CHAPTER 31

RETREATMENT OF NON-HEALING ENDODONTIC THERAPY AND MANAGEMENT OF MISHAPS

ALAN H. GLUSKIN, CHRISTINE I. PETERS, RALAN DAI MING WONG, CLIFFORD J. RUDDLE

In recent years, significant refinements in the delivery of endodontic services have increased both professional and public expectations for the successful retention of the natural dentition. Along with the salvation of those many millions of teeth every year comes the inevitable percentage of non-healed and unsuccessful treatments. The literature concerning non-healed endodontically treated cases and available retreatment options to return periapical pathosis to health offers a scarcity of prospective randomized controlled trials dealing with non-surgical retreatment and surgical revision. This lack of literature involving the highest level of evidence is not only true for the endodontic field but is similarly true for other areas of dentistry, including implant studies.¹ Best available evidence apart from randomized controlled clinical trials may include non-randomized controlled clinical trials, cohort and case control studies, cross-over, cross-sectional and case studies, or consensus opinions of experts in the field.² Many factors including microbial challenge, location of the infection, and host defense play a role in the decision whether to retreat a case non-surgically, address the problem surgically, or to extract and place an implant (Figure 1). The skills and preferences of the clinician treating the patient are also significant considerations. When comparable criteria are applied to outcomes, the survival rates of endodontic treatment and or extraction and implant placement are similar.³ However, an endodontic procedure is less expensive, significantly less time consuