), or protective “splinting” or co-contraction also exist. However, currently, there is little scientific information to allow clear distinction between these disorders, and for this reason they are grouped together as unclassified myalgias.⁹⁰

Myofascial Pain

MFP, a regional referred pain syndrome associated with focally tender Trigger Points (TrPs) in muscle, is a prevalent cause of pain in all parts of the body and has been reported as a common source of pain in numerous medical specialties.^{91,93} For example, almost 30% of patients presenting themselves with a complaint of pain in an internal medicine practice⁶¹ and over 80% of patients in a chronic pain center⁹³ had MFP as a primary diagnosis. It is also the most prevalent cause of painful symptoms in TMDs.^{93,302}

In a study conducted at the University of Minnesota TMJ and Facial Pain Clinic, doctors evaluated 296 consecutive patients with chronic head and neck pain complaints.¹⁶⁵ MFP was the primary diagnosis in 55.4% of these patients. Nonpainful internal derangements of the TMJs were felt to be a perpetuating factor to the MFP in 30.4%. In contrast, only 21% of these patients had a true TMD disorder as the primary cause of pain. In this 21%, the joint disorder included inflammation of the TMJ joint capsule or the retrodiscal tissues.

Despite its prevalence and the recent surge in scientific documentation, *MFP* remains poorly understood and frequently unrecognized by most health care providers. Many physicians and dentists alike insist on calling it MFP and think of it as a myalgia of the facial muscles and masticatory muscles. Others feel that it is a syndrome that involves some internal derangement of the TMJ plus associated local muscle soreness.

Symptoms. In *MFP*, the presenting pain complaint is usually a *referred symptom* with a *deep, dull aching quality* located in or about normal muscular or, importantly, nonmuscular structures. In the head and neck region, the patient may complain of such things as toothache, sinus pain, TMJ pain, or headache, yet evaluation of these areas does not yield any pathological change. In fact, *any undiagnosed deep, dull, aching pain may be myofascial in origin.* The

intensity of MFP should not be underestimated: the pain intensity has been documented to be equal or slightly greater than that of pain from other causes.⁹¹

Associated symptoms, thought to be owing to the physiological sensory, motor, and autonomic effects seen with prolonged pain, are common and may confuse the clinical picture.^{305,306} These effects were discussed earlier in the section under “Neurophysiology of pain.” Associated sensory complaints may include tenderness in the referred pain site, such as scalp pain on brushing the hair, or abnormal sensitivity of the teeth.³⁰⁷ Motor effects include increased EMG activity in the pain reference zone^{308,306,309} although patients rarely complain about this specifically. Autonomic changes such as localized vasoconstriction (pallor),³⁰⁸ sweating, lacrimation, coryza, increased salivation, and nausea and vomiting have also been reported.⁸³

Patients note worsening of symptoms with increased psychological stress, cold weather, immobility, and overuse of involved muscles. Hot baths, rest, warm weather, and massage are typical alleviating factors.

Etiology. Myofascial TrPs can be primary or secondary. When primary, injury to the muscle owing to *macrotrauma* or *cumulative microtrauma* is typically involved. Macrotrauma is easily identified and includes injuries such as those caused by falls, blows, sports injuries, motor vehicle accidents, or even *prolonged jaw opening* at the dental office. Microtrauma is more insidious and includes muscle overuse owing to poor posture and body mechanics, abnormal strain, and repetitive motion-type injuries.

Secondary myofascial TrPs develop in response to prolonged underlying disease, especially if painful, for which any process that activates nociceptors may induce secondary muscle contraction and TrP development (described under section “Physiological mechanisms modifying pain” at the beginning of this chapter). Secondary MFP may prolong and complicate pain owing to other causes.³⁰⁵ Examples include migraine, inflammatory disorders of the TMJ, chronic ear infections, persistent pulpalgia, PHN, cancer, or any other chronic painful condition³⁰⁵ including *bursitis of the tensor villi palatini muscle* as it passes over the hamulus.³¹⁰ MFP needs to be identified and treated to reduce pain and improve response to other therapies. Patients with what appears to be primary MFP, in whom TrPs and pain recur despite appropriate initial response to TrP therapies and compliance to home exercise, must be reevaluated for occult underlying disease or other perpetuating factors.

In MFP, the presenting pain complaint is always associated with a TrP located in a taut band of skeletal muscle that is often distant from the site of pain. TrPs are focally tender, firm, nodular areas in muscle that, with the application of 2 to 4 kg of pressure for 6 to 10 seconds, produce spontaneous referred pain or intensify existing pain in local or distant locations.³¹¹ Patients are typically unaware of the existence of these TrPs. TrPs are considered active when the referred pain pattern and associated symptoms are clinically present and latent when they are not. TrPs will vacillate between active and latent states depending on the amount of psychological stress the individual is under and the amount of muscle overload placed on the affected muscle.

The location of TrPs and their associated referred pain patterns are predictable and reproducible from patient to patient^{83,312,313} (Figures 26–29). A meticulous discussion

Figure 26 Referred pain patterns from trigger points (TrPs) (crosses) in the temporalis muscle (essential zone, blue, spillover zone, green). **A**, Anterior “spokes” of pain arising from anterior fibers (trigger point, TP1). of MFP, as well as a complete compendium of the pain referral patterns for most muscles of the body, has been brilliantly detailed by Travell and Simons.^{83,313}

Pathophysiology. With some training, myofascial TrPs are relatively easy to palpate. Despite the comparative ease of clinical identification of TrPs, controversy still exists about their structure and exact pathophysiology, but progress has been made. Muscle biopsy studies using light and electron microscopy, as well as histochemical analyses, have not shown consistent abnormalities, and there is no evidence for inflammation.^{314,315} However, careful monopolar needle EMG evaluation revealed *spontaneous electrical activity* or “SEA” at the TrP sites, while evaluation of the muscle surrounding the TrP was normal.³¹⁶ This objective laboratory finding opened the door for establishing MFP as a clinical entity with an electro-

Figure 28 Composite pain reference patterns of the trapezius muscle, suprascapular region. Trigger points (TrPs) are indicated by arrows, essential pain reference zones by blue on posterior teeth. Spillover pain zones are stippled. Note temporal “tension headache” and reference to the angle of the mandible with spillover to posterior teeth. Reproduced with permission from Travell JG, J. Prosthet Dent; 1960.

myographical marker. The SEA is significantly higher in subjects with clinical pain due to active TrPs than in subjects without clinical pain who have latent or no TrPs.^{316,317} SEA can be recorded only if the needle is precisely placed in the nidus of the TrP; movement of the needle tip as little as 1 mm is enough to lose the signal.³¹⁶

In addition, Shah et al.,⁹⁵ using a unique *in vivo* microanalytical technique, have demonstrated that concentrations of protons, bradykinin, CGRP, substance P, tumor necrosis factor- α , interleukin-1 β , serotonin, and norepinephrine are significantly higher in active TrP sites than in latent TrP sites or in normal muscle. In addition, pH was significantly lower in the active TrP sites than in the other two groups.

Psychological stress, that causes increased sympathetic output, has been shown to increase the SEA recorded from TrPs, whereas the EMG activity of adjacent non-TrP sites remains unchanged.³¹⁸ These data parallel the clinical observation that emotional stress activates or aggravates pain from TrPs. Similarly, intramuscular or intravenous administration of

Figure 29 Pain reference from the sternocleidomastoid muscle. Wms & Wilkins; 1999.

sympathetic blocking agents effectively abolishes the SEA,^{319–321} whereas curare and botulinum toxin, postsynaptic and presynaptic cholinergic blockers, respectively, have no effect on SEA in randomized, controlled studies.^{316,319}

Based on the psychophysical evidence available to date and the observation that myofascial TrPs are frequently located in and around the motor end-plate area of muscles,^{323,324} Simons and Reeves et al.³²⁵ hypothesized that the myofascial TrP represents an area of isolated sustained muscle contraction due to excess acetylcholine release. This would result in uncontrolled metabolism, and localized ischemia that is initiated by acute muscle injury or strain.^{309,325} This theory does provide a credible explanation for the palpable nodules and taut muscle bands associated with TrPs. The TrP nodule is described as a group of “contraction knots” in which a number of individual muscle fibers are maximally contracted at the end-plate zone, making them shorter and wider at that point than the noncontracted neighboring fibers. If enough fibers are so activated, a *palpable nodule* could result. As for the taut band, both ends of these affected muscle fibers would be maximally stretched out and “taut,” producing the palpable taut band (Figure 30).

Clinically, data exist documenting that TrPs are truly focally tender areas in muscles; pain with palpation is not owing to generalized muscle tenderness.^{325,326} Indeed, tenderness to palpation over non-TrP sites in subjects with MFP does not differ

significantly from normals.³²⁵ Also, muscle bands containing TrPs will display a local *twitch response*, a transient contraction of the muscle band with deep “snapping” digital palpation. This response, best appreciated in more superficial muscle fibers, has also been substantiated experimentally.³²⁷ A rabbit model of the twitch response has documented that, at least in rabbits, the twitch response is a spinally mediated reflex.^{328,329}

The mechanism of referred pain from myofascial TrPs is also under speculation. According to Mense⁵⁰ and Vecchiet et al.,³³⁰ the convergence-projection and convergence-facilitation models of referred pain (described earlier under section “Referred pain”) do not directly apply to muscle pain because there is little convergence of neurons from deep tissues in the dorsal horn.⁵⁰ These authors propose that convergent connections from other spinal cord segments are “unmasked” or opened by nociceptive input from skeletal muscle and that referral to other myotomes is owing to the release and spread of substance P to adjacent spinal segments^{50,331} (see Figure 6). Simons⁵² has expanded on this theory to specifically explain the referred pain from TrPs (see Figure 7).

The following is an excellent example of myofascial TrP pain developing in response to an acutely inflamed TMJ.

Case history. A 47-year-old man with a long-standing history of painless osteoarthritis of both TMJs presented himself with an acute left TMJ inflammation.

Figure 30 Schematic of a trigger point (TrP) complex of a muscle in the longitudinal section. **A**, The central TrP, which is drawn in the muscle end-plate zone, contains numerous “contraction knots,” maximally contracted individual muscle fibers that are shorter and wider at the end plate than the noncontracted neighboring fibers. **B**, is an enlarged view of part of the central TrP showing the distribution of five contraction knots. The vertical lines in each muscle fiber identify the relative spacing of its striations. The space between two striations corresponds to the length of one sarcomere. Each contraction knot identifies a segment of the muscle fiber experiencing maximal contracture of its sarcomeres. The sarcomeres within these contraction knots are markedly shorter and wider than the sarcomeres of the neighboring normal muscle fibers. In fibers with these contraction knots (note the lower three individual knots), the sarcomeres on the part of the muscle fiber that extends beyond both ends of the contraction knot are elongated and narrow compared with normal sarcomeres. At the top of this enlarged view is a pair of contraction knots separated by an interval of empty sarcolemma between them that is devoid of contractile elements. This configuration suggests that the sustained maximal tension of the contractile elements in an individual contraction knot could have caused mechanical failure of the contractile elements in the middle of the knot. If that happened, the two halves would retract, leaving an interval of empty sarcolemma between them. In patients, the central TrP would feel nodular as compared to the adjacent muscle tissue because it contains numerous “swollen” contraction knots that take up additional space and are much more firm and tense than uninvolved muscle fibers. If enough fibers are so activated, a palpable nodule could result. As for the taut band, both ends of these affected muscle fibers would be maximally stretched out and “taut,” producing the palpable taut band. Reproduced with permission from Travell JG & Simons DG, Vol I, 2nd edn. Wms & Wilkins; 1999.

This was conservatively treated with rest, soft diet, and anti-inflammatory medications. Severe symptoms subsided, but the patient continued to complain of persistent “aching of the left jaw.” Clenching the teeth together produced a high-pitched ringing in his left ear. Careful history revealed that the pain was no longer specifically over the joint but was actually inferior and anterior to the left TMJ over the masseter muscle. Active range of motion of the mandible had increased from 41 to 47 mm, and the joint was nontender to palpation. Despite the negative joint examination, the less astute clinician may still direct his or her energies toward treating the TMJs, especially since there is documented osteoarthritis bilaterally, worse on the left. However, the source of pain is now from myofascial TrPs and not the joint. Palpation of the masseter muscle, particularly the deep fibers, reproduced the patient’s current symptoms, including the ringing in his left ear (Figure 31). TrPs in this part of the masseter muscle have also been reported to cause unilateral tinnitus⁵² and accounted for the high-pitched sound that the patient complained of with clenching. Treatment must be directed at rehabilitating the masseter muscle and not at the asymptomatic joint.

Examination. Because the patient’s pain complaint is typically a referred symptom, it is usually distant from the muscle containing the guilty TrP,^{83,331} although some TrPs also cause more localized pain symptoms. Multiple TrPs can produce overlapping

areas of referred pain (Figure 32). The pattern of pain can be used in reverse to identify possible etiological TrPs. *Systematic fingertip examination* of suspected muscles and their contralateral counterparts, looking for taut bands and focal tenderness, is *essential* (Figure 33). Effective TrP palpation is a skill that must be learned and practiced. Depending on the muscle, the tip of the index finger should be used for flat palpation or the index finger and the thumb for pincer-type palpation.^{11–36} Once a TrP is found, 2 to 4 kg/cm² of pressure should be applied for 6 to 10 seconds to elicit the referred pain pattern, if any. The examination may replicate the patient’s pain so precisely that there is no doubt about the diagnosis. If uncertainty exists, specific TrP therapies, such as “spray and stretch” or TrP injections, described below, may be used diagnostically. *All head and neck muscles*

should be routinely examined in patients with a persistent pain complaint. This will help identify both primary and secondary MFP in addition to help identify TrPs in key muscles (e.g., upper trapezius or sternocleidomastoid) that may be inducing or perpetuating satellite TrPs in muscles located in the pain referral sites (e.g., temporalis).^{83,306}

Treatment. Recommended treatment of MFP involves most importantly identification and control of causal and perpetuating factors, patient education, and specific home stretching exercises. Therapeutic techniques such as “spray and stretch,” voluntary contract release, TrP pressure release, and TrP injections^{332,333} are useful adjunctive techniques that usually facilitate the patient’s recovery. *Myofascial TrP therapists* are especially adept at TrP examination, spray and stretch, and TrP pressure release techniques.

Perpetuating factors most commonly include mechanical factors that place an increased load on the muscles. Teaching patients good posture and body mechanics will go a long way in reducing referred pain from myofascial TrPs, especially in the head and neck region.³³⁴ An *intraoral stabilization splint* may be indicated to decrease the frequency of clenching or bruxing as a perpetuating factor.

Psychological factors, such as *stress* that has been shown to cause TrP, activation, or *depression* that lowers pain thresholds, will contribute to MFP. Sleep disturbance and inactivity are also common perpetuating factors. Simple stress management and relaxation skills are invaluable in controlling involuntary muscle tension if this is a problem. Mild depression and sleep disturbance can be treated with low doses of *tricyclic antidepressant drugs* and a structured exercise/activation program.

Other perpetuating factors include metabolic, endocrine, or nutritional inadequacies that affect muscle metabolism.⁸³ Patients should be screened for general good health and referred to their physician for management of any systemic abnormalities. In secondary MFP, the primary concomitant painful disorder, such as TMJ capsulitis, pulpitis, or PHN, must also be treated or managed.

Spray and stretch is a highly successful technique for the treatment of myofascial TrPs that uses a vapocoolant spray (Gebauer, Co., Cleveland, OH) to facilitate muscle stretching. Muscle stretching has been shown to reduce the intensity of referred pain and TrP sensitivity in patients with MFP.³³⁵ The vapocoolant is applied slowly in a systematic pattern over the muscle being stretched and into the pain reference

Figure 33 Muscle palpation for myofascial trigger points (TrPs). **A**, “Flat” fingertip palpation of the masseter muscle looking for taut bands and focal tenderness characteristic of myofascial TrPs. The flat palpation technique is also useful for temporalis, suboccipital, medial pterygoid, and upper back muscles. **B**, “Pincer” palpation of the deep clavicular head of the sternocleidomastoid muscle. **C**, “Pincer” palpation of the superficial sternal head. zone (Figure 34). This technique and alternatives not using a vapocoolant are described in detail in the Travell & Simons text.⁸³

Needling of TrPs with or without injection of solution has also been shown to be helpful in reducing the TrP activity to allow stretching.^{333,335–339} Dry needling or injection of “key” myofascial TrPs has been shown to reduce the activity and tenderness in related satellite TrPs.³⁴⁰ Although dry needling is effective, the use of a local anesthetic reduces postinjection soreness.³³⁵ If a local anesthetic is to be injected, 0.5% procaine or 0.5% lidocaine is recommended. Longer-acting amide local anesthetics or local anesthetics containing epinephrine

cause permanent muscle damage.³⁴¹ Injection must always be followed by stretch.⁸³ Trigger point injection in the absence of a home program that addresses relevant perpetuating factors will provide only temporary relief. Randomized controlled studies looking at the efficacy of botulinum toxin in comparison to dry needling, saline or other placebo solutions in trigger point injections have shown that overall Botox is no more effective than dry needling or other solutions.^{342,343}

Tension-type headaches. *Tension-type headaches* are usually bilateral, with a pressing, nonpulsating quality. They last 20 minutes to 7 days when episodic and may be daily without remission when chronic.⁸² Overlapping referred pain patterns from myofascial TrPs can produce a typical tension-type headache (see Figure 31). Studies have documented the presence of focally tender points and referred pain in this type of headache.^{184,344} Thus, the same treatment strategies used for MFP also work well for the reduction of tension-type headache.^{332,344}

Coexisting migraine and tension-type headache. *Coexisting migraine and tension-type headache* (previously termed mixed headache, tension-vascular headache, or combination headache and now often described under the term transformed migraine, chronic daily headache, or new daily persistent headache) combine features of both tension-type and neurovascular headaches. These patients have varying degrees of each of these two headache types. Typically, they complain of dull, aching, pressing head pain that progresses into a throbbing headache. This type of headache has an even higher incidence of pericranial muscle tenderness and referred pain than tension-type headache.¹⁸⁴ Treatment requires management of the MFP as well as judicious use of abortive or prophylactic migraine medications.

Although our patient did not complain specifically of deep, aching pains, secondary MFP does occur with most types of chronic pain input into the CNS system. Therefore, it is likely that secondary myofascial TrPs have developed. In fact, when the patient was initially examined, TrPs were found in the upper trapezius muscle that referred pain to the side of the temple and the face (see Figure 26). Even if this is not the primary cause of the pain, it is likely to be a contributing factor.

Unclassifiable Pains/Atypical Facial Pains

Mock et al.³⁴⁵ have stated, “The diagnoses of atypical facial pain and atypical facial neuralgia are often applied interchangeably to the patient with poorly

localized, vaguely described facial pain, nonanatomic in distribution with no evidence of a defined organic cause.” Technically, these are not “atypical” pains but idiopathic pains, pains for which we do not yet have a diagnosis or sufficient understanding. Yet if we look at the retrospective analysis of data collected on 493 consecutive patients who presented to a university orofacial pain clinic, a different picture emerges.³⁴⁶ A diagnosis of atypical facial pain was made if patients had persistent orofacial pain for more than 6 months for which previous treatments had been unsuccessful and the diagnosis was unknown on referral to the clinic. Of the 493 patient charts reviewed, 35 (7%) met these criteria. Using the American Academy of Orofacial Pain diagnostic criteria,⁹⁰ all but 1 (97%) had diagnosable physical problems and sometimes multiple overlapping physical diagnoses causing the pain. Over half (19 of 35 or 54%) were found to have MFP owing to TrPs as a primary cause or a significant contributing factor to the pain. Eleven (31%) had periodontal ligament sensitivity, eight had referred pain from dental pulpitis, three had neuropathic pain, and one each had burning mouth from oral candidiasis, sinus pathology, burning tongue from an oral habit, pericoronitis, or an incomplete tooth fracture.

There is currently significant controversy in the field about the diagnosis and classification of atypical facial pain. Myofascial TrP pain is clearly under-recognized^{296,296} and trigeminal neuropathies or “dysesthesias,” which many believe to be at fault for various “atypical” facial pains, are still inadequately understood.³⁴⁷ Although proposals for nomenclature and classification changes abound,^{347–349} this “atypical” nomenclature is likely to haunt the dental/orofacial pain profession for several years to come.

Two types of atypical pain that commonly appear in the dental office are *atypical odontalgia* (idiopathic toothache, phantom odontalgia,³⁴⁹ or trigeminal dysesthesia) and *burning mouth syndrome* (BMS) (Table 14). Although deafferentation (neuropathic pain) is believed to play a role in both of these pain syndromes, the mechanism and the etiology are still largely speculative. Therefore, it is as yet difficult to reliably classify them under any of the diagnostic categories already discussed.

Table 14 Unclassifiable Pains

Atypical odontalgia
Burning mouth syndrome

Atypical Odontalgia

In 1979, Rees and Harris³⁵⁰ described a disorder they called atypical odontalgia. Synonymous or almost synonymous terms include phantom tooth pain,³⁴⁹ idiopathic orofacial pain,³⁵¹ vascular toothache,¹⁰¹ and, more recently, trigeminal dysesthesia. Patients present with chronic toothache or tooth site pain with no obvious cause.^{352,353} It is extremely important for dentists to be aware of the existence of this syndrome to avoid performing unnecessary dental procedures and extractions. It has been postulated that as many as 3% to 6% of endodontic patients may suffer from this type of tooth pain, especially if they had pain prior to pulp extirpation.³⁴⁹

Symptoms. The chief complaint is a deep, dull, aching pain in a tooth or tooth site that is unchanging over weeks or months. The pain is fairly constant, with some diurnal fluctuation, and usually worsens as the day progresses. The molars are most commonly involved, followed by premolars. Anterior teeth and canines are less frequently affected.³⁵⁴ The vast majority of patients present themselves with unilateral pain, although other quadrants may become involved and other oral and facial sites may hurt.

Most patients are *female* and *over 40 years* of age. Table 15 lists the clinical characteristics of patients with atypical odontalgia as reported by several different authors. The onset of the pain may coincide with or develop within a month or so after dental treatment (especially endodontic therapy or extraction) or trauma or medical procedures related to the face.³⁴⁹ Patients may have a history of repeated dental therapies that have failed to resolve the problem. Chewing or clenching on painful teeth, heat, cold, and stress are typical but inconsistent aggravating factors.

Etiology. The true etiology of atypical odontalgia remains elusive. Bell¹⁰¹ classified it as a vascular disorder, as did Rees and Harris, who postulated a “painful migraine-like disturbance” in the teeth and periodontal tissues, possibly triggered by depression.³⁵⁰ There are no data to support this idea, although a study using subcutaneous sumatriptan in 19 atypical facial pain patients did show some small temporary positive effects,

Table 15 Clinical Characteristics of Patients with Atypical Odontalgia*

N = 30
Age 58.4 years
Duration 4.4 years
90% female

*Seen at the University of Florida College of Dentistry.³⁵⁶

possibly supporting a vascular contribution to the pain.^{355,356} Others have suggested depression or some other psychological disorder as the cause^{357,357} since many patients with atypical odontalgia report depressive symptoms on clinical interview.^{349,359,360} However, these results must be questioned owing to poor, uncontrolled study methodology and because there is a generally higher incidence of depression in patients with chronic pain. Of interest is the fact that standard *MMPI* scores for patients with *atypical odontalgia* compared with standard scores for a chronic headache group (matched for age, sex, and chronicity) were similar, and scales for both groups were within normal ranges,^{354,361} making a psychological cause unlikely.

A more probable cause of atypical odontalgia is *deafferentation* (partial or total *loss of the afferent nerve supply* or sensory input) with or without sympathetic involvement. Atypical odontalgia usually follows a dental procedure, and most dental procedures, including cavity preparation, cause varying degrees of deafferentation. Studies supporting this theory are also lacking, yet the symptoms and clinical presentations are consistent with *posttraumatic neuropathic pain*. Many cases respond to sympathetic blocks³⁵⁴ or phentolamine infusion,³⁶² implying that at least some may be sympathetically mediated or maintained. This theory would also explain why the pain remains even after the painful tooth is extracted. In addition, the preponderance of females suffering from this disorder raises the question of the role of estrogen and other female hormones as a risk factor in atypical odontalgia and related idiopathic orofacial pains.³⁶³

Examination. Intraoral and radiographic examinations are typically unrevealing. If the pain is in a tooth as opposed to an extraction site, responses to percussion, thermal testing, and electric pulp stimulation are variable. Clinically, there is no observable cause, yet thermographic evaluation is always abnormal.³⁶⁴ The majority of patients report little or no relief with diagnostic local anesthetic blocks,^{354,365} although sympathetic blocks seem to be helpful.³⁵⁴

Treatment. *Invasive, irreversible treatments*, such as endodontic therapy, exploratory surgery, extraction, or even occlusal adjustments, are contraindicated.^{349,365} This is because, despite possible transient relief, the pain is likely to recur with equal or greater intensity.

The current treatment of choice is the use of *tricyclic antidepressant agents* such as *amitriptyline* or *imipramine*.^{349,353,354} Pregabalin has also shown some promise.³⁶⁵ If the pain has a *burning quality*, the addition of a *phenothiazine*, such as *trifluoperazine*, may be helpful.^{349,365} Tricyclic antidepressants have

analgesic properties independent of their antidepressant effects and often provide good pain relief at a fraction of the dose typically used to treat depression.^{360,367,368} Pain relief normally occurs at doses from 50 to 100 mg. Dry mouth is an expected and usually unavoidable side effect. A history of significant cardiac arrhythmias or recent myocardial infarction, urinary retention, and glaucoma are contraindications for the use of tricyclic medications because of their atropine-like action. Patients may need reassurance that the pain is *real and not psychogenic* but that invasive procedures will not help.

If a patient complains of associated gingival hyperesthesia, the use of topical agents such as local anesthetic or capsaicin has been shown to be beneficial.³⁶² Unwanted stimulation of the area can be reduced by construction of an acrylic stent that can also be used to help apply any topical medication.

Burning Mouth Syndrome

BMS is an intraoral pain disorder that most commonly affects postmenopausal women. The National Institutes of Dental and Craniofacial Research report on the national Centers for Disease Control household health survey stated that 1,270,000 Americans (0.7% of the US population) suffered from this disorder.¹²⁴ When it primarily affects the tongue, it is referred to as burning tongue or glossodynia. Grushka and her colleagues³⁶⁹⁻³⁷² have conducted several studies to systematically characterize the features of this syndrome.

Symptoms. Patients complain of intraoral burning, the tip and sides of the tongue being the most common sites, followed by the palate. Dry mouth, thirst, taste and sleep disturbances, headaches, and other pain complaints are frequently associated symptoms. Onset is often related to a dental procedure. The intensity of pain is quantitatively similar to that of toothache, although the quality is burning rather than pulsing, aching, or throbbing. The pain increases as the day progresses and tends to peak in the early evening. Patients with BMS may complain of spontaneous tastes or "taste phantoms" (dysgeusia).³⁷³

Etiology. There are many obvious oral and systemic conditions that are associated with mucogingival and glossal pains. These include candidiasis, geographic tongue, allergies to dental materials, denture dysfunction, xerostomia, various anemias and vitamin deficiencies (iron, vitamin B₁₂, or folic acid), diabetes mellitus, several dermatological disorders (lupus, lichen planus, erythema multiforme), human immunodeficiency virus, or systemic medications (either directly or indirectly through resultant

xerostomia).^{124,374,375} However, in BMS, controlled studies have documented that the oral mucosa appears normal, and no obvious organic cause can be identified.^{372,375} There is evidence for a higher incidence of immunological abnormalities in BMS patients than would be expected in a normal population, and several BMS patients have been shown to have Sjögren's syndrome.³⁶⁹

Recent research supports a theory that damage to or dysfunction of the chorda tympani branch of CN VII contributes to the dysgeusia and pain of burning mouth.³⁷⁶ The special sense of taste from the tongue is mediated by the chorda tympani (anterior two-thirds) and CN IX (posterior one-third). The chorda tympani innervates the fungiform papillae of the tongue, which, in turn, are surrounded by pain fibers from cranial nerve V. The chorda tympani normally inhibits both cranial nerve V (pain fibers) and cranial nerve IX (taste). Damage or partial deafferentation of the chorda tympani appears to release inhibition of both cranial nerves V and IX, producing both pain and taste phantoms, respectively.^{374,377}

BMS is not to be confused with postmenopausal oral discomfort that has a burning component. In the latter condition, estrogen replacement therapy is effective about half of the time.³⁷⁸ Psychological factors, although present in some of this population, do not appear to be etiological.³⁷⁹

Examination. The patient with BMS generally has a negative intraoral examination.³⁷⁵ Obvious tissue-irritating causes such as denture soreness, rough crowns or teeth, and other causes of tissue irritation such as candidiasis or true vitamin deficiencies must, of course, be ruled out.

Tests. Candidiasis should be tested for, even if the mucosa looks normal. *Local anesthetic rinse* will decrease the pain of other conditions such as geographical tongue or candidiasis but increase the pain of burning mouth. This increase in pain is thought to be owing to further loss of A β fiber inhibition. Sedimentation rate may be mildly elevated, and, in view of the higher incidence of immunological abnormalities, rheumatological evaluation should be considered.

Treatment. The management of BMS is still not satisfactory. Studies assessing therapeutic outcome are lacking and BMS does not appear to remit spontaneously. Few studies report relief without intervention. Emerging evidence supports the effectiveness of the antioxidant, alpha lipoic acid,^{380,381} but because BMS is thought to be neuropathic in origin, treatment is typically with medications that may suppress neurological transduction, transmission, and even pain signal facilitation more centrally.³⁸²

Recapitulation

The pain our patient complains of has none of the characteristics of either atypical odontalgia or BMS except for the burning quality. It is therefore unlikely that these diagnoses are causing her pain.

Thus we have the following differential:

1. Rule out RSD (sympathetically maintained pain) of the left side of the face.
2. Rule out posttraumatic neuralgia of cranial nerve V1–V3 on the left.
3. Myofascial TrP pain is likely to be contributing to the pain complaint.
4. There is internal derangement of the left TMJ with questionable contribution to the total pain complaint.

How can one differentiate between 1 and 2? Sensory blocks of the trigeminal nerve in the past have provided temporary but not long-lasting relief. In fact, the pain returned with the return of sensation. To differentiate between a purely sensory neuralgia and RSD (sympathetically maintained pain), the definitive test is a stellate ganglion block. This will provide dramatic relief if the pain is sympathetically mediated and no relief if it is owing to a neuralgia.

Left sympathetic stellate ganglion block does indeed relieve this patient's pain, and the pain relief outlasts the duration of the local anesthetic. Now that the patient is pain-free, it is possible to complete a thorough musculoskeletal examination. Range of motion is restricted in the left TMJ, with deviation of the jaw to that side on opening. At 30 mm of the mandibular depression, a loud "crack" is audible, and the patient is able to open wider. Active myofascial TrPs that refer pain into the forehead and along the side of the face are found in the upper trapezius, masseter, and lateral pterygoid muscles.

Management of this patient's pain will require repeated sympathetic blockade to control the sympathetically maintained pain. In addition, postural and stretching exercises, along with an intraoral stabilization splint, are indicated to reduce the MFP and stabilize the left TMJ. Spray and stretch, TrP pressure release, and/or TrP injections may facilitate the resolution of the MFP even further. Ultimately, dental treatment to restore left posterior dental support is indicated. Stress management and relaxation training may further help this patient control her pain. This is true because somatic and psychological factors are never separate in maintaining pain. Stress and anxiety will increase the sympathetic activity, which will activate RSD and myofascial TrPs, which are intimately involved in the patient's pain.

This case illustrates the complexity of dealing with patients with persistent orofacial head and neck pain complaints. Multiple diagnoses and contributing factors are common. The biopsychosocial model of chronic pain and illness emphasizes the need for an interdisciplinary pain management approach, including cognitive behavioral therapy, in order to be effective.^{382,383} As mentioned previously, in addition to changes in their neurophysiology resulting in increased pain perception and nociceptive dysregulation, patients with chronic pain may develop anxiety, depression, and anger, and may have poor coping skills.⁶⁰ Interdisciplinary or multidisciplinary treatments are often required for successful rehabilitation. Rehabilitation includes treatment of the pathoma causing the pain, as well as altering lifestyle habits and psychological concomitants that perpetuate the problem. A good liaison with a competent psychologist and a physical therapist is invaluable when evaluating and treating these patients. Even a brief intervention with cognitive behavioral therapy, either in a group setting or individually, has been shown to drastically improve overall coping, pain and activity levels.³⁸⁴

Conclusion

In conclusion, it is a time-consuming and difficult task to understand and manage people suffering chronic pain. Many interdisciplinary pain clinics employ orofacial pain dentists; physicians; psychologists; nurses; physical, occupational, and myotherapists; and other health professionals to coordinate patient care and to provide a comprehensive healthy environment for rehabilitation. Chronic pain management, including orofacial pain, has become a growing specialty in health care. It takes years of training and experience to gain adequate insight into these complex cases. Several dental schools across the United States now offer 2-year postgraduate orofacial pain programs to train interested dentists in the field of orofacial pain. Dentists with competence in this field can be identified by contacting the American Board of Orofacial Pain. This organization awards diplomate status to qualified dentists who pass their certification examination. Orofacial pain dentists, armed with knowledge, interest, curiosity, and patience, and, finally, the instruments of diagnosis, enjoy the most rewarding experience—identifying the source of pain and relieving the suffering of a fellow human being. The orofacial pain dentist, oriented toward looking at the patient as a whole person, can gain much

satisfaction from arriving at a correct diagnosis and saving teeth or preventing unnecessary surgery.

The complex and personal nature of good diagnosis cannot be overemphasized. This is the area in which the dentist is most likely, on a professional basis, to earn the respect and friendship of colleagues, both dental and medical, as well as patients.

CHAPTER 12

PULPAL PATHOSIS

G. R. HOLLAND, STEPHEN B. DAVIS

“The pulp lives for the dentin and the dentin lives by the grace of the pulp. Few marriages in nature are marked by a greater affinity.” Alfred L. Ogilvie

Response of the Pulp to Dental Caries

BACTERIA ARE RESPONSIBLE FOR MOST PULPAL DISEASE

Bacteria are responsible for most pulpal disease. The classic study by Kakehashi et al.¹ proved that exposed pulps in gnotobiotic (germ free) rats did not become inflamed while similarly exposed pulps in rats with a full oral flora did. Dental caries and the pulpal inflammation beneath it are clearly microbial in origin. The pulpal injury beneath restorations is also microbial and not due to cytotoxicity of the materials. Bacteria and their products occur between the restoration and the dentin as a result of microleakage.²⁻⁴

DENTAL CARIES IS THE MOST COMMON SOURCE OF BACTERIA AND THEIR BY-PRODUCTS AFFECTING THE PULP

Dental caries begins beneath a biofilm of dental plaque when environmental factors favor the growth and metabolism of acidogenic bacteria. The population of bacteria that are present in carious lesions is mixed and variable. Chhour et al.⁵ demonstrated the presence of 75 species in 10 samples of carious dentin. Up to 31 taxa were represented in each sample. A diverse collection of lactobacilli were found to comprise 50% of the species, with prevotellae also abundant, comprising 15% of the species. In another study significant positive associations were found between *Micromonas micros* and *Porphyromonas endodontalis* detection and inflammatory changes in the pulp.⁶ These anaerobes have been strongly implicated in endodontic infections that occur as sequelae to carious pulpitis. Accordingly, the

data suggest that the presence of high levels of these bacteria in carious lesions may be indicative of irreversible pulpal pathosis.

A variety of products are released or formed on the death of the bacteria. These include acids and proteinases that dissolve and digest the enamel and dentin, and toxins including lipopolysaccharide (LPS) and lipotechoic acid (LTA). Although bacteria can readily travel within dentinal tubules (Figure 1), toxins pass through dentin and enamel well ahead of the bacteria themselves. Thus, the pulp's inflammatory response is to the toxins rather than the bacteria themselves. Bacteria only invade the pulp at a late stage of the caries process that clinically would present as a carious exposure. More detail of the microbial basis of caries will be found in Chapter 7. Diverse groups and different proportions of species are found in carious lesions. Thus, it has not been possible to produce an antibiotic to inhibit the progress of caries or a vaccine to prevent

Figure 1 Bacteria in dentinal tubules in vitro. Brown and Brenn.¹⁹⁷ Photo courtesy of Dr. C. Sedgley.

it. The bacteria inhabiting the margins between restorations and dentin are similarly highly variable.

A variety of by-products are produced by cariogenic bacteria. The investigation of these is incomplete and our knowledge about them limited. The toxins that have thus far been recognized include LPS and LTA. LPS results from the breakdown of the walls of gram-negative bacteria and LTA from the breakdown of gram-positive bacteria. As gram-negative bacteria predominate in the plaque over carious lesions, we may assume that LPS is the primary toxin. LPS is a generic term and there are many variations of its molecular structure, and differing virulence, depending on the species of bacteria producing it. The speed of progress of both dental caries and pulpal inflammation is variable, perhaps as a result of variations in the quantity, nature, and combination of toxins.

BACTERIA AND THEIR BY-PRODUCTS CAN REACH THE PULP FROM OTHER SOURCES

Anomalous Crown Morphology, Fractures, and Cracks

Any feature that allows the accumulation of bacteria will increase the likelihood of pulpal inflammation. In most cases, the inflammation will be secondary to caries. In cracked teeth, if they are symptomatic, the cracks will be lined with bacteria that have easy direct access to the pulp (Figure 2).⁷

Figure 2 Bacteria within a crack in dentine extending from the crack into dentinal tubules. Brown and Brenn.¹⁹⁷ Photo courtesy of Dr. H. Trowbridge.

Periodontal Disease

Biofilms form on the root surface of periodontal pockets. Their flora is similar to dental caries and would, presumably, release similar toxins. Caries itself is not commonly found in this situation, but toxins may enter the pulp via lateral canals or by diffusing along dentinal tubules. The outward flow of dentinal fluid would oppose this and the relative impermeability of radicular dentin would prevent or reduce it. It has been demonstrated by the examination of extracted teeth with periodontal disease, but no caries, that pathologic changes do occur in the pulp when periodontal disease is present.⁸ By removing the cementum layer, periodontal scaling might be thought to allow greater ingress of bacteria and toxins. This has not been supported experimentally.⁹ That the pulp has considerable powers to oppose invasion via the dentinal tubules has been clearly demonstrated by observations showing bacteria invading dentinal tubules of devitalized teeth much more readily than the tubules of vital control teeth.¹⁰ Teeth with periodontal disease reaching the apex often remain vital. The consensus seems to be that periodontal diseases may lead to some pulpal changes but they rarely, if ever, lead to necrosis unless there is apical involvement.

Blood Stream (Anachoresis)

Bacteria in circulating blood may be deposited in the pulp. An experimental study on dogs in which some pulps were exposed and capped and then bacteria released in to the blood stream showed accumulations of bacteria in the capped pulps but not in normal pulps.¹¹ Whether this phenomenon is of clinical significance is unknown.

THE IMMUNE RESPONSE IN THE DENTAL PULP IS THE SAME BASIC PROCESS THAT OCCURS ELSEWHERE BUT IN A UNIQUE ENVIRONMENT

All connective tissues are capable of mounting an immune response that will follow the same basic pattern but is affected by local factors. The pulp's response differs from that in some other tissues. Because bacteria enter the tissue only at a very late stage, the pulp's blood supply is limited and the tissue is within a low-compliance chamber. If the tissue is presented with a new antigen, the innate immune response is initiated and is followed a few days later by the specific response. If the tissue is presented with an antigen it has met before, the specific response will be initiated immediately.

The tissue response to foreign antigens is described in molecular terms in Chapter 9, "Inflammation and

Immunological Response.” This present chapter will relate these processes to histologic and physiologic changes in the pulp and to the tissue’s attempts at repair.

ANTIGEN RECOGNITION IN THE DENTAL PULP

All three antigen-presenting cell types expressing the type II major histocompatibility complex (MHC) surface proteins, macrophages, dendritic cells, and B lymphocytes, are present and active in the pulp’s response to bacteria and toxins. In addition, it is now becoming clear that odontoblasts, being in the ideal position to detect antigens via Toll-like receptors (TLRs), produce a variety of cytokines and chemokines.¹²

In a normal healthy pulp, *macrophages* (Figure 3)¹³ are present in a resting form, as monocytes. Macrophages require stimulation by bacteria or cytokines before they express type II MHC molecules.¹⁴ At rest they are found predominantly around blood vessels¹⁵ though a few are distributed throughout the tissue.

Dendritic cells (Figure 4) are characterized by the shape that provides their name. They form a network throughout the pulp concentrating around blood vessels (Figure 5)^{15,16} and the odontoblast layer. Some of the dendritic cells in the odontoblast layer extend their processes into the dentinal tubules (Figure 6).¹⁷ They constantly express the MHC

Figure 3 Macrophage from the central pulp. Immunohistochemistry. Reproduced with permission from Jontell et al.¹³

Figure 4 Dendritic cells (brown) in and around the odontoblast layer. Some dendritic cells have processes extending into dentinal tubules (arrows). Immunohistochemistry with blue counterstain. Reproduced with permission from Yoshida K et al.¹⁷

Figure 7 Two different types of dendritic cells (here stained red or green) differentiated by immunohistochemistry. The nuclei of odontoblasts and fibroblasts are stained blue. In this experiment, the pulp was injured and the three images were taken at different time points after the injury. Reproduced with permission from Zhang J et al.¹⁸

molecules on their surface without provocation. Recent studies¹⁸ indicate that there are two populations of dendritic cell in the dental pulp, one beneath the odontoblast layer and the other around the blood vessels (Figure 7). The number of dendritic cells increases in the pulp when it becomes inflamed and they accumulate beneath the carious lesion (see Figure 6).¹⁷

B cells are specialized lymphocytes that will become plasma cells. They secrete antibodies during the specific immune response and express the MHC molecules. They have also been reported in the normal pulp but are rather rare.^{19,20} Their role in the initial stages of antigen recognition and presentation in the pulp is unclear. Occasional T cells are found in normal pulp (Figure 8) and may be activated by antigen-presenting cells locally.

Figure 8 Dendritic cell (Dc) and a T-helper cell (Tc) adjacent to a blood vessel in the pulp. Immunohistochemistry. Reproduced with permission from Jontell et al.¹³

Figure 9 Confocal microscope image of a dendritic cell (red) and a nerve fiber (green). Where they are close together is yellow. Reproduced with permission from Okiji et al.¹⁵

In the pulp, there is a close anatomic relationship between nerve fibers and dendritic cells (Figure 9), and both increase in parallel when the pulp is inflamed.^{17,21} The sympathetic nervous system has recently been shown to have a modulating influence on pulpal inflammation.^{22–24} The sympathetic system inhibits the production of proinflammatory cytokines, although stimulating the production of anti-inflammatory cytokines.²² In addition, T lymphocytes and other leukocytes produce antinociceptive molecules such as β -endorphin and somatostatin during inflammation (Figure 10) which reduce the excitability of pain fibers.²⁵

Odontoblasts are the first cells to encounter an antigen diffusing along the dentinal tubules. Veerayutthilai et al.¹² have described how several markers of innate immunity have been demonstrated on odontoblasts and that their processes include chemokines and TLRs. Odontoblasts respond differentially to the toxins produced by gram-positive and gram-negative bacteria. A gram-negative toxin activating TLR-4 up-regulates mRNAs for interleukin-1 β , interleukin-8, tumor necrosis factor- α , and chemokines and TLRs. A synthetic peptide mimicking a toxin from gram-positive bacteria activating TLR-2 down-regulates these mRNAs. Interleukin-1 β , tumor necrosis factor- α , and chemokine (C-C motif) ligand 20 were also up-regulated from 6-fold to 30-fold in odontoblast preparations from decayed teeth. These data show that odontoblasts express microbial pattern recognition receptors in situ, allowing differen-

Figure 10 **A**, Area of inflammation in a pulp exposed 1 week earlier and left untreated (hematoxylin and eosin). **B**, and **C**, Same section of the pulp photographed through different color filters after immunofluorescent staining. In **B**, the staining for β -endorphin is seen and in **C**, the staining for T lymphocytes. Some cells are labeled by both stains indicating that T lymphocytes produce β -endorphin. Reproduced with permission from Mudie and Holland.²⁵

tial responses to gram-positive and gram-negative bacteria. They also suggest that pro-inflammatory cytokines and innate immune responses in decayed teeth may result from TLR signaling¹² (Figure 11).

Figure 11 Immunohistochemistry showing Toll-like receptors (green) for bacterial components on odontoblasts (blue nuclei). Some dendritic cells are also stained (red). Toll-like receptors when activated by bacterial components lead to the release of chemokines that participate in the immune response. Reproduced with permission from Zhang et al.¹²

Other studies on odontoblasts *in vitro* suggest that in response to a bacterial toxin they produce chemokines that attract dendritic cells.²⁶

The Process of Antigen Recognition

Dendritic cells and macrophages bind to and phagocytize antigen that is then processed intracellularly, bound to MHC molecules, and moved to the cell membrane for recognition by T cells. B cells bind antigen to specific cell surface receptors. All the antigen-presenting cell types enter the blood stream and carry the surface molecules to the lymph nodes where T cell activation takes place, though some may occur locally (see Figure 8).¹⁶ Each type of antigen-presenting cell carries different types of antigen. The T cells respond not to the antigen itself but to the modified complex in the cell membrane of the antigen-presenting cells. Being stationary, the odontoblast does not participate directly in the activation of T cells but, presumably, activates dendritic cells.

HISTOLOGIC CHANGES IN THE EARLY STAGES OF CARIOUS ATTACK DURING THE NONSPECIFIC IMMUNE RESPONSE ("ACUTE INFLAMMATION")

The classic description of the histology of the inflamed dental pulp beneath caries was published by Seltzer et al. in 1963.²⁷ They attempted, with limited success, to find a relationship between the clinical

presentation of the patient and the histology of the pulp. In so doing, they looked at many examples of pulpitis at many different stages. This and other studies^{19,20} have made it possible to piece together a hypothetical description of pulpal changes during the progression of dental caries.

The description is very much hypothetical as dental caries is a highly variable disease and its progress has never been followed continuously in a single tooth. This description was obtained largely by examining paraffin-embedded sections stained with hematoxylin and eosin under the light microscope. Other approaches have been used more recently, particularly immunohistochemistry, electron microscopy, and molecular techniques, but the original microscopic description provides a framework on which newer data may be hung.

Cariogenic bacteria in the dental plaque produce a mixture of acids and enzymes that dissolve the mineral elements of enamel and dentin and then digest the organic matrix. The initial removal of mineral makes the enamel more permeable and the bacterial toxins will diffuse well ahead of cavitation. Once the dentin is reached, the toxins and, much later, the bacteria themselves will travel along the dentinal tubules (see Figure 1). Clearly, variations in the composition and thickness of enamel and dentin, and particularly the patency of the dentinal tubules, will determine the rate at which these toxins reach the pulp. In vital teeth, this movement will be opposed by the outward flow of dentinal fluid. Toxins, however, reach the pulp at a very early stage relative to surface changes. Brannstrom and Lind²⁸ looked at a large number of extracted teeth and found that in approximately 50% of teeth with white spot lesions and no cavitation, there was histologic evidence of inflammation in the underlying pulp (Figure 12).

Figure 12 Early inflammatory response (arrow) beneath a non-cavitated carious lesion (hematoxylin and eosin).

Figure 13 Poorly fixed section of pulp and dentin. The vacuoles and disruption of the odontoblast layer are artifacts (hematoxylin and eosin).

The first cells contacted by the toxic bacterial broth, diffusing down the dentinal tubules, will be the odontoblasts. Some studies describe structural changes in the odontoblast layer even at an early stage. This may not be truly happening when seen in hematoxylin and eosin stained sections. All histologic procedures are subject to artifacts; man-made changes which are not linked to any biologic change. Teeth that have been examined in this way have probably been extracted with forceps and compressed in the process, causing aspiration and damage to the odontoblast layer. The teeth are then fixed usually in formaldehyde, which often causes the pulp to shrink away from the dentin. The later stages of preparation, demineralization, embedding in wax, and sectioning may also cause damage (Figure 13). From studies using other techniques, we now know that odontoblasts respond to toxins and can create a reactionary dentin barrier. It is more than likely that the morphologic changes reported in the odontoblast layer early in the carious process are artifactual.

With hematoxylin and eosin stained sections, dendritic cells cannot be distinguished, but macrophages and neutrophils can be distinguished. The macrophages (and dendritic cells) will recognize a foreign antigen and carry its details to the lymph nodes, though this is a histologically invisible process. Resting macrophages (monocytes) enlarge and become active. Neutrophils leave the blood stream by diapedesis and migrate to the scene of action (Figure 14). This accumulation of phagocytic cells is dominated numerically by neutrophils, recognizable by their lobed nuclei, and is the key morphologic feature in the early response to

Figure 14 Polymorphonuclear leukocytes in early inflammation (hematoxylin and eosin). Photo courtesy of Dr. H. Trowbridge.

caries. Mast cells may also be present,^{29,30} but they are difficult to detect in routine preparations due to their extreme fragility. They are most common in surface tissues in response to inhaled or ingested antigens. At the same time, vascular and then neural changes (described elsewhere in this chapter) occur. Nerves are not well visualized in hematoxylin and eosin stained sections, and observations of changes in them during inflammation require other techniques. Sometimes an apparent dilation of local blood vessels may be seen.

HISTOLOGIC CHANGES IN THE LATER STAGES OF CARIOUS ATTACK DURING THE SPECIFIC IMMUNE RESPONSE (“CHRONIC INFLAMMATION”)

The immediate “inflammatory” phase of the immune response begins very shortly after the antigen arrives in the tissue. If the body has been exposed to the antigen on a previous occasion, then the record of that exposure will have been maintained by the memory T cells. The production of lymphocytes synthesizing specific antibodies will begin very quickly (within a few hours). If the antigen has not been encountered before, new clonal lines of lymphocytes will be developed, which takes several days. In either case, the production of specific lymphocytes will take place in the lymph nodes. With a known antigen, however, there may also be a second challenge, a local interaction between antigen-presenting cells and resident T lymphocytes.¹⁶

Whether the antigen is new or returning, the histologic appearance of the tissue will be the same, only the time scale will be different. At this stage, the appearance of the pulpal response is characterized by the

Figure 15 Chronic inflammation. D = dentin. An attempt at fibrous repair (F) is going on at the same time as inflammation. The inflammatory cells are predominantly lymphocytes (hematoxylin and eosin). Photo courtesy of Dr. H. Trowbridge.

dominating presence of lymphocytes (Figure 15). The numbers of lymphocytes present increases with the severity of clinical symptoms.²¹

A commonly used definition of chronic inflammation, often called a granuloma, is “inflammation of slow progress marked chiefly by the presence of lymphocytes and the formation of reparative tissue” (see Figure 15). This is commonly seen in the dental pulp of extracted carious teeth, some of which may be asymptomatic.

The pulp is a remarkably robust tissue and can, by the production of tertiary dentin, protect itself from persistent carious attacks. If the carious lesion is not treated, however, the increasing quantity of irritants will eventually cause irreversible changes. These are at first limited in size and may even form a “pulpal abscess.” The bulk of the tissue around it appears healthy (Figure 16). This local necrosis, unless checked, will progress gradually throughout the tissue and into the periradicular tissues. The progress of tissue damage in the pulp is determined by the presence and spread of bacterial toxins and is not due to the “strangulation” of blood vessels.

HEMODYNAMIC CHANGES IN THE PULP DURING CARIES

An understanding of the vascular component of the immune response in the dental pulp is critical to planning or executing vital pulp therapy. Unfortunately, there are relatively few studies on pulpal vascular changes under carious lesions in humans.^{31–36} Several investigators have looked at the effect of experimentally induced inflammation in animal models.^{37–41} There are some excellent recent reviews of the vascular physiol-

Figure 16 Pulpal abscess (A) beneath a deep cavity preparation (C). Away from the diseased area, the appearance of the pulp is normal (hematoxylin and eosin). Photos courtesy of Dr. H. Trowbridge.

ogy of the dental pulp⁴⁰ as well as well the description contained in Chapter 5.

Blood Flow

Measuring blood flow in the dental pulp, even in experimental animals, is a difficult procedure, and data generated are a challenge to interpret. Using plaque extract to initiate inflammation in a rat incisor model, Kim et al.⁴² reported a 40% increase in blood flow in a “moderately inflamed” pulp but a 35% reduction in a “partially necrotic” pulp. A more recent study by Bletsa et al.,⁴¹ in a similar model, showed that the application of LPS to the pulp resulted, after 10 minutes, in a reduction in blood flow that continued for the 3-hour duration of the experiments. This was interpreted as a limited ability of the pulp to respond.

Interstitial Fluid Pressure

The healthy dental pulp has an interstitial pressure of 5 to 10 mm Hg.^{37,43} One of the key changes during inflammation is the movement of fluid from within the capillaries into the interstitial space. By the laws of physics, increasing the amount of fluid in a rigid chamber leads to an increase in pressure. It was

assumed, for a long time, that such a pressure rise in the pulp would cause compression of the blood vessels leading to vascular stasis and necrosis. It was even suggested that this pressure change could lead to strangulation of the vessels at the apex causing necrosis in areas of the pulp not directly affected by the bacterial toxins. Experimental work by Tonder³⁷ (later Heyeraas) and by Van Hassel⁴³ measured interstitial fluid pressure in the pulps of experimental animals and showed that although the pressure rose in the area immediately beneath an injury a short distance (2 mm) away, the pressure stayed within normal limits. Even within areas of raised interstitial fluid pressure, capillaries remain patent because of a balancing increase in intra-luminal pressure. The increased interstitial fluid pressure may be beneficial as, when combined with increased capillary permeability, it would lead to an accelerated rate of fluid exchange across the capillary membrane.⁴⁰ Any net increase in tissue fluid, especially macromolecules, will be removed by the lymphatics. The presence of lymphatics in the dental pulp has been controversial, but recent studies using ultrastructural and histochemical techniques have established their existence.⁴⁴⁻⁴⁶ Necrosis occurs beneath persisting carious lesions only when bacterial toxins, spreading throughout the pulp, poison cells directly.

NEURAL CHANGES DURING PULPAL INFLAMMATION

Sympathetic nerves control blood flow by constricting precapillary sphincters⁴⁷⁻⁴⁹ and by interaction with other elements of inflammation. Sympathetic activity inhibits the production of proinflammatory cytokines although stimulating the production of anti-inflammatory cytokines⁵⁰ and is involved in the recruitment of inflammatory cells to the area.^{23,51,52} Sympathetic nerves have an inhibitory effect on odontoclasts and stimulate reparative dentin production. In the dental pulp, sympathectomy has no apparent effect on the degree of inflammation induced by mustard oil,⁵³ whereas Haug et al.⁵¹ found less abscess formation 4 days after deep cavity preparation in normal teeth when compared with sympathectomized teeth. Nor is it possible to detect any differences in the extent or severity of inflammation after pulp exposure injury in sympathectomized rat molars after a waiting period of more than 20 days.⁵¹

Afferent sensory fibers from the trigeminal system also play an important role in the response to toxins and injury. The afferent fibers release two important neuropeptides, substance P and calcitonin gene-

related peptide (CGRP). Both cause vasodilatation and increased capillary permeability. Sympathetic activity causes vasoconstriction and also reduces the release of peptides from afferents. Thus, the sympathetics and the afferents seem to act in opposing directions.

In injured pulps, there is an increased expression of nerve growth factor (NGF) and its receptors.^{54,55} A concomitant sprouting of the afferent terminals and increased presence of substance P and CGRP⁵⁵⁻⁶⁰ also takes place. Sprouting of sensory nerve fibers occurs as early as 1 day after dental injury⁶¹ and decreases 3 to 4 weeks after pulp exposure injury, a time when sympathetic nerve sprouting occurs.⁶²⁻⁶⁵

Pulpal injury and inflammation are also associated with neural changes outside the pulp itself. In the trigeminal ganglion after pulpal injury, the expression of various neuropeptides increases,^{66,67} Trk-B receptors (associated with pain) increase,⁶⁸ and nitric oxide synthesis is enhanced.⁶⁹ There are also detectable changes in the supporting cells of the ganglion.⁷⁰ In the trigeminal nucleus (pars caudalis has been the most studied), pulpal injury and inflammation lead to degenerative changes⁷¹ and to cFos expression, an indication of possible changes in the pain system.⁷² Perhaps, most significantly from a clinical point of view are changes in the nucleus related to central sensitization.⁷³⁻⁷⁷ This may help explain the variable presentation of pulpitis in terms of pain.

ANTI-INFLAMMATORY AND ANTINOCICEPTIVE MECHANISMS IN THE DENTAL PULP

During inflammation, there are important interactions between the nervous and immune systems.⁷⁸ Neuroimmune interactions control pain through the activation of opioid receptors on sensory nerves by immune-derived opioid peptides.⁷⁹ Opioid-containing leukocytes migrate to peripheral sites of inflammation. On exposure to stress, opioid peptides are released, bind to opioid receptors on peripheral sensory neurons, and induce endogenous antinociception. Although much of the research in this area has been done on skin and joints (in relation to arthritis), the efficacy of adding as little as 1 mg of morphine to the local anesthetic used in oral surgery has been demonstrated.⁸⁰ Although no published studies focus directly on the effect of local opioids on pulpalgia, the underlying elements have been demonstrated. Opioid receptors are present on pulpal nerves^{22,81} and β -endorphin has been shown to be present in, at least, lymphocytes in the inflamed pulp²⁵ (see Figure 10). Pulpal pain and its modulation

and management are discussed in depth in Chapter 10, “Mechanisms of Odontogenic and Nonodontogenic Pain.” It is important to see this as a part of the pulpal response to injury. The extent of this antinociceptive mechanism may be variable depending on, for one possibility, the exact nature of the antigen presented. This may, in part, explain the wide variation in the pain experienced as a result of pulpal inflammation.

LESS COMMON PULPAL RESPONSES: CALCIFICATION AND RESORPTION

Calcification of the pulp takes a variety of forms. Discrete pulp stones occur in a large proportion of the population. In one Australian study of young adults (dental students), 46% of the group had radiographic evidence of pulp stones in at least one tooth. Ten percent of all the teeth included in the study contained a pulp stone.⁸² The vast majority of pulp stones are found in molars (Figure 17). Although the etiology of pulp stone formation is unknown, there is evidence that pulp stones are more common in patients with atherosclerotic cardiovascular disease (74%) than in those without (39%).⁸³ A higher incidence of pulpal mineralization is associated with some genetic disorders such as Ehlers–Danlos syndrome⁸⁴ and amelogenesis imperfecta.⁸⁵ A generalized, more diffuse mineralization of the pulp may occur after trauma^{86,87} and is one of

Figure 17 Multiple pulp stones in the pulp chamber of a molar (hematoxylin and eosin). Photo courtesy of Dr. H. Trowbridge.

Figure 18 Internal resorption. Multinuclear odontoclasts can be seen within lacunae in the dentin (arrows) (hematoxylin and eosin). Photo courtesy of Dr. H. Trowbridge.

several good reasons for follow-up radiographs. In this case, there is a clear indication for root canal therapy. Discrete pulp stones are not considered pathologic. Their only clinical significance is that they can add to the adventure of locating and instrumenting root canals.

Internal resorption has been considered an alternative sequela to trauma though most of the literature on this condition consists of case reports (Figure 18). An alternative is to suggest that internal resorption is “idiopathic.” The difficulty in establishing a correlation with trauma is probably related to the length of time between the traumatic incident and the diagnosis.

WHEN THE PULPAL RESPONSE SUCCEEDS: REPAIR AND REGENERATION

The immune response, including inflammation, is only one part of the pulp’s total response to toxins or injury. When effective, it neutralizes and removes any foreign material and allows and probably initiates the second part, recovery, repair, and regeneration. The repair process can take several forms. The most obvious distinctions relate to the severity of the injury. When no cells are killed, the original odontoblasts can form reactionary (tertiary) dentin (Figure 19). When the odontoblasts are killed, new dentin-forming

Figure 19 Reactionary (tertiary) dentin (Rc) that has developed beneath a deep cavity preparation. The tubules in the reactionary dentin are continuous with those of the primary dentin (P) (hematoxylin and eosin). Photo courtesy of Dr. H. Trowbridge.

cells develop from stem cells (undifferentiated mesenchymal cells) and form reparative (tertiary) dentin (Figure 20).^{88,89} The repair of larger areas of damage is more variable and depends on the nature of any clinical intervention. It seems that normally organized pulp tissue does not re-form. An example of extensive tissue damage from which the pulp recovers is the pulp polyp (Figure 21). Rapidly advancing caries in young molars can result in collapse of the crown with a large but self-cleansing pulp exposure. Epithelial cells from the oral mucosa settle on the exposed

Figure 20 A layer of reactionary (tertiary) dentin (Rc) has formed beneath an injury which has then become severe enough to kill the original odontoblasts resulting in the formation of reparative (tertiary) dentin (Rp), which having been formed by new odontoblasts is atubular (hematoxylin and eosin). P = primary dentin. Photo courtesy of Dr. H. Trowbridge.

pulp and form an epidermis (Figure 22). This attests to the pulps ability to respond to injury, but in this case it is futile as the molars involved are often not restorable.

Figure 21 Pulp polyp, also known as hyperplastic pulpitis (arrows). Caries of the lower first permanent molars in a young patient has proceeded so quickly that the walls of the cavity collapsed, leaving a largely self-cleansing area. The pulp survives and its surface has been colonized by epithelial cells shed from the buccal mucosa. Photo courtesy of Dr. H. Trowbridge.

Dentin (D) is present on each side of the polyp that has a dense infiltrate of inflammatory leukocytes (hematoxylin and eosin). Photo courtesy of Dr. H. Trowbridge.

Sometimes the progress of caries and the defensive response can reach a stalemate. The irritant continues but is contained. This, by one definition, is chronic inflammation with injury and repair going on at

the same time. Many inflammatory cells, largely lymphocytes, are present as well as areas of fibrous tissue representing an attempt to “wall off” the diseased tissue.

ENCOURAGING A SUCCESSFUL RESPONSE

From a clinical standpoint, it is important to recognize that the pulp has a strong innate ability to respond and repair. Most of our strategies for encouraging pulpal repair involve removal of the irritant and diseased tissue and the prevention of further injury. Calcium hydroxide, for example, probably does nothing directly to stimulate reparative dentin formation but is permissive of the pulp’s inherent activity. Mineral trioxide aggregate may have some stimulatory activity, but its main property may be its high level of biocompatibility and its success in preventing recontamination. With the discovery of biologically active molecules such as growth factors and matrix proteins, there is the possibility of stimulating repair.^{90,91} The development of cultures of pulpal cells and supporting scaffolds may allow tissue regeneration. Neither of these approaches is, at present, ready for clinical adoption.⁹²

FACTORS LIMITING THE PULP’S RESPONSE

The only significant factor that limits the pulp’s ability to respond to injury is age. The older pulp has a reduced number of cells,⁹³ innervation,⁹⁴ and vascularity,^{95,96} but the immune response remains active.^{88,89}

Iatrogenic Effects on the Dental Pulp

LOCAL ANESTHETICS

Local anesthetics reduce pulpal blood flow by approximately half when they contain vasoconstrictors.^{97,98} This effect is due almost entirely to the vasoconstrictor. It is important to remember that when preparing a cavity in an anesthetized tooth the pulp is in a suboptimal condition to respond. Much of what we know about the pulp’s response to cavity preparation and materials has been from animal experiments in which general rather than local anesthetics were used.

CAVITY/CROWN PREPARATION

Heat: Experimental Observations

The basic effect of heat on mineralized tissue has been best documented on bone.⁹⁹⁻¹⁰² From this work, a value of 10 °C above body temperature is frequently cited as the threshold to cause irreversible damage to vital tissues.⁹⁹ Higher temperatures and increased application times lead to greater damage. An increase of surface temperature to 47 °C held for only 1 minute resulted in minor reversible injury. Increasing the duration to 5 minutes caused irreversible damage to calcified bone and marrow that healed by repair. Raising the temperature to 50 °C but reducing the duration back to 1 minute produced injury similar to the injury caused by raising the temperature to 47 °C at 5 minutes. Temperatures of 60 °C and higher will result in bone necrosis.⁹⁹ Severe cold will, of course, also damage tissue. The formation of water crystals within cytoplasm will kill a cell. This occurs at a temperature of approximately 2 °C below zero,¹⁰³ a temperature never likely to be experienced in the mouth.

Moderate elevation of temperature on the external surface of a tooth can raise the internal temperature of the pulp to the point that injury occurs. A temperature increase of 5.5 °C above body temperature as observed by Zach and Cohen¹⁰⁴ is frequently cited as the threshold for damage to the pulp. This observation was made after applying a soldering iron preheated to 275 °C to the teeth of monkeys for a limited time. When the same temperature was applied for a longer period of time, generating an 11.1 °C increase in pulp temperature, 60% of pulps became necrotic. However, this very abrupt application of high heat may not translate directly to clinical situations.

A more recent study applied a gradually increasing heat stimulus until the patient indicated sensitivity then sustained it for 30 seconds. The temperature change across the dentin was measured after extraction. The maximum temperature increase was 14.7 °C reaching a measured temperature of 50.9 °C. Histologic examination of the heated pulp revealed neither necrosis nor even alteration of the odontoblast layer. All the patients remained symptom free through the duration of the study, and all teeth responded to cold testing just before extraction.¹⁰⁵ These *in vivo* experimental observations were made on un-restored, noncarious human teeth scheduled for extraction for orthodontic treatment. These are young patients and their pulps will have a good blood supply and will not have been affected by previous injury. This model may not be fully revealing of the effects of heat on the mature pulp.

The more moderate pulp responses observed by Baldissara et al.¹⁰⁵ are borne out by earlier studies. Pulps from human subjects that were examined immediately and 1 month after a 30-second application of 150 °C to dentin 0.5 mm thick were found to have localized areas of injury though no pulps were completely necrotic.¹⁰⁶ The most common histologic observation was a breakdown of the odontoblast layer. Some of the pulps had localized areas of necrosis. The affected areas were not surrounded by inflammatory cells. None of these injuries was symptomatic. Other studies have reported similar results.^{107,108} It appears the dental pulp has some capacity to adapt to a moderate, gradually increased rise in temperature.

Heat: Cutting Dentin

The amount of heat produced during cutting is determined by the sharpness of the bur, the amount of pressure exerted on the bur, and the length of time the cutting instrument contacts tooth structure. The temperature on the surface of a rotating dental bur in contact with dentin has been reported to be as high as 417 °C.¹⁰⁷ High-speed air-driven handpieces require some method of cooling the tooth in order to safely use these handpieces. The two cooling methods most frequently applied have been air-cooling and water-cooling. Pulp temperatures with air-cooling alone rise to 60 °C whereas with water-cooling the temperature falls to 26 °C.¹⁰⁹

Damage has been observed in the pulps of teeth cut with air-cooling only.¹¹⁰ Odontoblasts were dislocated into dentinal tubules and there were vacuoles throughout the odontoblast layer. By contrast, with water-cooling, displacement of odontoblasts occurred in less than half the teeth and was less marked when it did occur. Fifteen days after cavity preparation, inflammation was noted in all the pulps under cavities prepared with air-cooling only. On the other hand, inflammation occurred in only 25% of water-cooled group. In both groups, recovery occurred within 200 days with the formation of tertiary reparative dentin.

Dentin is a good insulator and thus careful cutting is not likely to damage the pulp unless the thickness of dentin between preparation and pulp is less than 1.0 mm.¹¹¹ Even then, the response should be mild.

The "blushing" of dentin during crown preparation is thought to be due to frictional heat resulting in vascular injury (hemorrhage) in the pulp.¹⁰⁶ The dentin takes on an underlying pinkish hue soon after the operative procedure. The most intense level of frictional heat is generated with a large diamond stone

when teeth are prepared for a full crown. Crown preparation performed without the use of a coolant leads to a marked reduction in pulpal blood flow, presumably because of vascular stasis and thrombosis.

The safest way to prepare tooth structure is to use ultrahigh speeds of rotation (100,000–250,000 rpm), with an efficient water-cooling system, light pressure, and intermittent cutting. During cutting at high speeds, the revolving bur creates an area of turbulence that tends to deflect a stream of water. Therefore, an air–water spray with sufficient volume and pressure must be used if the coolant is to overcome the rotary turbulence. The bur–dentin interface should be constantly wet. Cavity preparation with a low-speed handpiece, sharp bur, and light, intermittent pressure is only slightly more injurious than cutting at high speeds. Hand instruments and low-speed cutting are relatively safe ways to finish a cavity preparation, rather than using a high-speed handpiece with the water coolant shut off.

Heat: Laser Beams

The use of laser beams to fuse enamel and reduce the likelihood of carious invasion has been suggested.¹⁰⁸ Different lasers with different energy levels may also be used to remove caries. Laser irradiation can generate a large increase in temperature within dentin and pulp tissue.¹¹² Proper power setting, time of application, and use of water spray will mitigate the temperature increase to levels below the heat threshold of pulp damage.^{113,114} The use and effects of laser irradiation in endodontic treatment is thoroughly reviewed in Chapter 26E, “Lasers in Endodontics.”

PINS

Pulp damage may result from pinhole preparation or pin placement. Coolants do not reach the depth of the pin preparation. During pinhole preparation, there is always the risk of pulp exposure. Furthermore, friction-locked pins often produce micro-fractures that may extend to the pulp, subjecting the pulp to irritation and the effects of microleakage. The use of pins should be discouraged.^{115,116}

CAVITY CLEANSING

A prolonged blast of compressed air aimed onto freshly exposed vital dentin will cause a rapid outward movement of fluid in patent dentinal tubules.¹¹⁷ Tubule diameter midway between the pulp and the dentin-enamel junction (DEJ) is only 1.5 μm . Therefore, the removal of fluid from the tubules by a blast of air activates strong capillary forces. These in turn

lead to a rapid outward flow of dentinal fluid.¹¹⁸ Fluid removed from the tubules at the dentin surface is replaced by fluid from the pulp.

The rapid outward flow of fluid in the dentinal tubules stimulates nociceptors in the dental pulp producing pain. Rapid outward fluid movement may also result in odontoblast displacement.¹¹⁸ Odontoblasts are dislodged from the odontoblast layer and drawn outward into the tubules. Within a short time, the displaced cells undergo autolysis and disappear. Providing the pulp has not been severely injured either by caries or by other factors, displaced odontoblasts are replaced by new cells derived from stem cells deeper in the pulp. In this way, the odontoblast layer is reconstituted by “replacement” odontoblasts capable of producing tertiary dentin. Even vigorous drying of dentin alone does not result in severe injury to the underlying pulp. Drying agents containing lipid solvents such as acetone and ether have been used to clean cavity floors. Because of their rapid rate of evaporation, application of these agents to exposed dentin produces strong hydrodynamic forces in the tubules causing odontoblast displacement. Cavities should be dried with cotton pellets and short blasts of air rather than harsh chemicals. Disinfectants have, in the past, been used in cavity cleansing. There seems to be no particular benefit to this, and they are now rarely used as they are potentially toxic to the pulp.

Etching Dentin/Smear Layer

Cutting dentin results in a smear layer on the cut surface consisting of fragments of microscopic mineral crystals and organic matrix.^{119–125} This layer may interfere with the adherence of adhesive restorative materials although some newer bonding agents reportedly bond well to the smear layer. Acidic cavity-cleansing products and chelating agents have been used to remove the smear layer, but the use of these depends on the nature of the restorative material. The smear layer does have one desirable property. By blocking the orifices of dentinal tubules, the smear plugs greatly decrease the permeability of dentin. While the smear layer is a semipermeable membrane, it is not a barrier to bacteria or bacterial products.

Complete dissolution of the smear layer opens the dentinal tubules, significantly increasing the permeability of dentin. If the dentin is left unsealed, the diffusion of irritants to the pulp may intensify and prolong the severity of pulpal reactions. Available experimental evidence is contradictory. Some evidence indicates that etching as a step in restoration may reduce microleakage.¹²⁶ Other evidence suggests that etching, when there is less than 300 μm of

remaining dentin thickness (RDT), causes pulpal damage.¹²⁷

In the absence of microleakage, acid etching of dentin does not appear to produce injury to the pulp, because calcium and phosphate ions are released producing a buffering action. Even when placed in deep cavities, acid etchants produce only a small increase in hydrogen ion concentration in the pulp.¹²⁸

IMPRESSIONS AND TEMPORARY CROWNS

Temperatures of up to 52 °C have been recorded in the pulp during impression taking with modeling compound. Modeling compound may be damaging because of the combination of heat and pressure.^{129–132} Fortunately, this technique is no longer used. Rubber base and hydrocolloid materials do not injure the pulp.

The heat generated during the exothermic polymerization of autopolymerizing resins may also injure the pulp. Cooling is strongly recommended when provisional crowns are fabricated directly. Before cementing provisional crowns, the crown preparation should be carefully lined with temporary cement to minimize microleakage. The temporary crown/cement should be in place for a short period of time; temporary cements are not stable and will eventually wash out. Microleakage around temporary crowns is a common cause of postoperative sensitivity.

CROWN CEMENTATION

During the cementation of crowns, inlays, and bridges, strong hydraulic forces may be exerted on the pulp as cement compresses the fluid in the dental tubules.¹³³ In deep preparations, this can result in a separation of the odontoblast layer from the predentin. Vents in the casting will allow cement to escape and facilitate seating.

DENTAL MATERIALS

Microleakage

The most important characteristic of any restorative material, in determining its effect on the pulp, is its ability to form a seal that prevents the leakage of bacteria and their products onto dentin and then into the pulp.^{2,127,134}

Cytotoxicity

Certain restorative materials are composed of chemicals having the potential to irritate the pulp. However, when placed in a cavity, the intervening dentin usually neutralizes or prevents leachable ingredients from reaching

the pulp in a high enough concentration to cause injury. For example, eugenol in zinc oxide–eugenol (ZnOE) is potentially irritating, but very little can reach the pulp. Phosphoric acid is a component of silicate and zinc orthophosphate (ZnOP) cements and was thought to be highly injurious to the pulp. However, the buffering capacity of dentin greatly limits the ability of hydrogen ions to reach the pulp. It is now clear that the problems following use of these materials were due to their high degree of shrinkage and subsequent microleakage.⁴

Clearly, the thickness and permeability of dentin between a material and the pulp affect the response to the material. In addition, the penetration of some materials through dentin may be limited by the outward flow of fluid through the tubules that will be increased if the pulp is inflamed.¹³⁵ This is a factor that has been overlooked in many *in vitro* studies focusing on the passage of materials through dentin.

Many cytotoxicity studies focus on isolated cell types in culture and do not take into account the immunocompetent cells present in the intact pulp. Materials may have a differential effect on these cells by either stimulating or inhibiting their activity.¹³⁶

Materials are more toxic when they are placed directly on an exposed pulp. Cytotoxicity tests carried out on materials *in vitro* or in soft tissues may not predict the effect these materials have on the dental pulp. The toxicity of the individual components of a material may vary.^{137,138} A set material may differ in toxicity from an unset material. The immediate pulpal response to a material is much less significant than the long-term response. Upon examination a few days after placement, there may be a strong inflammatory response. After a few months, the inflammatory response may have receded and repair has taken over. The best measure of long-term response is the thickness of tertiary dentin laid down by the affected pulp.

Heat upon Setting

Many restorative materials have exothermic setting reactions. Temperature increases during setting procedures may be over 10 °C¹³⁹ but can be limited to 2 to 3 °C with care.^{132,140} Cooling techniques include the use of air-/water-cooling and removing the temporary upon initial polymerization.¹⁴¹

Some luting cements generate heat during setting; it has been suggested that this might cause pulpal injury. The most exothermic luting material is ZnOP cement. However, during setting, an intrapulpal temperature increase of only 2 °C was recorded. Heat of this magnitude is not sufficient to injure the pulp.

Desiccation by Hygroscopy

Some hygroscopic materials may potentially cause injury by withdrawing fluid from dentin. However, little relationship exists between the hydrophilic properties of materials and their effect on the pulp. Moisture absorbed by materials is probably much less than that removed from dentin during cavity drying, a procedure that produces an insignificant amount of pulpal inflammation.¹⁴⁰

Specific Materials

ZINC OXIDE–EUGENOL

ZnOE has many uses in dentistry, having had a long history as a temporary filling material, cavity liner, cement base, and luting agent for provisional cementation of castings. Before the introduction of calcium hydroxide, ZnOE was the material of choice for direct pulp capping.^{127,142–144}

Eugenol, biologically the most active ingredient in ZnOE, is a phenol derivative and is toxic when placed in direct contact with tissue.¹⁴⁵ It also possesses antibacterial properties.¹⁴⁶ Eugenol's usefulness in pain control is attributed to its ability to block the transmission of nerve impulses.¹⁴⁷ A thin mix of ZnOE significantly reduces intradental nerve activity when placed in a deep cavity preparation in cat's teeth; a dry mix of ZnOE has no effect.¹⁴⁸

When included in cements to temporize crown preparation, some eugenol does reach the pulp, but the amounts are small and unrelated to RDT. In *in vitro* studies "desensitizing" agents do not seem to reduce the penetration of eugenol, though time does.¹⁴⁹ The release of eugenol is by a hydrolytic mechanism that is dependent on the presence of fluid. With little fluid available, release is low.^{142,143}

The most important property of ZnOE is that it provides a tight marginal seal preventing microleakage. Its superiority as a temporary restorative material is enhanced by its antimicrobial properties.

ZINC PHOSPHATE CEMENT

ZnOP is a popular luting and basing agent. It has a high modulus of elasticity and therefore is commonly used as a base beneath amalgam restorations. The phosphoric acid liquid phase was formerly thought to injure the pulp. However, recent studies have shown that this is not the case. Cementation of castings with ZnOP is well tolerated by the pulp. Researchers reported that ZnOP is more likely to produce pulpal sensitivity at the time of

cementation and 2 weeks after cementation than glass ionomer. However, 3 months after cementation, there is no difference in sensitivity.^{150–153}

POLYCARBOXYLATE CEMENT

When placed in cavities or used as a luting cement, zinc polycarboxylate does not irritate the pulp. In cementing well-fitting crowns and inlays, neither polycarboxylate nor ZnOP cements contract enough to permit the ingress of bacteria. Consequently, it is unnecessary to apply a varnish or liner to cavity walls; doing so only reduces cement adhesion.^{153–155}

RESTORATIVE RESINS

The first adhesive bonding and resin composite systems that were developed contracted during polymerization, resulting in gross microleakage and bacterial contamination of the cavity. Bacteria on cavity walls and within axial dentin are associated with moderate pulpal inflammation. Over a period of time, some composites absorb water and expand; this tends to compensate for initial contraction. To limit microleakage and improve retention, enamel margins are beveled and acid etched to facilitate mechanical bonding. When compared with unfilled resins, the newer resin composites present a coefficient of thermal expansion similar to that of tooth structure. With recently developed hydrophilic adhesive bonding composite systems, the problem of marginal leakage appears to have been diminished.^{156–158}

GLASS IONOMER CEMENTS

Glass ionomer cement's original use was as an esthetic restorative material but now has also found use as liners, luting agents, and pulp-capping agents (sometimes in conjunction with calcium hydroxide). When placed on exposed pulps in noncarious teeth, glass ionomer cement shows a degree of bacterial microleakage similar to that of composite resins but less than half that of calcium hydroxide cement.^{159,160} The incidence of severe pulpal inflammation or necrosis caused by glass ionomer cement on exposed healthy pulps is similar to that for calcium hydroxide but greater than that for composite resins.¹⁶⁰ When placed in cavities in which the pulp is not exposed and where there is a narrow RDT (0.5–0.25 μm), both calcium hydroxide and composite resin show faster deposition of tertiary dentin than glass ionomer cements.¹⁶¹

When used as a luting agent, the pulpal response to glass ionomer cements is similar to that of polycarboxylate and ZnOP cements.¹⁵¹ For some time after their introduction as luting agents, glass ionomer

cements were associated with post-cementation sensitivity. A more recent clinical trial has shown that, using appropriate technique, the incidence of sensitivity using these agents is no greater than that with other commonly used luting agents.¹⁵²

AMALGAM

Amalgam alloy is widely used material for restoring posterior teeth. There is shrinkage during setting, which results in microleakage.¹⁶² This decreases as corrosion products accumulate between restoration and cavity walls and can be reduced by the use of liners.¹⁶³ Amalgam is the only restorative material in which the marginal seal improves with time. Esthetics and public concern with the mercury content of amalgams have led to an accelerated use of composite resins as posterior restorative materials. Their use, however, is more technique sensitive than amalgams. In deep cavities in posterior teeth, composites are associated with more pulpal injury than amalgams because of microleakage.¹⁵⁸

Polishing Restorations

Polishing glass ionomer and composite restorations does not cause an increased temperature at the pulp–dentin interface.¹⁶⁴ Polishing amalgam restorations, however, can produce temperatures that may be damaging. With high contact pressure, high speed, and no coolant, *in vitro* temperature increases of greater than 20 °C have been recorded within 30 seconds.¹²⁷ However, a handpiece rotating at 2,500 rpm that was held for 60 seconds with a relatively light (55 gm) force generated a maximum temperature increase of only 6.2 °C.¹²¹ This occurred when a Burlew disk without coolant was used as the polishing agent. With air-cooling, the increase was 2.0 °C. When polishing an amalgam restoration with continuous pressure and no water coolant, it is recommended to not exceed 4,000 rpm.¹⁶⁵ With use of coolant, light pressure, and intermittent contact during polishing, there is a low likelihood of heat-generated pulp damage.

Post-restorative Hypersensitivity

Many patients complain of hypersensitivity after a restorative procedure.^{139,152} This may be due to any one or an accumulation of the factors listed above. Discomfort is usually of short duration. If pain is prolonged, a preexisting pulpitis may have been exacerbated. If delayed in onset by days, the cause may be microleakage of bacterial toxins under a poorly sealed temporary restoration. The absence of postoperative

sensitivity after restoration with modern composites of both class I and II preparations has been demonstrated in clinical studies suggesting that variations in technique may be responsible for the anecdotal reports of sensitivity.^{164,166} The use of hydroxymethacrylate and glutaraldehyde “desensitizer” does not reduce the incidence of sensitivity.¹⁶⁵ Self-etching, self-priming dentin-bonding systems reduce the incidence of sensitivity following the restoration of deep carious cavities.¹²¹

If pain evoked is by biting on a recently restored tooth, an intracoronal restoration may be exerting a strong shearing force on the dentin walls of the preparation. It is more likely to be due to injury to the periodontal ligament resulting from hyperocclusion. Hyperocclusion from an extra-coronal restoration is not injurious to the pulp but may cause a transient hypersensitivity.

Vital Tooth Bleaching

Overnight external bleaching of anterior teeth with 10% carbamide peroxide causes mild pulpitis that is reversed within 2 weeks.¹⁶⁷ *In vitro* studies show that the principle bleaching agent, hydrogen peroxide, can reach the pulp¹⁶⁸ after application to the enamel. Whether this occurs *in vivo* is unknown. Outward fluid flow in dentinal tubules and other factors would reduce the effect. Both short-term and long-term (9–12 years) clinical observations on bleached teeth report no significant pulpal changes.¹⁶⁹ Heat-activated bleaching agents can cause intrapulpal temperatures to rise by 5 to 8 °C when measured *in vitro*.¹⁷⁰

Vitality Testing

Thermal “vitality” testing utilizes media at temperatures that certainly have the potential to damage tissues. Heated gutta-percha reaches a temperature of around 200 °C just before the smoke point, and a cold-test substance like carbon dioxide snow has an inherent temperature of –78 °C. A heat-testing device like the System B with the appropriate tip is recommended to be set at a temperature of 200 °C. The question must be asked whether these extreme temperatures are transmitted to dental pulp during clinical testing and whether there is any likelihood that the tissue may be damaged. Rickoff et al.¹⁷¹ reported combined *in vivo* and *in vitro* findings with no damage to pulp tissue following use of flame-heated gutta-percha and carbon dioxide snow. Gutta-percha was heated to the smoke point and then applied to a tooth surface in

vivo. The gutta-percha remained in contact for 1 to 10 seconds. For cold testing, a carbon dioxide pencil of 3.5 mm diameter was held to the tooth for 5 seconds to 5 minutes. The teeth were extracted and examined histologically. To measure the temperatures generated at the pulpal–dentin junction (PDJ), a thermistor was placed onto the dentin surface of an extracted tooth. Internal temperature was recorded as the external surface was heated to different temperatures. The maximum PDJ temperature reached with heat testing was 39.9 °C (10-second application) and for cold was 9.5 °C (5-minute application). These temperatures do not reach the thresholds at which tissue damage will occur. Additionally, the time of application falls within the range of likely clinical application.

Augsburger et al.¹⁷² observed similar temperature decreases with their *in vitro* and *in vivo* measurements. The greatest temperature drop in their *in vitro* evaluation was 6.3 °C. This fall in temperature occurred in a tooth with a full gold crown, which received a 5-second application of carbon dioxide snow. The greatest temperature drop in noncarious teeth was 2.5 °C (also with carbon dioxide). They also tested water and skin refrigerant that had maximum temperature drops at the PDJ of 2.8 and 1.8 °C, respectively. The greatest temperature transference between adjacent teeth was a decrease of 1.7 °C between a tooth with a gold crown and one with an amalgam. Rickoff et al.¹⁷¹ experienced a similar, very small temperature drop of 0.9 °C, after applying carbon dioxide to four premolar teeth *in vitro*. *In vivo* histologic analysis revealed no alteration from normal tissue appearance after a 2-minute¹⁷³ or a 5-minute¹⁷⁴ application of carbon dioxide. When carbon dioxide was held to a tooth for 20 minutes, the pulp suffered with necrosis of odontoblasts.¹⁷⁵ It is safe to conclude that heat and cold testing within normal clinical parameters will not damage the dental pulp.

Orthodontics

TOOTH MOVEMENT

Orthodontic tooth movement of a routine nature does not cause clinically significant changes in the dental pulp. Responses to pulp testing, especially electrical, may be unreliable.¹⁷⁵ The heavy forces used to reposition impacted canines frequently lead to pulp necrosis or calcific metamorphosis.¹⁷⁶ Intrusion but not extrusion reduces pulpal blood flow for a few minutes as the pressure is applied.¹⁷⁷ Capillaries proliferate in the pulps of moving teeth.¹⁷⁷ A variety of growth factors are produced including vascular

endothelial growth factor (VEGF) that may explain this increase in vascularity.^{178–180}

REMOVAL OF ORTHODONTIC BRACKETS

Some of the methods of removing brackets at completion of orthodontic treatment have the potential to cause injury to the pulp.^{181–186} Brackets may be simply ground off, or pincher-type pliers may be used to mechanically remove an orthodontic bracket. A third method of bracket removal is use of an electrothermal device (ETD) that heat-softens the bonding composite expediting removal of the bracket. Heat transferred from the ETD has been measured as high as 45.6 °C¹⁸⁷ on the pulpal side of dentin *in vitro* experiments, though most reports have been in a lower range.^{181,188,189} When residual composite is cleaned up by grinding it away, pulp-side temperature actually decreased below ambient temperature when water coolant was used.¹⁸¹ Metal brackets seem to have a greater capacity to transmit heat to inner dentinal surfaces than ceramic brackets.¹⁸³

In vivo evaluation has recorded much lower temperatures and has reported limited pulpal damage. Jost-Brinkman et al.¹⁸² observed no pulpal inflammation 4 weeks after electrothermally debonding brackets from human teeth. The maximum temperature recorded was 6.9 °C over a period of 43 seconds. There has been consensus that electrothermal debonding does not cause gross damage or necrosis of dental pulp. However, there may be limited peripheral disruption of odontoblasts with slight inflammation.^{181,185,186,190}

Ultrasonic Scaling

Activation of ultrasonic instruments generates large amounts of heat. Although dentin is not a particularly good thermal conductor, this heat can still transfer through dentin to affect pulp tissue. Ultrasonic scaling of roots requires prolonged contact of an ultrasonic device, and the potential for pulp damage exists. As with other heat-generating dental procedures, proper cooling with water prevents gross pulpal damage. In live dogs, ultrasonic scaling did not create heat-induced pulpal damage when water coolant was used.¹⁹¹ Interestingly, histologic examination did reveal acute pulpitis, but it was attributed to the vibratory effects of the ultrasonic device rather than the temperature, because the measured temperature did not reach a level sufficient to cause damage. An interesting phenomenon of ultrasonic dental scalers is that the load of force with which

the ultrasonic tip is held against the tooth has a much greater effect (4×) on the heat generated in the dentin substrate than the power setting.¹⁹² One investigation found greater heat generation with diamond sonic tips versus smooth surface tips and greater heat production with heavy versus light force (1 N and 0.3 N).¹⁹³ A diamond tip with heavy pressure resulted with in vitro measurement of 36°C increase. When water coolant was used, all measurements were below 4.2°C increase. Proper water-

cooling of both ultrasonic and sonic scalers will prevent excessive heat production in the pulp.

Systemic Factor

HEREDITARY HYPOPHOSPHATEMIA

An unusual and rare cause of pulpal dystrophy and necrosis is found in individuals afflicted with hereditary

Figure 23 Unusual pulp dystrophy in *hereditary hypophosphatemia*. Incomplete calcification of dentin and large pulps leave these teeth vulnerable to infection and necrosis. **A**, Maxillary incisors at the age of 13. Note large pulp spaces. **B**, Mandibular incisors have been traumatized and pulp necrosis has developed. **C**, Large pulps can be seen in molar and premolar teeth. The pulp in the first molar later became necrotic. **D**, Large pulp size and shape are also apparent in the deciduous dentition. On the basis of these childhood radiographs, diagnosis can be made early about the patient's condition. Timely vitamin D therapy may prevent dwarfing. From Ingle JI. *Endodontics*, 1st ed. 1965. Ingle JI. Etiology of pulpal inflammation, necrosis or dystrophy.

hypophosphatemia. This disease, which results in dwarfism and “tackle deformity” of the legs, was formerly called refractory rickets, renal rickets, or vitamin D-resistant rickets. Its involvement in dentistry was first reported by Everett and Ingle.¹⁹⁴ It is characterized dentally by the abnormally large pulps and incomplete calcification of the dentin (Figure 23). The pulps in these teeth appear to be fragile and succumb to minor irritating stimuli. In one report, the patient had 11 pulpless teeth requiring endodontic treatment.

The diagnosis of this condition can be made through viewing oral radiographs, even of the deciduous teeth. It allows differentiation of this condition from achondroplastic dwarfism, which does not affect tooth pulps.

A report from Montreal pointed out that two different diseases are operative in this syndrome, namely autosomal dominant hypophosphatemic bone disease (HBD) and X-linked hypophosphatemia (XLH).¹⁹⁵ Although victims of HBD and XLH share similar dental abnormalities (large pulp spaces and pulp necrosis), patients with XLH have severe malocclusions as well. Unfortunately, the dental abnormalities are not prevented by early systemic treatment.¹⁹⁵

The classic oral features of hypophosphatasia, namely, premature tooth loss and large pulp spaces, were found in a young adult woman with bone and joint pains. A study of 22 family members revealed several with dental abnormalities such as abnormal enamel, dentin, or cementum formation, decreased mandibular bone density, and abnormally large pulp spaces. Only a sister fulfilled the biochemical criteria for hypophosphatasia.¹⁹⁶ Biochemical examination of an extracted tooth from this sister showed phosphate and alkaline phosphate values 7 to 10 times lower than normal.

CHAPTER 13

PERIAPICAL LESIONS OF ENDODONTIC ORIGIN

ZVI METZGER, ITZHAK ABRAMOVITZ

Periapical lesions of endodontic origin will be discussed in this chapter in terms of function and form. An emphasis is placed on the understanding of the biological function of the lesion, with special attention to processes leading to its formation and to changes it may go through, as observed by either the clinician or the histopathologist. The content of this chapter requires some knowledge of microbiology and immunology. The reader is referred to Chapters 7 and 9 dedicated to these subjects, which provide the essential background in detail. Periapical lesions, *not inflammatory in nature*, will be discussed in Chapter 8.

Periapical lesions of endodontic origin are produced by an inflammatory response at the root apices of teeth with nonvital pulps. Because the necrotic pulp cavity is relatively inaccessible to the immune response, it becomes a reservoir of infection. The establishment of an inflammatory response is believed to be an attempt to prevent the spread of infection to periapical tissues. Periapical lesions of endodontic origin are generated by the immune system. The response may occur at any portal of exit from the root canal system. Since most such portals are found in the apical area, and for the sake of convenience for the reader, the terms “periapical” or “apical” will be used as a uniform term, for inflammatory lesions of endodontic origin.

Bacterial Elimination in Periapical Lesions

The elimination of bacteria emerging from the apical foramen and the prevention of their spread to other tissues are important functions of apical periodontitis.^{1,2} Even though bacteria are present in infected root canals, most periapical lesions successfully contain them. Thus, periapical inflammatory lesions may be considered to be a successful host response to bacteria and bacterial by-products in an infected root canal

system. The elimination of the invading bacteria is one of the main functions of the immune response. The key role in this process is played by the polymorphonuclear leukocytes (PMNs) that eventually phagocytize and kill the bacteria. PMNs originate from progenitor cells in the bone marrow and enter the bloodstream where they circulate for 7–10 hours, ready to be called to duty. To reach the bacteria emerging from the apical foramen, PMNs must first leave the bloodstream and find their way to that site. This process is initiated by a stage termed “margination,” which is mediated by a locally elevated expression of attachment molecules such as intercellular attachment molecule-1 (ICAM-1) on the surface of the endothelial cells in the area.^{3–5} The “right area” for margination is defined for the PMNs by local production of IL-1 and tumor necrosis factor (TNF) that results in an elevated expression of the attachment molecules.^{3,6} Once attached, the PMNs can leave the blood vessels by passing between endothelial cells in a process termed “diapedesis.” PMNs follow the gradient of the chemotactic factor C5a that is generated by the activation of the complement system at the site where bacteria are present. This gradient serves as a chemotactic signal; the random motion of the PMNs becomes directional and they follow this gradient from low to high concentration. Complement may be activated directly by bacterial constituents such as bacterial endotoxin (lipopolysaccharide, LPS), using the “alternative” or “properidin” pathway. This represents the basic, innate immune response of the host. The “classical pathway” of complement activation is dependent on specific IgG or IgM that binds to antigens present on the bacterial surface. This, in turn, triggers complement activation by C1q molecules of the complement cascade. Complement activation is a “chain reaction” type of response that generates large amounts of three types of molecules that may be considered as major life-sustaining factors. Two of them are small and readily

diffusible factors, C3a and C5a, while the third is a larger molecule, C3b, that remains attached to the bacterium and serves as a signal that marks the targets for PMNs to engage and phagocytize.

Effective phagocytosis requires marking the bacteria with a dual signal, the other signal being a specific IgG molecule attached to the bacterium. PMNs have two distinct receptors, C3b receptor and Fc receptor, on their membrane that engage the relevant molecules allowing for effective phagocytosis. The latter attaches to the Fc portion of an IgG molecule that has been attached to the bacterial surface antigen via its binding sites (located at its Fab region). This mechanism is termed “opsonization” and is essential for the effective elimination of bacteria by the PMNs.⁷ Antibodies may come from the bloodstream, but evidence for their local production will be discussed below.

It is also clear that an effective and continuous local supply of complement constituent is essential for the above-mentioned process to take place. This is achieved by an increased permeability of the capillaries in the area, induced by C3a and C5a via activation and degranulation of local mast cells. When vascular permeability is normal, large molecules are kept within the blood vessels. They serve to maintain the essential osmotic pressure that will draw water back into the venous part of the capillaries and maintain the blood and tissue volumes at equilibrium.

From the above sequence of events, it becomes apparent that even though the PMNs are responsible for phagocytizing and killing bacteria, an elaborate infrastructure of cells is required to locally provide at least two main types of molecules, without which the PMN response will be handicapped: IgG *specific* to the involved bacteria and the cytokines IL-1 and TNF.

CELLS, IMMUNOGLOBULINS AND CYTOKINES IN PERIAPICAL LESIONS

Qualitative and quantitative studies of the cellular composition of periapical granulomas have been profoundly influenced by the methodology available. Initial attempts to characterize the cells participating in these lesions were based on the classical morphology of the cells, followed by the use of electron microscopy. With the introduction of immunohistological methods, the first attempts to specifically identify plasma cells in periapical lesions by their immunoglobulin content were reported.⁸ In recent decades, the intensive use of monoclonal antibodies against subsets of T lymphocytes, B lymphocytes, macrophages, dendritic cells, plasma cells, and PMNs resulted in a major breakthrough in the

understanding of the immunobiology of the periapical host response, in both naturally occurring human periapical lesions and those experimentally induced in the rat. The most recent approach involves molecular biology methods, such as in situ hybridization or the polymerase chain reaction.

Cells with distinct morphology, such as PMNs, mast cells, lymphocytes, plasma cells, and osteoclasts, have been easily identifiable. However, in earlier studies only cells with “classical” macrophage morphology could be identified as such. Monoclonal antibodies make it possible to identify macrophages and dendritic cells of diverse morphology as well as to recognize subsets of these and other cells.

EVOLUTION OF THE IMMUNOBIOLOGICAL CONCEPT OF PERIAPICAL LESIONS

The availability of new methodologies has influenced the type of studies performed and eventually affected the evolution of the immunobiological understanding of the complex nature of the periapical host response.^{9–11} Initially, the commercial availability of specific antibodies directed against human IgG, IgM, IgA, and IgE allowed for the immunofluorescent or immunohistochemical detection of these molecules in periapical lesions, either in a free form or as markers of subsets of B lymphocytes and plasma cells.¹² Later, the combination of these antibodies with those directed against human complement allowed the demonstration of *activity* rather than the *simple presence* of immunoglobulins in periapical lesions. Johannesen et al. demonstrated intracellular colocalization of IgG and C3b in macrophages in periapical inflammatory lesions, suggesting phagocytosis of bacteria via dual opsonization by both opsonins.¹³

The availability of monoclonal antibodies against various T lymphocyte subsets made it possible to explore the presence of these cells in both human periapical lesions as well as in those experimentally induced in rats. T-cells in human periapical granulomas were studied by Cymerman and others.^{14–16} It became apparent that both T helper (CD4⁺) and T suppressor (CD8⁺) lymphocytes were present in these lesions.¹⁴ In delayed hypersensitivity in humans, a typical T helper/T suppressor relation is about 2:1.¹⁷ It was therefore of interest to define whether T lymphocytes in periapical lesions follow this trend. Babal et al. found a T helper/T suppressor ratio of <1.0 in periapical granulomas, while Barkhordar and Desouza reported a ratio of ~1.0.¹⁵ It seemed that the predominance of T helper lymphocytes, which is typical of delayed hypersensitivity, does not exist in a

chronic periapical granuloma. Nevertheless, this is not a uniform finding, as Kopp and Schwarting found a T helper/T suppressor ratio of 3:2 in periapical granulomas, which diminished to ~1.0 in periapical scars.¹⁸

In a rat model, Stashenko and Yu demonstrated that during the early, active, phase of lesion development, helper (CD4⁺) T cells predominated, while at the later chronic stage, suppressor (CD8⁺) T cells outnumbered the helper T-cell population.¹⁹ The initial Th/Ts ratio of 1.7 lessened to <1.0 at the later stage, as compared to a Th/Ts ratio of 2.0 in peripheral blood. These findings were interpreted as the initial active function of T lymphocytes, which is later downregulated and controlled by suppressor T cells. The balance of their activities is expressed in chronic periapical lesions, such as those encountered in humans.

THE PROTECTIVE FUNCTION OF T LYMPHOCYTES IN THE PERIAPICAL GRANULOMA

A protective role of helper T lymphocyte function should eventually be expressed as a better ability of the host to prevent bacteria from spreading from the infected root canal. This may be accomplished by (1) the local production of antibodies and (2) increasing the local availability and enhancing the function of phagocytes (Figure 1). Local activation of antigen-specific T helper lymphocytes is a prerequisite for the local production of antibodies that are specific to the bacteria that periodically emerge from the root canal.^{20,21} This in turn will enable effective opsonization of the bacteria, followed by phagocytosis and killing.

Local macrophage activation is accomplished mainly by interferon- γ (INF- γ) produced by the activated T helper cells (see Figure 1). Even though activation of the lymphocytes is antigen-specific, once macrophages are activated, the result is nonspecific, and their phagocytic and killing abilities, as well as cytokine production, will be greatly enhanced. IL-1 and TNF production by activated macrophages will locally elevate ICAM-1 molecule expression by endothelial cells in the capillaries, thus enhancing the local attachment of PMNs and monocytes and enhancing their migration into the periapical area.^{3,6} IL-8 produced by these macrophages will chemotactically attract the PMNs and activate them, making them more available and more competent to engage and kill the bacteria²²⁻²⁴ (see Figure 1). Thus, macrophage activation has a major role in maintaining the two lines of phagocytic cell defense that are typically

Figure 1 Protective functions of T lymphocytes and macrophages in the periapical granuloma. Specifically activated T lymphocytes produce a plethora of cytokines, some of which promote activation, proliferation, and maturation of B lymphocytes to become plasma cells producing immunoglobulins specific to the root canal bacteria. Macrophage activation is mediated by interferon- γ (INF- γ) produced also by these cells. Activated macrophages produce IL-1 and IL-8 that are essential for effective local recruitment and activation of PMNs. Bacterial endotoxin (LPS) can bypass the T lymphocytes and directly activate macrophages. Bone resorption in apical granuloma is mediated by IL-1 β (an activated macrophage product) and by TNF- β (an activated T lymphocyte product). It may be considered a negative side effect of the ongoing protective process in the apical granuloma.

described in the periapical lesion: an inner area, closer to the apex, in which PMNs predominate and the area around it in which the phagocytic macrophages are observed.²⁵ The defensive function of helper T lymphocytes is achieved *indirectly* by allowing (1) activated specific B lymphocytes to proliferate and mature into plasma cells that will produce antibodies and (2) the activation of nonspecific effector cells, the macrophages. In order to avoid an endless loop of mutual activation of macrophages and T lymphocytes, the process is actively controlled and downregulated by suppressor T lymphocytes.²⁶⁻²⁸

The essential role of the T lymphocytes in this process was well established and accepted by the late 1980s of the last century.^{28,29} A turning point occurred with the first studies that utilized athymic mice and rats to study the formation of periapical inflammatory lesions to determine the critical role of T lymphocytes in the formation of these lesions.^{30,31} Unexpectedly, both groups demonstrated that periapical lesions could also develop independent of T-lymphocyte activity, thus leaving the center stage to another key actor: the macrophage (as will be detailed below).

B CELLS, PLASMA CELLS, AND IMMUNOGLOBULIN PRODUCTION

The presence of *plasma cells*, the cells that produce immunoglobulins, in apical granulomas has been well documented by many investigators.^{16,32–35} In addition, the presence of *B lymphocytes*, the precursors of plasma cells, has also been documented in apical granulomas.^{12,36,37} Immunoglobulin-containing cells (B Ly + plasma cells) may constitute 11–50% of the mononuclear cells in apical granulomas.^{12,36} Among these cells, a majority of them produce IgG (70–85%) while small fractions of them produce IgA, IgE, and IgM.^{12,36} It must be kept in mind that the presence of IgG and IgG-producing cells in the periapical tissue does not necessarily mean that the immunoglobulins will be specific to the bacteria that reside in necrotic infected root canals. Baumgartner and Falkler²⁰ and Kettering et al.²¹ demonstrated that antibodies specific to root canal bacteria are indeed present in the periapical tissue. Both groups independently demonstrated that specific immunoglobulins that bind to bacteria typically found in infected root canals are present in human periapical granulomas.^{20,38} IgG concentrations reported in periapical exudates are four times higher than those found in the serum of the same patients.³⁷ This may indicate but not prove the local production of these immunoglobulins in periapical lesions. Baumgartner and Falkler^{39,40} convincingly demonstrated that the local production of immunoglobulins does indeed take place in the human apical granuloma.

Immunoglobulin production by plasma cells is the end result of a complex and well-controlled process that starts with the exposure of antigen-presenting cells (APCs) to the relevant antigen. In turn, they present the antigen, in conjunction with their major histocompatibility complex class II (MHC II) surface molecule, to specific T lymphocytes. This specific signal, together with a nonspecific signal in the form of the cytokine IL-1, results in the activation of the antigen-specific set of T cells.⁴¹ Once activated, the T cells proliferate and produce several cytokines, two of which are essential for immunoglobulin production, IL-4 and IL-5, which induce the proliferation of B lymphocytes and their maturation into plasma cells. Both serve as nonspecific signals that allow a clone of antigen-specific B cells that were exposed to the same specific antigen to respond by proliferation and maturation into specific plasma cells. These cells will eventually produce immunoglobulin that is specific to that antigen.

MHC II molecules expressing macrophages and dendritic cells were found by Kaneko et al. in

experimentally induced periapical lesions in rats.^{42,43} The presence of HLA-DR+ cells, which are the human equivalent of the MHC II-positive cells, was studied in human granulomas in a dispersed cell cytometric flow immunochemistry study.⁴⁴ Activated macrophages (HLA-DR+, CD14⁺) and mature dendritic cells (HLA-DR+, CD83⁺) were found in great numbers. Thus, antigen presentation is possible and likely in the confinement of the apical granuloma.

T LYMPHOCYTES IN THE PERIAPICAL GRANULOMA

T lymphocytes are a major constituents of the chronic inflammatory response at the periapical region.^{16,18,19,25,34–36,45} They may constitute up to 40% of the mononuclear inflammatory cells.^{35,36} During the active phase of development of an induced apical periodontitis in rats, T helper cells outnumbered T suppressor lymphocytes with a Th/Ts ratio of 1.7.¹⁹ When active lesion expansion subsided, by day 20, this ratio reversed to 0.9 and remained at 0.7 for the remaining 70 days of the experiment. In an established human apical granuloma, T helper (CD4⁺) cells outnumber T suppressor cells (CD8⁺) by a ratio of 1.5–2.0.¹⁹ Even though large numbers of T cells are present, it is most likely that only the *activated T cells* play a role in the protective response, and these may constitute as few as 6% of the total T-cell population.³⁵ When activated, these cells produce a plethora of cytokines that regulate the immune response. T helper (CD4⁺) lymphocytes may be divided according to their cytokine expression pattern and classified as either T helper 1 (Th1) cells that produce and secrete IL-2 and INF- γ or Th2 cells that produce and secrete IL-4, IL-5, IL-6, IL-10, and IL-13. Th1 type cytokines augment cytotoxic T-cell functions and stimulate proinflammatory cytokine production in other cells, such as macrophages, while Th2 type cytokines participate in B-cell stimulation to mount a humoral immune response and in downregulation of inflammatory reactions.^{46,47} Among the cytokines produced by activated T cells, IL-2 is involved in T-lymphocyte proliferation while IL-4, IL-5, and IL-6 are involved in B-cell proliferation, differentiation, and maturation into plasma cells, thus leading to immunoglobulin production (see Figure 1). INF- γ is the key proinflammatory cytokine produced by activated T lymphocytes. Its major function is to activate macrophages that have several key roles, as will be discussed below. Activated macrophages, in turn, are the major source of IL-1 in the periapical lesion and, thus, may contribute to several protective processes including immunoglobulin production, at

its initiation stage. TNF- β is another important cytokine produced by activated T cells, which has been implicated as a major factor in the activation of osteoclastic bone resorption in humans, as will be discussed below.⁴⁸

MACROPHAGES IN THE PERIAPICAL GRANULOMA

Macrophages have a major role in several processes that take place in these lesions.⁴⁹ Macrophages make up to 46% of the periapical inflammatory cells found in tissue sections of human periapical granulomas.⁴⁵ When Stern et al.⁵⁰ dispersed periapical granulomas to cell suspensions, 30% of the resulting cells were macrophages. Macrophages were also found as the predominant inflammatory cell when Kopp and Schwarting¹⁸ used monoclonal antibodies to identify them in human periapical lesions. Piatelli et al.³⁵ similarly reported that macrophages outnumbered T lymphocytes in human periapical granulomas. In the rat model, Kawashima et al.²⁵ recently demonstrated that macrophages were the predominant immunocompetent cell type throughout the development of the lesion. The kinetics of their presence in these experimental periapical lesions was studied by Akamine et al.,³² who followed the periapical lesions for as long as 150 days. Macrophages increased in number during the first 10 days and maintained their numbers through day 60, followed by a gradual decline thereafter (Figure 2A,B).

POTENTIAL ROLE OF MACROPHAGES IN THE PERIAPICAL GRANULOMA

Macrophages have a central role in (1) innate, nonspecific immunity; (2) the onset, regulation, and outcome of antigen-specific, acquired immunity; and (3) the regulation of connective tissue destruction and repair. Macrophages are “professional” phagocytic cells that can internalize and kill bacteria by several mechanisms, some of which are part of innate immunity, while others require the presence of specific antibodies against the bacterium and should be considered to be part of the effector arm of specific, acquired immunity. Bacteria, new to the host, may activate the complement system by the alternative pathway, resulting in their opsonization by the C3b component. This, in turn, will result in their phagocytosis by the macrophages via a C3b receptor-mediated process. Other bacteria may attach to the macrophages through lectin-mediated mechanisms, leading to lectinophagocytosis that is independent of the common C3b receptor–ligand binding.⁵¹ Once specific antibodies to a strain of bacteria are present, either

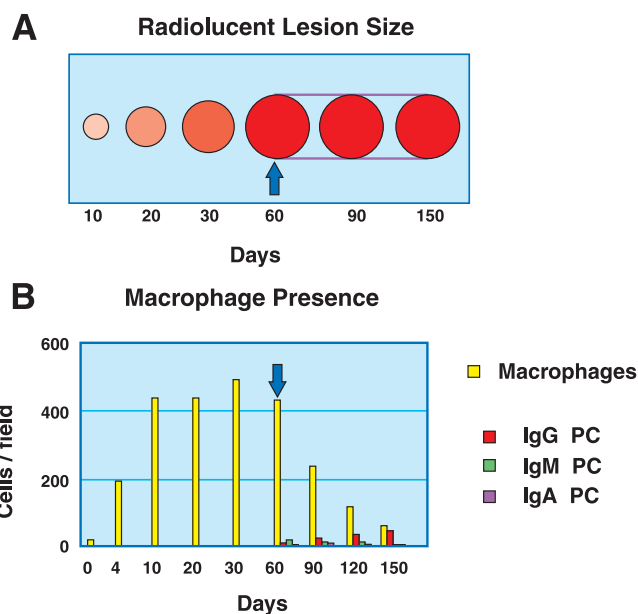

Figure 2 Macrophages and bone resorption in developing periapical lesions in rats. **A**, The periapical lesion gradually enlarges up to 60 days, and then its size remains stable. **B**, Macrophage domination in the lesion coincides with the period in which the lesion grows and diminishes afterwards, with the appearance of plasma cells. Adapted from Akamine A et al.³²

by developing through the course of the current infection or as a result of a former encounter with these bacteria, a more efficient form of phagocytosis will occur, involving *dual* opsonization by IgG and C3b and engagement of both the Fc and C3b macrophage receptors.

It is the innate immunity that enables the host to survive the initial steps of infection, while the acquired, specific immunity allows the host to efficiently eliminate the invading microorganisms. Macrophages present in the periapical granuloma may contribute, by their function as phagocytes, to the effective prevention of the dissemination of bacteria from the infected root canal. Macrophages may also serve as “APCs” in the essential initial steps of the induction of acquired immunity. They process the antigen and present it to the antigen-specific clones of helper T lymphocytes by a process involving recognition of an MHC II molecule on macrophages by lymphocytes. Additionally, they produce the cytokine IL-1, which is an essential complementary signal for the activation of these lymphocytes. Macrophages that carry MHC II molecules, and thus may serve as APCs, have been identified in periapical granulomas in both humans and the rat model (also termed HLA-DR or Ia antigen-positive cells).^{18,52}

Macrophages are considered to be a main source of the cytokines IL-1 α , IL-1 β , and TNF- α that contribute to the initiation and regulation of the inflammatory process. Additionally, they produce a plethora of other active molecules, including metalloproteases (collagenase and elastase) and prostaglandins that may also contribute to the destructive outcome of the periapical inflammatory process. Some of these products directly damage connective tissue constituents, while others, including the cytokines produced by the macrophages, activate other cells to exhibit either (1) destructive activities such as osteoclast activation and bone resorption or (2) constructive repair processes by activation of fibroblast proliferation and collagen production by these cells.

Though it is commonly assumed that *all* of the above-listed potential activities of the macrophage take place in the periapical granuloma, this is not entirely true. Subsets of macrophages that may exist in relatively small numbers are responsible for a specific activity. Emerging evidence indicates that some of these functions, such as active production of IL-1, involve only a small number of activated macrophages. In chronic human periapical granulomas, these cells do not exceed 2% to 3% of the macrophages present in these lesions, and only these cells have been shown to express mRNA for IL-1 β .^{9,53}

KINETICS OF MACROPHAGE PRESENCE IN PERIAPICAL LESIONS

The unique study by Akamine et al.³² followed rat periapical lesions for as long as 150 days. An analysis of their data reveals that the active growing stage of periapical lesions in the rat, which lasted for the first 60 days, coincides with a peak of macrophage presence in this lesion. When the active growth stops and a stationary stage is reached, the presence of macrophages in the lesion gradually declines (Figure 2). This may be a coincidence, but nevertheless, it may indicate a significant correlation. Further support may be found in a recent study by Kawashima et al. that showed that macrophage infiltration in the periapical lesions was associated with bone resorption in the area.²⁵ In their study, macrophage infiltration preceded that of lymphocytes and gradually increased throughout the 56 days of the experiment.

IL-1 AND MACROPHAGES IN THE PERIAPICAL GRANULOMA

The presence of IL-1 β in association with a subpopulation of the macrophages in periapical lesions has been

reported by several investigators.^{9,53,54} Artese et al.⁵³ reported that there were very few cells (2% to 3%) in established human periapical granulomas with immunoreactivity of IL-1 β and TNF- α and that these cells had a macrophage morphology. Tani-Ishii et al.⁵⁴ used a rat model to demonstrate that IL-1 α and TNF- α were associated with macrophages in the periapical lesion as soon as two days after the exposure of the pulp and persisted through the 30 days of the experiment. In contrast, TNF- β and IL-1 β could not be detected in their sections.

It should be kept in mind that the presence of cytokines, in association with these cells, does not necessarily prove that they are the source of these molecules. A cytokine may potentially have been attached to or may have been taken up by the macrophages, rather than produced by them. Recently, direct proof has been provided that clearly demonstrates that the activated macrophages actually produce IL-1 β in periapical lesions. In an *in situ* hybridization study, Hamachi et al.⁹ demonstrated the presence of IL-1 β mRNA in macrophages in human periapical lesions. This proves not only that these cells are capable of producing cytokines in general and that cytokines are associated with them in the periapical lesion, but also that subpopulations of macrophages are actively engaged in the production of this cytokine in periapical granulomas.

BACTERIA IN PERIAPICAL LESIONS

For many years, periapical lesions were considered “not an area in which bacteria *live*, but in which they are *destroyed*.”⁵⁵ This concept had its origin in experiments that failed to produce viable bacteria from closed apical granulomas,⁵⁶ and it gained support from the common clinical experience that once bacteria are eliminated from the root canal, most lesions will heal. With the development of adequate anaerobic cultivation methods,⁵⁷ it became apparent that this concept may be true “in most cases” but clearly not in all of them. Initially, the concept that viable bacteria may be present outside of the root canal in the periapical tissue was accepted for few specific bacteria.^{58–61} The concept that *extraradicular infection* may survive independent of what occurs in the root canal has recently become more widely accepted.^{62–68} It is widely accepted that viable bacteria may be cultured from chronic periapical abscesses with a sinus tract and that some closed periapical lesions may contain viable bacteria outside of the root canal: an extraradicular infection. The latter point was initially considered to be a unique condition related only to specific bacteria, such as strains of *Actinomyces* and

Arachnia.^{58–61} However, evidence has accumulated that other bacteria may also survive outside of the root canal in certain lesions.^{62–68} Even though this concept is not yet uniformly accepted,^{69,70} the original concept that the periapical granuloma is *always* a sterile lesion should be reconsidered in favor of the more moderate statement that it is sterile in *most* cases. This inevitably leads to an understanding that the equilibrium between bacteria and the host, in the periapical environment, is more complicated than believed in the past.

THE EQUILIBRIUM BETWEEN BACTERIA AND THE HOST

An apical granuloma and a chronic periapical abscess with a sinus tract represent two distinct types of equilibriums established between bacteria in the root canal and the host response. The front between bacteria and the host response is established at or near the apical foramen where bacteria or bacterial products/antigens are immediately engaged by the immune system. PMNs will attempt to kill any bacteria within their reach. PMNs are relatively short-lived cells and once they migrate into the tissues they have up to a 3-day life span. Those arriving into the area adjacent to the bacteria will remain there and spontaneously die within a short period, followed by cellular disintegration. The remaining dead bacteria and remnants of the PMNs are taken up by abundant local tissue macrophages. When enzyme-containing PMNs disintegrate, they also release lytic enzymes, such as collagenase, elastase, and hyaluronidase, in the area that damage the host tissue.⁷¹ In histological sections taken under such conditions, only the long-living cells, such as lymphocytes, plasma cells, and macrophages, will be found. The short-lived PMNs will be found only in small numbers, either on their way from adjacent blood vessels or where they accumulate, adjacent to the apical foramen. It is important to realize that macrophages, lymphocytes, and fibroblasts, seen in the histological sections, were there a few days ago and would have been there many days after the section was taken. On the other hand, any PMN seen in the section is a new comer: it left the bloodstream a few hours beforehand and would have died, disintegrated, and disappeared within a few hours or a couple of days. They are not residents of the tissue, but rather are temporary visitors.

An apical granuloma may develop into an acute apical abscess or into a chronic periapical abscess with a sinus tract, a phenomenon termed “phoenix abscess.”⁷² A shift in the balance between bacteria and the host may be the likely cause. Such a change

may be quantitative, qualitative, or both. If the amount of bacteria introduced into the lesion suddenly increases, the amount of complement-derived chemotactic factor will increase, followed by an increased number of PMNs reaching the area per given time period. More PMNs will die and more damage will be caused by the released enzymes. This rate of destruction may exceed the cleaning capacity of local macrophages and the local tissue may become solubilized by proteolytic and hydrolytic enzymes, resulting in a liquefied area surrounded by migrating PMNs in a background of chronically inflamed tissue. This results in the formation of an abscess.

If the change in the amount of bacteria is transient in nature, macrophages will clean the area, repair will take over, and the tissue will return to its previous state with connective tissue heavily infiltrated with lymphocytes, plasma cells, and macrophages.

A shift in the equilibrium could also be qualitative in nature: a shift in the bacterial population. Some bacterial strains developed a variety of phagocytosis-evading mechanisms that allow them to survive a massive host PMN attack. Some *Porphyromonas gingivalis* strains isolated from suppurating periapical lesions have the capacity to evade phagocytosis due to an antiphagocytic capsule they possess.⁷³ Other strains have a potent protease that attacks and destroys the C3 and/or C5 complement molecules, thus disrupting this essential antibacterial mechanism.^{74–76} Some strains developed a unique evasion strategy and have proteases that clip off the Fc portion of IgG molecules that attach to their surface, thus creating host-derived shields made of Fab fractions that protect them from phagocytes.⁷⁷ Strains of *Actinomyces israelii* have yet another strategy: they form aggregates and biofilms that cannot be penetrated by the PMNs and are too large to be phagocytized.^{59,61,78–80} A frustrated host response will continuously pour large amounts of PMNs into the battle field only to result in local tissue destruction and pus formation but without any real effect on the bacteria. A draining sinus tract is the clinical expression of the resulting chronic apical abscess.

FLARE-UPS IN PERIAPICAL LESIONS: AN IMMUNOBIOLOGICAL VIEW

A flare-up represents a shift from the equilibrium previously established between bacteria in the root canal and the host response⁸¹ (Chapters 7 and 20). The immune response to extruded bacteria and bacterial by-products results in two main events that occur concomitantly and result in the above symptoms: a

vascular and a chemotactic response. Antibodies bind to their specific bacterial antigens, thus activating the complement system via C1q and the “classical pathway.” Large amounts of C3a and C5a are generated that drive these two main events. C5a and C3 bind to receptors on local mast cells, causing them to degranulate and release vasoactive amines, such as histamine, in the area.^{12,35} The resulting vasodilatation and increased vascular permeability provide additional complement and systemic, plasma-derived, specific antibodies to the ongoing response. Other large proteins also leave the blood vessels. This, in turn, results in a disturbance of the osmotic system that is responsible for the water balance between blood and adjacent tissues. Normally, fluid that leaves the blood vessels in the arterial part of the capillary bed, under the driving force of hydrostatic blood pressure, should be drawn back into the bloodstream in the venous part. This occurs due to the osmotic pressure generated by the large molecules that stay in the blood vessels. When this gradient is disrupted by the large molecules that leave the blood vessels, due to the increased permeability, water stays in the tissue, which results in edema. Since the bony crypt, in which the periapical lesion is contained, cannot expand, this process will result in increased pressure. The one direction in which this pressure may be partially relieved is moving the tooth occlusally, as far as the periodontal ligament fibers will allow. This tooth may now occlude prior to the adjacent teeth, causing an additional mechanical trauma, and the patient experiences more pain.

The other process caused by local complement activation will be a massive chemotactic signal that will attract large amounts of PMNs into the area that may result in abscess formation by the mechanisms discussed above.

PAIN IN APICAL PERIODONTITIS

Pain associated with symptomatic apical periodontitis is sometimes of moderate or severe nature, whereas most periapical lesions are not associated with pain at all.^{82,83} It may be a spontaneous pain or a painful response to mechanical stimuli such as percussion, occlusal loading, or sensitivity to palpation of the periapical tissues.⁸⁴ Pain is defined as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage.”⁸⁵ Accordingly, it has peripheral, as well as central, components and is subjected to modulation at each of these levels.

The key peripheral event is the stimulation of nociceptors, neurons that are preferentially sensitive to noxious stimuli or to stimuli that would become

noxious in a prolonged exposure.⁸⁵ Peripheral nociceptors may respond to mechanical, chemical, or thermal stimuli, the first two being of significance in apical periodontitis. Local sensitization of nociceptors may be induced by numerous mediators that are present in the inflamed periapical tissue (Figure 3). Some of these mediators, such as IL-1 α , IL-1 β , TNF- α , IL6, or nerve growth factor (NGF), are locally produced by cells of the immune system.^{86–89} Others such as CGRP and Substance P derive from stimulated nerve fibers that may become abundant in the area by a sprouting process associated with chronic inflammation.⁹⁰ Blood-derived bradykinin may also be locally present.⁹¹ Some local, peripheral mediators, such as bradykinin and serotonin, may directly induce action potential in the nociceptors.⁹¹ The effect of others, such as prostaglandins, NGF, cytokines, serotonin, nitric oxide and adenosine, is indirect, as they lower the stimulatory threshold of these nerve fibers.⁸⁶ Pressure building up in the bony crypt, due to edema, is unable to release by swelling, as would be the case in soft tissues. Triggering of pressure nociceptors that have a lowered threshold will result in pain that is often described as an “excruciating pain” and may be relieved only by either natural or artificial drainage.⁹²

The proalgesic effect of some cytokines such as IL-1 β , IL6 and TNF- α may be partially explained by

Figure 3 Local activation of nociceptors in an apical granuloma. Nociceptors (N) respond to mechanical and chemical stimuli. Bradykinin (BK) may directly induce action potential in a nociceptor. Others such as prostaglandins, nerve growth factor (NGF), and cytokines may act indirectly by lowering the stimulatory threshold of the nociceptors or by increasing their expression of BK receptors. All the mediators above have a proalgesic effect (black arrows). Opioids, endocannabinoids, and somatostatin (SRIF) generated by macrophages and PMNs have an analgesic effect (purple arrows).

enhancement of local prostaglandin production.⁸⁸ Nevertheless, some will have additional indirect effects. IL-1 β enhances the production of NGF by mast cells and T lymphocytes.^{93,94} NGF, in turn, binds to its receptors on the primary afferent neuron, resulting in the release of neurotransmitters.⁹⁵ It will also increase the expression of bradykinin receptors and increase the neuron's sensitivity to acidic pH that is often encountered in inflamed tissues.⁹⁶ IL-1 β also enhances the local formation of another pain-inducing arachidonic acid metabolite: LTB₄.⁸⁸ In addition, bradykinin itself may initiate a cascade of cytokine release that mediates hyperalgesic state by contributing to the above-mentioned mechanisms.⁹⁷

The presence of the above-mentioned mediators in symptomatic periapical tissues is well documented.^{22,98,99,100} Nevertheless, pain is not a typical symptom of asymptomatic apical periodontitis. This may be a simple quantitative issue: it could be that only when local proalgesic mediators reach a certain threshold, pain does appear.^{98,101,102} Nevertheless, it seems to be more complicated.

Local proalgesic effects of the mediators mentioned above are partially balanced by analgesic mediators derived from inflammatory cells (see Figure 3). Macrophages release somatostatin (SRIF) that has a local analgesic effect.¹⁰³ Endocannabinoids secreted by macrophages and opioids released by PMNs and macrophages most probably partially counterbalance the proalgesic mediators in the inflamed tissue.^{104–108} This concept was recently elegantly supported by blocking the migration of these cells into inflammatory sites. Inhibition of this migration was achieved by specific antibodies against certain integrins and selectins that mediate margination and diapedesis. It generated a strong proalgesic effect, most probably due to the lack of the effect of the analgesic peptides in the inflammatory site.^{109,110}

Central modulation of pain signals is also of major significance and is discussed in detail in Chapter 10. Pain associated with apical periodontitis is an end result of the balance between proalgesic and analgesic mediators that result in a certain level of stimulation of local peripheral nociceptors that is then transmitted centrally, where it is further modulated, resulting in a sensation of "pain."

BONE RESORPTION IN PERIAPICAL LESIONS

Bone resorption is one of the clinical hallmarks of periapical pathosis. The resorption may be viewed

either as an undesirable destructive by-product of the host response, as is the case with periodontal disease, or alternatively, as is traditionally presented, as a process by which a bone is removed from a risky area, thus allowing a "buffer zone" to be formed in which host response constituents engage the bacteria. In any case, it is bone resorption in the periapical area that serves the clinician as a major indicator of the presence of a periapical pathological process and the progression of its healing. As such, it has been thoroughly studied in both humans and animal models.

POTENTIAL VERSUS ACTUAL BONE-RESORBING AGENTS

Bone resorption occurs through the activation of the bone-resorbing cells: the osteoclasts. A wide range of biologically active molecules have been demonstrated to have the capacity to activate osteoclastic bone resorption in *in vitro* models. These include prostaglandins,¹¹¹ bacterial endotoxin,¹¹² complement activation products, as well as the inflammatory cytokines IL-1 α , IL-1 β , TNF- α , TNF- β , IL-6, and IL-11 that, as a group, were previously referred to as "osteoclast-activating factor."¹¹³ Among these, IL-1 β is the most active cytokine and its bone-resorbing capacity is 13-fold of that of IL-1 α and 1000-fold of that of TNF- α or TNF- β .¹¹⁴ When considering the periapical bone resorption associated with infected root canals, all of these have been mentioned and most of them were demonstrated in periapical lesions.^{6,12,33,48,53,98,100–102,115,116} The question was which of these *potential* bone-resorbing stimuli is actually involved in the activation of osteoclasts in these lesions?

Two studies by Wang and Stashenko⁴⁸ have provided convincing evidence that among the long list of *potential* mediators that may activate osteoclasts and cause periapical bone resorption, the main factors and those that are most important in human chronic periapical lesions are IL-1 β and TNF- β . In the rat model of induced active periapical bone resorption, IL-1 α and, to a lesser extent, IL-1 β and TNF- β are the major bone-resorbing cytokines.¹¹⁷ Both studies suggest that osteoclast activation by these cytokines may be mediated in part by *de novo* formation of cyclooxygenase pathway products such as prostaglandins, as the effect could be significantly blocked by nonsteroid anti-inflammatory drugs (NSAIDs).^{48,117}

The formation of periapical lesions was studied in the rat model by Kakehashi, Stashenko, and others.^{9,19,25,31,118,119} Following exposure and bacterial contamination of the pulp chamber and the root

canal, an inflammatory response is activated in the periapical region that is associated with rapid growth of a periapical lesion, the size of which can be monitored using either radiographs or histological sections. This rapid growth persists for 15 days and is associated with “bone-resorbing activity” that can be detected in homogenates of the lesions and measured using an *in vitro* bone resorption assay.¹¹⁹ Following the active resorptive phase, the lesions remain at a stable size for as long as 30 days.¹²⁰ During this stationary phase, the bone-resorbing activity declined to 10% to 30% of that in the active growing stage. This last stationary phase is considered to be equivalent to an existing chronic, periapical granuloma in humans that also contains bone-resorptive activity.⁴⁸ The cytokines defined in the above studies are found in human periapical lesions in measurable amounts. Lim et al.¹⁰² found significant amounts of IL-1 β in homogenates of human periapical lesions, even though none of the patients had detectable serum levels of this cytokine. Noninflamed pulp tissue, which served as a control, was also free of the cytokine. Periapical exudates were studied by Matsuo et al.¹²¹ for their IL-1 α and IL-1 β contents. Exudates, obtained through the root canal, contained an average level of 6.57 (± 0.73) ng/mL of IL-1 β and 3.23 (± 0.66) ng/mL of IL-1 α . The cytokine profile change following root canal treatment with a tendency of IL-1 α to increase and of IL-1 β to decrease.^{122,123}

CELLULAR SOURCES OF BONE-RESORBING CYTOKINES

Even though IL-1 and TNF may be produced by many cell types, the activated macrophage is considered to be the main source of IL-1 α , IL-1 β , and TNF- α .¹²⁴ On the other hand, TNF- β is commonly considered to be an activated T-lymphocyte product.¹²⁵ In view of the above, two cell types should be considered as being responsible for bone-resorbing activity in human periapical lesions: activated T cells and activated macrophages. Not all T lymphocytes or macrophages in the periapical lesion are in a state of activation. Kopp and Schwaring¹⁸ have found that only 6% of the T lymphocytes in human periapical granulomas were activated. Artese et al.,⁵³ who also used human periapical granulomas, demonstrated that while 41% of the mononuclear inflammatory cells were macrophages, only 2% to 3% of these cells were activated and produced IL-1 β and TNF- α . The activation states of these cells are closely related to each other: T helper lymphocytes may be activated in an antigen-specific manner by antigen-presenting macrophages that also

produce the IL-1 required to accomplish this process. Macrophage activation, as part of the acquired, specific immune response, may be achieved by cytokines such as IFN- γ that are produced by the activated T lymphocytes (see Figure 1). Macrophages may also be activated by other routes, such as by exposure to bacterial endotoxin (LPS), as part of innate, nonspecific immunity.¹²⁶

STUDIES IN ATHYMIC ANIMALS

Athymic rats and mice are powerful tools used to study and demonstrate the essential role of T lymphocytes in other immunobiological processes.^{127,128} These animals lack T cells, and consequently T-cell function is missing, rendering a variety of immune responses inactive. Such animals were used in two studies that assumed that periapical bone resorption and the development of periapical lesions would be defective in athymic animals. The results of these studies should be viewed as a turning point in the understanding of the immunobiology of the host response and bone resorption in periapical lesions. Wallstrom et al.¹²⁹ demonstrated that no significant difference existed between the periapical bone resorption of conventional and athymic rats. Similar results were reported in a study by Tani-Ishii et al.³¹ using athymic mice. They also found that periapical lesions developed in the T-cell-lacking animals at a rate that precluded the possibility that T lymphocytes are essential prerequisites in the development of these lesions. Even though T lymphocytes may, and most probably do, contribute to the process, alternative routes likely exist, enabling the formation of lesions in their absence.

Activated macrophages may serve in such a route in the formation of periapical lesions. Macrophage activation may occur by a variety of pathways. Cytokines such as IFN- γ , produced by antigen-specific activated T lymphocytes, are the main immune response-related activators of the macrophage.^{124,130} In their absence, bacterial endotoxin (LPS) may successfully accomplish this task.^{126,131,132} This activation of the macrophage may be viewed as part of innate immunity, independent of a specific response to antigens. This may have been the mechanism by which the lesions developed in the athymic animals. The bacterial content of the infected root canals in these animals gradually developed to 46% gram-negative flora.¹³³ LPS, derived from these gram-negative bacteria, could activate macrophages in the periapical area, independent of T lymphocytes. These macrophages, in turn, produce their cytokines IL-1 α , IL-1 β and TNF- α that

activate osteoclastic bone resorption. This does not preclude the participation of T cells in the process in normal animals, but rather turns the spotlight to *the main effector cell*: the macrophage. This result is in agreement with the finding that in the rat model, IL-1 α is the major bone-resorbing cytokine while TNF- β , the T-cell product, could not be detected in these lesions by antibody-blocking or immunohistochemical studies.^{54,117}

OSTEOCLAST ACTIVATION: UPDATED CONCEPT

The concept of osteoclast activation had a missing link for many years. It was well known that both systemic factors such as parathyroid hormone (PTH) and local factors such as IL-1 β activate osteoclastic bone resorption. Nevertheless, osteoclasts do not have receptors for either of these agents. The presence of other cells such as osteoblasts or stromal bone marrow cells that do have the proper receptors is required.¹³⁴ An intermediate factor, produced by other bone cells and affecting the osteoclasts, had been hypothesized in an attempt to solve this enigma.¹¹³ It was also recognized that bone cells and osteoclasts have to be *in proximity* to each other to allow the activation to take place.^{134,135}

The missing link has recently been discovered.^{134,136–139} (Figure 4A,B). A group of cell surface receptors and ligands as well as soluble ligands is responsible for up-and-down regulation of osteoclastic bone resorption. When bone cells are activated by either PTH or IL-1 β , they express a ligand named osteoprotegerin ligand (OPGL, RANK-Ligand) on their surface that has the following two main functions:

- (1) Binding to a surface receptor RANK (receptor activator of nuclear factor κ B) on mononuclear preosteoclasts, thus inducing their maturation to multinucleated mature osteoclasts
- (2) Binding to RANK, also expressed on the surface of mature but inactive osteoclasts, thus activating them to become active bone-resorbing cells with a fully expressed ruffled border.¹³⁴

This process results in increased numbers of active osteoclasts and bone resorption. Such a mechanism also explains the well-established need for cell proximity during osteoclast activation: both receptors and ligands are *surface molecules* that require proximity for binding. Inflammatory bone resorption may have yet another avenue of osteoclast activation, as activated T cells may also express OPGL on their surface, allowing them to directly activate the osteoclasts.^{140–142} Down-

Stimulation of Osteoblasts / Stromal cells

A

Osteoclast Activation

B

Figure 4 Osteoclast activation via osteoprotegerin ligand (OPGL) (RANK-ligand). **A**, Osteoblasts and bone marrow stromal cells express OPGL (RANK-ligand) when stimulated by either PTH (parathyroid hormone) or the cytokines IL-1 and tumor necrosis factor- β (TNF- β). **B**, Osteoclast precursors that carry the receptor RANK on their surface are activated to develop into multinucleated osteoclasts, thus increasing the number of osteoclasts in the area. Osteoclasts that are present are activated through their receptor RANK to become active in bone resorption, expressing a ruffled border. Osteoclast activation is downregulated by the soluble competitive inhibitor osteoprotegerin (OPG) that inhibits the binding of RANK to its ligand OPGL.

regulation of bone resorption is carried out by a soluble inhibitor, osteoprotegerin (“bone protector,” OPG), that binds to OPGL and serves as a competitive inhibitor of RANK, preventing its binding to OPGL. This soluble inhibitor was among the first to be discovered. It has been clinically tested as an osteoporosis preventing agent with promising results.¹⁴³

OPGL was recently demonstrated to be present in human periapical granulomas where it was found on macrophages and dendritic cells.^{144,145} This, taken together with the recent demonstration of OPG production by periodontal ligament fibroblasts, may have important future implications and applications.¹⁴⁶

Histopathology of Periapical Lesions of Endodontic Origin

The discussion of the histopathology of periapical lesions includes the *apical granuloma*, as well as two entities that may develop within it or from it: *apical abscess* and *apical cyst*.

The *apical granuloma* is an inflammatory lesion dominated by macrophages, lymphocytes, and plasma cells (Figure 5A,B). Abundant capillaries may be found with numerous fibroblasts and connective tissue fibers. It is often encapsulated in collagenous connective tissue. Epithelial cell proliferation is a common finding in apical granuloma. Serial sectioning reveals that epithelial proliferation occurs in 6% to 55% of these lesions.^{81,147} They are believed to originate from the

Figure 5 Apical granuloma: histopathology. **A**, The lesion is dominated by lymphocytes (green arrow) and macrophages (yellow arrow), with abundant fibroblasts (blue arrow). **B**, A chronic periapical lesion with a polymorphonuclear leukocyte (PMN) infiltrate (yellow arrow).

Figure 6 Epithelial strands in an apical granuloma. Epithelial strands form a network in an apical granuloma. They may be observed in a longitudinal section (blue arrow) or at cross section (yellow arrow and enlargement). This epithelium originated from the rest cells of Malassez that proliferate under the influence of cytokines and growth factors in the apical granuloma. They are the source of the epithelial lining of cysts that may develop in apical granulomas.

epithelial cell rests of Mallasez that proliferate under the influence of cytokines and growth factors generated in the periapical granuloma (Figure 6). Thus, the presence of epithelial cells in a granuloma is a common finding, and its development into a cyst may be considered to be an event that occurs with time within an existing apical granuloma.

PMNs are found in varying numbers in an apical granuloma and may reach a local dominancy within a given area of the granulomatous tissue when an abscess is formed. Thus, an apical abscess may be considered to be a transient or persistent event (in the case of a chronic apical abscess) that occurs within an existing apical granuloma. In general, the histological picture of granulomas varies considerably.^{81,148} The simple, well-organized morphological description of apical periodontitis, based on a zonal pattern, hardly represents the common reality. It was originally an extrapolation from observations by Fish in an experimental model.¹⁴⁹ The experimental lesions were produced in guinea pigs by drilling holes in bones and packing them with wool fibers saturated with microorganisms and were not associated with infected root canals. This zonal pattern has been a conceptually useful teaching aid and, as such, has survived through the generations.^{150–152} Nevertheless, one should not expect to find it in random biopsies of periapical granulomas, as it does not seem to represent the actual structural variation

seen in most periapical lesions. In fact, great structural heterogeneity is the *norm* for apical periodontitis, particularly in chronic lesions.^{81,148}

The hallmark of an *apical abscess* is the presence of pus: an area containing liquefied tissue. Abscesses are usually found within a pre-existing apical granuloma and represent a shift in cellular dynamics. The influx of PMNs is dramatically increased to the extent that tissue macrophages are no longer able to effectively cope with the tissue damage caused by hydrolytic enzymes released from a vast number of dying PMNs. Connective tissue constituents such as collagen and hyaluronic acid are degraded and the tissue in the center of the abscess is liquefied. On the periphery of the abscess, the tissue of the apical granuloma persists and its adjacent layer is infiltrated with a large number of PMNs that are migrating from the nearest blood vessel to end their life in the pus-containing center of the abscess.

A histological continuum may be found between an apical granuloma that contains a small number of infiltrating PMNs, through a granuloma with a large number of infiltrating PMNs, and an established apical abscess. The former may be histologically termed a granuloma with acute inflammation, but only the latter warrants the term apical abscess.

An *apical cyst* is an epithelium-lined cavity that contains fluid or semisolid material and is commonly surrounded by dense connective tissue (Figure 7). Apical cysts are associated with teeth that have necrotic pulps and an infected root canal system and develop within the periapical inflammatory lesion, the granuloma. The cyst cavity is most

Figure 7 Apical cyst. A partial view of the wall of a space that was filled with liquid and lined with stratified cuboidal epithelium (yellow arrow and enlargement), originating from the epithelial rests of Malassez.

commonly lined with stratified squamous epithelium of varying thickness that originates from the epithelial rest cells of Malassez. Nevertheless, lining with ciliary epithelium that originates from an adjacent maxillary sinus may also be found.¹⁵³ The epithelial lining may be continuous, but it is often disrupted or even completely missing, most probably due to a secondary infection. Periapical cysts are divided into *pocket cysts* (bay cyst) and *true cysts*.^{154–156}

A periapical pocket cyst (bay cyst) is an apical inflammatory cyst that contains a sac-like, epithelium-lined cavity that is open to and continuous with the root canal space.^{154–156} True apical cysts are located within the periapical granuloma with no connection between their cavity and that of the root canal space. More than half of the apical cysts are true apical cysts while the remainder are of the pocket cyst variety.^{81,154–156}

The mechanism of cyst formation in periapical inflammatory lesions has been the subject of much debate.^{81,157–159} Two main theories were proposed. The “nutritional deficiency theory” assumes that epithelial proliferation results in an epithelial mass that is too large for nutrients to reach its core, resulting in necrosis and liquefaction of the cells in its center, thus forming the cystic cavity. The “abscess theory” assumes that tissue liquefaction occurred first, at the central part of an abscess, that was later lined by locally proliferating epithelium, due to the inherent nature of epithelial cells to cover the exposed connective tissue surfaces.¹⁵⁹ The mechanism by which cysts grow and expand is not fully understood and most probably involves inflammatory mediators that are present in the lesion.⁸¹

CLINICAL MANIFESTATION AND DIAGNOSTIC TERMINOLOGY

Periapical lesions of endodontic origin vary greatly in their clinical manifestation. Their classification is based on the clinical presentation at a given time point; it may shift from one diagnosis to another, with time. Such shifts may be understood and explained on the basis of the biological events discussed above.

The diagnostic terminology used here will include *normal periapical tissues*, *symptomatic apical periodontitis* (acute apical/periradicular periodontitis), *asymptomatic apical periodontitis* (chronic apical/periradicular periodontitis), *acute apical abscess* (acute periradicular abscess), *chronic apical abscess* (chronic periradicular abscess and suppurative apical/periradicular abscess), *cellulitis*, *condensing osteitis* (focal sclerosing osteomyelitis, periradicular

osteosclerosis, sclerosing osteitis, and sclerotic bone), and *apical scar*.

Clinical manifestations that are used to make a periapical diagnosis derive from (1) subjective information derived from a patient's anamnesis and objective data derived from (2) radiographic examination, as well as (3) results of direct observation and physical examination of the patient, the subjected tooth, and surrounding tissues.

A correlation between the clinical diagnosis and that derived from histopathological examination of the tissue is limited. An apical abscess may be clinically recognized by the presence of pus; however, clinical findings and conventional radiographs cannot predict if another lesion is a granuloma or a cyst.^{160,161} Accordingly, clinical manifestations and diagnostic terminologies were discussed in this chapter separately from histopathological features of periapical lesions. A discussion of the latter was in terms of form and function in order to allow the reader to understand the processes that lead to the clinical manifestations.

Inflammatory lesions of endodontic origin appear in response to stimuli originating from a root canal. As such, they are located around any of the root canal system portals of exit. Pathogenesis and pathology of the inflammatory lesions will be similar at any of those portals of exit; nevertheless, the clinical and radiographic manifestation may vary greatly with the location of the involved portal. The term *periradicular* rather than periapical has often been used to express this diversity.^{66,102,162-165} The terms *apical* or *periapical* were used throughout this text for the sake of simplicity, as well as to express the fact that this is the most common manifestation of inflammatory lesions of endodontic origin.

NORMAL PERIAPICAL TISSUES

In normal periapical tissues, the tooth is not tender to percussion or pressure and there is not any tenderness to palpation of the mucosa overlying the periapical region. There is no swelling and there are no symptoms noted by the patient.¹⁶⁶ Radiographically, the lamina dura is intact and the periodontal ligament space has a normal and consistent width along the entire root, which is similar to that of the adjacent teeth.¹⁶⁶ Recognition of "normal" is essential to estimate changes that may occur with disease, as well as their gradual disappearance with healing.

SYMPTOMATIC APICAL PERIODONTITIS

Symptomatic apical periodontitis occurs within a previously healthy periapical region in response to either

microbiological or physical irritation.¹⁶⁶ The former may result from an initial emergence of bacteria or their products from an infected root canal into the apical periodontium. The latter may result from endodontic treatment when there is mechanical or chemical injury to the apical tissues. They may occur together when the physical insult carry bacteria with it, from the infected root canal into the apical periodontium.

If the insult was short in nature, such as with trauma induced by a file passing through a sterile, noninfected pulp tissue, the symptoms will usually soon subside and healing will take place. On the other hand, if the insult is continuous and persistent, such as the permanent communication between bacteria growing in the root canal and the host response in the apical periodontium, events may take one of two other routes. It may either become more and more symptomatic, a process that may develop into an acute apical abscess and facial cellulitis. Alternatively, it may take a quieter route and gradually become asymptomatic apical periodontitis, with slight or no symptoms and with typical periapical bone resorption. Factors that dictate which route will be taken are not completely clear, but they most probably involve the nature of the bacteria. Their susceptibility or ability to survive the host response may shift the balance one way or the other. Symptomatic apical periodontitis may also represent a shift of the balance established between the bacteria and the host, in an asymptomatic apical periodontitis lesion (see below). Such shifts may occur due to a variety of reasons, starting with naturally occurring events and ending with iatrogenically induced exacerbation.

ASYMPTOMATIC APICAL PERIODONTITIS

Asymptomatic apical periodontitis is a long-standing periapical inflammatory lesion with radiographically visible periapical bone resorption but with minimal or no clinical symptoms. Its development may be uneventful and often goes unnoticed by the patient until it is discovered on a radiograph or until it develops into a symptomatic lesion. Histologically, the radiolucent area associated with asymptomatic apical periodontitis will be either a granuloma or a cyst. The radiological appearance of the lesion may take a wide range of shapes and sizes that has tempted clinicians to search for a correlation between size and morphology of the lesion and its histological nature. The appearance of the radiolucent area in conventional radiographs cannot predict its histological diagnosis.^{160,161,167,168} Recent innovative technologies may be more predictive (see Chapter 15).

ACUTE APICAL ABSCESS

An acute apical abscess is characterized by rapid onset, spontaneous pain, tenderness of the tooth to pressure, pus formation, and eventual swelling of the associated tissues. At the initial stages of its formation, the process may be extremely painful, as pressure builds up in the restricted periapical space. The establishment of drainage through the root canal may, in some cases, end the agonizing process. Left to natural events, an acute apical abscess will sometimes subside. In most cases, the overlying cortical plate will eventually perforate and purulence will accumulate under the periosteum producing a painful condition. Only with the perforation of the periosteum will the pus be able to drain into overlying tissues and allow the major pain to subside. At this stage, a local swelling will appear and an incision for drainage should be made in the overlying tissues to allow final drainage. In some cases, natural drainage will be established within a few days by perforation of the covering tissue. In other cases, the swelling will remain for some time before it gradually subsides.

CHRONIC APICAL ABSCESS

A sinus tract is the hallmark of the *chronic apical abscess*. The inflammatory process perforates one of the cortical plates and a draining sinus tract is established that allows for continuous discharge of pus forming in the periapical lesion through the oral mucosa or, in rare cases, through the skin. Typically, a stoma of a parulis can be detected that, from time to time, will discard the pus. Sometimes a sinus tract will lead to the maxillary sinus and will go unobserved. A sinus tract may also exit in the gingival sulcus a furcation area and must be differentiated from periodontal disease. A chronic apical abscess is most commonly, but not always, associated with an apical radiolucency. It is asymptomatic or only slightly symptomatic, and the patient may often be unaware of its presence. This may last as long as the sinus tract is not obstructed. Even when such an obstruction occurs, it is most likely that any swelling will be of limited duration and will be limited to the local area of the sinus tract, as both the bone and the periosteum are already perforated.

CELLULITIS

Cellulitis is a symptomatic edematous inflammation associated with diffuse spreading of invasive microorganisms throughout connective tissue and facial planes. Diffuse swelling of facial or cervical tissues is its main clinical feature. Cellulitis is usually a sequel of

an apical abscess that penetrated the bone, allowing the spread of pus along the paths of least resistance, between facial structures. This usually implies the facial planes between the muscles of the face or the neck (see Chapter 20). Spreading of an infection may or may not be associated with systemic symptoms such as fever and malaise. Since cellulitis is usually a sequel of an uncontrolled apical abscess, other clinical features typical of an apical abscess are also expected. Spreading of an infection into adjacent and more remote connective tissue compartments may result in serious or even life-threatening complications. Cases of Ludwig's angina,¹⁶⁹ orbital cellulites,¹⁷⁰ cavernous sinus thrombosis,¹⁷¹ and even death from a brain abscess¹⁷² originating from a spreading dental infection have been reported.

CONDENSING OSTEITIS

Condensing osteitis (focal sclerosing osteomyelitis) is a diffuse radiopaque lesion believed to represent a localized bony reaction to a low-grade inflammatory stimulus, usually seen at the apex of a tooth (or its extraction site) in which there has been a long-standing pulp pathosis. It is characterized by overproduction of bone in the periapical area, mostly around the apices of mandibular molars and premolars that had long-standing pulp pathosis. The pulp of the involved tooth may be chronically inflamed, but since such inflammation may lead to pulp necrosis, it may be expected that, at some stage, the involved pulp is nonvital. The radiopacity may or may not respond to endodontic treatment.

APICAL SCAR

Apical scar is not an inflammatory lesion, but rather an uncommon pattern of healing of an apical inflammatory lesion. It consists of a dense collagenous connective tissue in the bone at or near the apex of a root with a distinctive radiolucent presentation.^{173,174} It represents a form of healing that is usually associated with a root that has been treated surgically. Perforation of both facial and lingual osseous cortices is believed to result in collagenous rather than osseous healing.^{173,175} Maxillary lateral incisors are the most frequently affected teeth. Definitive clinical diagnosis is very difficult without histopathological examination. A case history may be helpful, especially when a detailed surgical report is included. Periapical inflammation that, with time, resorbed and perforated both cortices may also result in an apical scar. Since such cases are quite rare,^{160,174,176} the probability that a given nonresponsive periapical lesion, with no surgical involvement, is actually an apical scar is

extremely low when compared to that of a rather common posttreatment disease.

Traditional Concepts Versus a Futuristic View

The current concept and rationale of endodontic treatment of periapical lesions has not changed significantly for many years. It is centered on one issue: stopping the bacterial stimulation of the host response at the apical foramen/foramina that would allow healing of the lesion. Methods used to achieve this goal include the following:

- (1) Cleaning, shaping, and disinfection, aimed at thorough elimination of bacteria from the root canal system, followed by obturation
- (2) In case the above procedure fails, surgical removal of residual infected tissue in apical ramifications of the root canal system inaccessible to the above-mentioned procedure and thus may still harbor bacteria
- (3) Root-end sealing of the root canal system to prevent continuous bacterial stimulus that may still exist after the completion of stages "1" and/or "2" described above.

This comprises a simple and rather mechanistic rationale that has worked well for several generations. Nevertheless, by limiting itself to this concept alone, the profession may ignore, or at least make no use of the vast information and potential tools generated over the last two decades in bone biology research and in studies aimed to pharmacologically modulate destructive immune responses.

The ideas, information, and concepts that follow should not be taken as proven or approved clinical therapeutic protocols. They should rather provide a conceptual framework for understanding possibilities and new avenues of thought that will most probably become possible in the coming years. They are aimed to prepare the minds and hearts of future leaders of the profession and inspire them to look into additional therapeutic avenues. Endodontics should not limit itself only to better ways of cleaning, shaping, and obturation. Biological research may provide, in the not so far future, new concepts and methods to supplement traditional ones.

Endodontic treatment is aimed to eliminate bacteria from infected root canals that will later be sealed to prevent recontamination. With the elimination of the bacterial stimuli that evoked the periapical

inflammation, the periapical lesion should resolve and repair should take place. Healing of the lesions may take many months.^{177–180} It may be argued that if a given lesion eventually heals in 12, 24, or even 36 months, there is no benefit in rushing the process. Nevertheless, shortening the healing time may have clinical importance, as it may (1) allow earlier decisions in regard to the restorative treatment plan related to the treated teeth and (2) limit the period for which temporary crowns and bridges are used; temporary restorations that may leak and allow recontamination of the treated root canal.

The prolonged healing process of many periapical lesions raises the possibility that the activated cells in the lesion may maintain their state of activation long after the initial cause of their activation has been eliminated. Namely, the activation state may outlive its useful purpose and become a burden. Macrophages are known to persist in tissues for many months and if their state of activation persists, they may inhibit the fibroblasts, maintain osteoclastic activity, and inhibit osteogenesis, thus preventing both soft connective tissue and bone repair from taking place.^{126,181} Indirect support for this notion may be found in a study carried out, for a totally different purpose, by Kvist and Reit.¹⁷⁸ Healing of periapical lesions was compared following surgical and nonsurgical retreatment. At 12 months, a significant difference was found in favor of surgical treatment that faded by 48 months to almost no difference between the groups (Figure 8). If

Figure 8 Healing of periapical lesions following surgical removal of the chronically inflamed tissue, compared to healing after retreatment. By 48 months, no difference was found between the groups. Nevertheless, healing was much faster when the tissue was surgically removed, with a significant difference at 12 months. Adapted from Kvist T and Reit C.¹⁷⁸

the idea presented above is true, these results may support the concept that early surgical removal of the tissue containing activated macrophages, allowed its replacement with fresh granulation tissue that contains a fresh set of cells that will not delay repair.

If this concept is valid, it may be important and possible to monitor the state of activation of periapical macrophages by sampling the interstitial fluid of the lesion through the root canal.^{121,123,182} Recently Kuo et al.¹²² were successful in performing such measurements and were able to quantify the IL-1 β concentration in apical exudates and correlate it with clinical and radiological features of the lesions. A longitudinal study that evaluates the correlation between the diminishing IL-1 β content of the lesions and their gradual radiographic repair will be required to prove this point.

Assuming that such inhibitory mechanisms are involved in the prolonged and delayed repair of periapical lesions, pharmacological modulation of the process may be considered (Figure 9). Stashenko et al.¹¹³ demonstrated that an IL-1 receptor antagonist may be used in animals to reduce the bone-resorbing activity and the formation of periapical lesions. Similarly, NSAIDs were successfully used for a similar purpose in both experimental and human periodontal diseases, as well as in the cat model for periapical lesions.^{183,184}

Figure 9 Potential pharmacological modulation of the healing of apical granuloma. **A**, Traditional endodontic approach: elimination of the bacteria from the root canal, followed by obturation of the root canal to prevent recontamination. **B**, Potential additional sites for pharmacological modulation. Either the local production and release of bone-resorbing cytokines or their effect on bone cells is a potential target for “turning off” the lesion, once its activity had outlived its useful, protective purpose.

These two approaches were directed at either blocking the *binding* of the already produced cytokine to its target cells or *interfering with its action* on osteoclasts and osteoblasts that may involve prostaglandin production.^{48,117}

Tetracyclines may be used to inhibit cytokine *secretion* by activated macrophages.^{185,186} Shapira et al.¹⁸⁶ studied tetracycline inhibition of TNF and IL-1 production by LPS-activated macrophages and found its effect to be at a post-transcriptional level: both mRNA and the cytokines themselves were produced but they were not secreted into the cells’ surroundings. Tetracyclines may also inhibit bone resorption by other mechanisms that are unrelated to their antimicrobial capacity. This is mediated by inhibition of connective tissue metalloproteases.¹⁸⁷ Accordingly, it has recently been demonstrated that systemic low-dose tetracycline inhibits the formation of periapical lesions in rats by a mechanism(s) that is (are) unrelated to their antimicrobial effects.¹⁸⁸

An alternative strategy may be to try to locally “turn off” the activated macrophages, thus lowering the local *production* of IL-1 in the lesion. Modulation of macrophage activation has been attempted both in vivo and in vitro using glucocorticoid steroids.^{126,130,189,190} Macrophages, activated to become tumoricidal, were “turned off” in vivo by a process involving cortico steroids.¹⁸⁹ Recently, Metzger et al.¹²⁶ reported that suppression of fibroblast proliferation by LPS-activated macrophages was reversed using hydrocortisone. Dexamethasone also inhibited periapical lesion formation in the rat model, most probably by a similar mechanism.¹⁹¹ Such effects on macrophage activation and production of its mediators have also been reported by others and were attributed to inhibitory effects of the steroids at the gene transcription level.^{130,192,193}

If and when bacteria are no longer present in the root canal, the state of activation of the macrophages may outlive its useful and beneficial purpose. Attempts to “turn off” the host response and its effects in the lesion may represent a *new biological treatment modality* that may alleviate suppression and enhance repair in these lesions (see Figure 9). Local delivery of desired pharmacological agents should be simpler in the closed environment of the periapical lesion, as compared to similar attempts in periodontal pockets. *Local sustained delivery* of drugs aimed at this goal may easily be achieved. By using biodegradable slow release devices in the form of a point that may be inserted through the root canal into periapical tissues, it may locally deliver the drug or drug combination for a predetermined period of time.

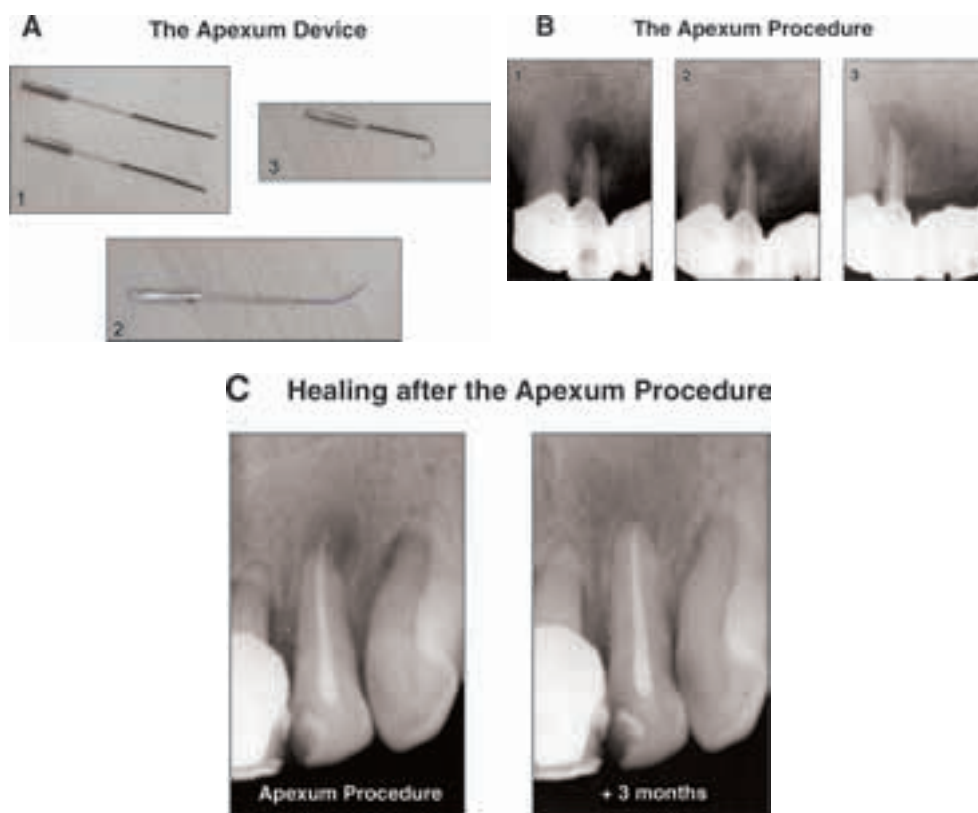

Figure 10 Apexum©: A method for minimally invasive removal of periapical tissues through the root canal. **A**, The Apexum NiTi Ablator© (1, 2). The black tube contains a nickel–titanium wire that is protruded when pushed through the apical foramen. Upon entering the periapical area, it takes a specially designed form (2) and is rotated at 300 rpm, mincing the soft tissue, while being deflected from the surrounding bone. The Apexum PGA Ablator© (3) has a fiber made of biodegradable material that is rotated in the periapical area at 5000 rpm, grinding the tissue to a thin suspension that is then washed out with saline. **B**, (1) The nickel–titanium tube is inserted to the working length. (2) The Apexum NiTi Ablator is pushed and inserted into the periapical area. (3) Once the Apexum procedure is completed, the root canal is obturated with a root canal filling. **C**, A maxillary incisor immediately after the completion of the procedure and 3 months later. Note the rapid bone healing in the periapical area.

A better understanding of the immunobiology of periapical lesions may eventually result in a different endodontic practice than is encountered today. Chair-side diagnostic kits that will allow definition of a periapical lesion as “active” or “healing,” by sampling via the root canal prior to obturation, seem logical and possible. Similarly, pharmacological modulation of the healing process may also be near.

An alternative, simpler, approach has recently emerged with the development of a device that allows enucleation of the periapical tissue, through the root canal and the apical foramen. The Apexum™ protocol is applied just before root canal obturation. Once

cleaning, shaping, and disinfection of the root canal is completed, the apical foramen is enlarged by passing a No. 35 rotary file to 1 to 2 mm beyond the apex. This passage is used to insert a specially designed nickel–titanium wire into the periapical tissue that rotates and minces the tissue (Figure 10A,B). This is followed by a biodegradable fiber rotated at a higher speed that turns the tissue into a thin suspension that is then washed out with saline using a 30-G needle. A fresh blood clot forms in the periapical bony crypt. Ongoing clinical trials indicate that much faster periapical healing occurs, similar to that encountered with apical surgery (see Figure 10C).

ALVEOLAR OSTEOPOROSIS ASSOCIATED WITH BRUXISM

Ingle¹⁹⁴ and then Natkin and Ingle¹⁹⁵ have described a syndrome (“Ingle’s Syndrome”) affecting adolescent females related to protrusive bruxism. By the age of 13 or 14, over one-third of the mandibular incisors had been “ground away” (see Figure 11A–D). Most of the lingual enamel of the maxillary incisors were also destroyed. In one case, a pulpal horn had already been exposed. In all the

cases, osteoporotic bone destruction in the mental area of the mandible is apparent radiographically. Also seen radiographically, from left to right, is a graceful curve formed by the worn incisal edges of the lower anterior teeth.

When one realizes that this amount of destruction had occurred since eruption, within 6 or 7 years, one recognizes the intensity of the habit. The first girl seen was also a serious nail biter; “down to the quick” as she stated.

Figure 11 A–D, Osteoporosis and pulp death in 14-year-old identical twin sisters with the same syndrome—Adolescent Female Protrusive Bruxism. In both cases, incisal wear involving mandibular anterior teeth from compulsive protrusive bruxism. Nearly one-third of the teeth have been destroyed in 7 or 8 years. Radiographs demonstrate the osteoporotic bone loss, the periapical lesions, and the graceful curve, left to right, of the worn incisal edges common to this condition.

Not only the involved teeth were mobile, even though normal periodontal attachments were present, but also some of the pulps were necrotic. Consulting pathologists termed the bony destruction “traumatic osteoporosis” comparable to leg bone destruction seen in industry wherein a worker constantly presses a treadle downward, day after day.

Why do these girls grind their teeth in a protrusive motion rather than the usual lateral grinding chewing motion seen in most bruxers? The answer might be that they derive pleasure from this habit. One consulting psychiatrist suggested that this protrusive motion is the same suckling motion used by infants in nursing. Babies do not nurse by sucking (as adults do through a straw), but by moving the mandible forth and back, “milking” the nipple. This is a pleasurable and satisfying period of time in a baby’s life. And these girls might well have some psychological need to continue the habit. Following endodontic therapy, “night guards” were constructed for these patients. They either threw them away after 2 or 3 months or chewed through them.

EXAMINATION, EVALUATION, DIAGNOSIS AND TREATMENT PLANNING

CHAPTER 14

DIAGNOSIS OF ENDODONTIC DISEASE

A. ENDODONTIC EXAMINATION

ROBERT A. HANDYSIDES, DAVID E. JARAMILLO, JOHN I. INGLE

“For I seek the truth by which no man has ever been harmed.”

—Marcus Aurelius, *Meditations VI. 21, 173 AD*

Diagnosis is arguably the most critical component of all dental treatment, and endodontics is no exception. *Stedman’s Medical Dictionary* describes clinical diagnosis as “the determination of the nature of a disease made from a study of the signs and symptoms of a disease.”¹ The diagnostic process therefore is an essential part of treatment and treatment planning. Collection of information, history, signs and symptoms, a thorough clinical examination, and objective testing are mandatory prior to recommending and initiating treatment. Only after collecting this information can one come up with a diagnosis that benefits the patient. “Providing the wrong treatment for a patient could not only intensify a patient’s symptom but make it even more difficult to arrive at the correct diagnosis.”² The Hippocratic Oath counsels “First, do no harm.”

To achieve this goal, one must dedicate oneself to becoming an astute diagnostician.

To become this type of diagnostician, one must develop numerous personal attributes that will complement and enhance one’s ability and efficiency for arriving at the correct diagnosis. The art of listening has often been a neglected diagnostic tool. Most clinicians have tried to develop a thorough knowledge

of examination procedures: percussion, palpation, probing, and pulp testing. Knowledge of endodontic disease, radiographic interpretation, and clinical manifestations is an integral and important part to achieving the correct diagnosis. But the most basic skill of all is **listening** to the patient. Through careful and attentive listening one develops a strong patient-clinician rapport. Such relationships enhance the patient’s reliability as a historian.³

Requirements of a Diagnostician

Diagnosis is often derived from personal and cognitive experiences. Good diagnosticians use past experience, based on knowledge and diagnostic tools. Diagnosing any orofacial disease, odontogenic or non-odontogenic, is similar to other medical diagnoses. Radiographs and other testing procedures can facilitate the diagnosing of dental or facial disease, just as a host of various other radiographs and testing can facilitate medical diagnosis.

To become a successful diagnostician, one must develop a number of assets. The most important of these are **knowledge, interest, intuition, curiosity, and patience**. The successful diagnostician must also have acute senses and the necessary examining equipment for diagnosis.

KNOWLEDGE

Knowledge must be listed as the most important attribute a clinician possesses. Typically clinicians, practicing dentistry by themselves, are in relative isolation from outside help. They must be prepared to assess various types of orofacial pain, and the sources vary from odontogenic to numerous systemic, neurologic, and psychological causes. They must intimately understand the changes that pain can bring in patients. These changes range from physical and perceptual to emotional and behavioral. Every clinician has a different level of experience and knowledge that is ever evolving. One of the most important aspects of knowledge is recognizing when one needs help. The astute clinician will recognize that the problem is outside the scope of his or her field of training. Rather than pursue what is hoped is the best, consultation from an appropriate source is advisable. Even if the problem appears to be within the scope of one's training, yet the diagnosis or treatment is beyond the comfort level of the practitioner, referral is often appropriate. Recognition of one's limitations and fallibility is a major asset not only for the clinician but also for the patient.

INTEREST

Interest is an attitude. If one is interested in a subject, usually one excels in that area. It is human nature to develop one's interests, but it is difficult to do so if one is uninterested. The uninterested clinician often makes a guess, prescribes inappropriate treatments, and shows a lack of concern for the patient's condition. The interested clinician will be supportive and understanding of the patient seeking the source of a problem.

INTUITION

Intuition is a very helpful tool in diagnosis. A good diagnostician will sense something out of the ordinary. This sense allows the clinician to delve deeper and look more closely into atypical situations. Intuition allows one to suspect the unusual, and then curiosity takes over. Intuition needs to be used with common sense. It is not good to get sidetracked to the obscure when the obvious is right in front of you. Unless one is on a safari in Africa, one must recall the saying, "When you hear hoof beats, think horses, not zebras."

CURIOSITY

As stated in the 5th edition of *Endodontics*, "the clinician must pursue or develop a natural curiosity about the patient and his condition if perseverance is to be maintained in arriving at a diagnosis."⁴ Dr. Harry Sicher often likened dental diagnosis to "the actions

of a good detective, and curiosity is a detective's greatest asset" (H. Sicher, personal communication with Dr. John Ingle, 1954). Medawar described diagnosis as the "use of the hypothetico-deductive system."⁵

PATIENCE

Patience is something that is often in short supply for both the clinician and the patient when it comes to pain. A definitive diagnosis of unusual pain may take anywhere from hours to months to develop. Some patients may have suffered this pain for years, so it is unreasonable for the clinician to expect to always make a diagnosis in a matter of minutes. This is one reason why a difficult diagnosis may be unrewarding financially but very rewarding emotionally.

History

The first step in arriving at a diagnosis is the recollection of the patient's signs and symptoms, the past as well as the present. The importance of this "history" goes beyond medicolegal protection. A complete history (Table 1) will often modify endodontic treatment and may even determine the total treatment. It may also deny treatment, although it seldom does. The "history" should be broken down into a medical and a dental history.

A complete medical history is very important as the overall picture of a patient's health. A thorough history may help define risks to the clinician and staff, as well as identify risks to the patient. The medical history must be regularly updated to monitor any changes in the patient's health status. Recording the patients' vital signs, at the onset of the examination, is strongly encouraged. Vital signs may give early warning of unsuspected systemic disease. If indicated, the patient should be encouraged to visit his or her physician for an examination and appropriate treatment. The American Society of Anesthesiologists has developed a system for organizing and assigning risk (see Figure 1 in Chapter 23, "Management of Medically Complex Patients").

As stated in the 5th edition of *Endodontics*, once the status of the patient's general health has been established, a dental history follows.⁴ This is best developed by following the time-honored formula of determining the **chief complaint**, enlarging on this complaint with questions about the **present dental illness**, relating the history of past dental illness to the chief complaint, and combining this with information about the patient's general health (**medical history**) and the examination results.

Table 1 Medical History Form*

MEDICAL HISTORY			
Name _____	Sex _____	Date of Birth _____	
Address _____			
Telephone _____	Height _____	Weight _____	
Date _____	Occupation _____	Marital Status _____	

MEDICAL HISTORY		CIRCLE	
1. Are you having pain or discomfort at this time?		YES	NO
2. Do you feel very nervous about having dentistry treatment?		YES	NO
3. Have you ever had a bad experience in the dentistry office?		YES	NO
4. Have you been a patient in the hospital during the past 2 years?		YES	NO
5. Have you been under the care of a medical doctor during the past 2 years?		YES	NO
6. Have you taken any medicine or drugs during the past 2 years?		YES	NO
7. Are you allergic to (ie, itching, rash, swelling of hands, feet, or eyes) or made sick by penicillin, aspirin, codeine, or any drugs or medications?		YES	NO
8. Have you ever had any excessive bleeding requiring special treatment?		YES	NO
9. Circle any of the following which you have had or have at present:			
Heart Failure	Emphysema	AIDS or HIV	
Heart Disease or Attack	Cough	Hepatitis A (infectious)	
Angina Pectoris	Tuberculosis (TB)	Hepatitis B (serum)	
High Blood Pressure	Asthma	Liver Disease	
Heart Murmur	Hay Fever	Yellow Jaundice	
Rheumatic Fever	Sinus Trouble	Blood Transfusion	
Congenital Heart Lesions	Allergies or Hives	Drug Addiction	
Scarlet Fever	Diabetes	Hemophilia	
Artificial Heart Valve	Thyroid Disease	Venereal Disease (Syphilis, Gonorrhea)	
Heart Pacemaker	X-ray or Cobalt Treatment	Cold Sores	
Heart Surgery	Chemotherapy (Cancer, Leukemia)	Genital Herpes	
Artificial Joint	Arthritis	Epilepsy or Seizures	
Anemia	Rheumatism	Fainting or Dizzy Spells	
Stroke	Cortisone Medicine	Nervousness	
Kidney Trouble	Glaucoma	Psychiatric Treatment	
Ulcers	Pain in Jaw Joints	Sickle Cell Disease	
		Bruise Easily	
10. When you walk up stairs or take a walk, do you ever have to stop because of pain in your chest, or shortness of breath, or because you are very tired?		YES	NO
11. Do your ankles swell during the day?		YES	NO
12. Do you use more than two pillows to sleep?		YES	NO
13. Have you lost or gained more than 10 pounds in the past year?		YES	NO
14. Do you ever wake up from sleep short of breath?		YES	NO
15. Are you on a special diet?		YES	NO
16. Has your medical doctor ever said you have a cancer or tumor?		YES	NO
17. Do you have any disease, condition, or problem not listed?		YES	NO
18. WOMEN: Are you pregnant now?		YES	NO
Are you practicing birth control?		YES	NO
Do you anticipate becoming pregnant?		YES	NO

To the best of my knowledge, all of the preceding answers are true and correct. If I ever have any change in my health, or if my medicines change, I will inform the doctor of dentistry at the next appointment without fail.
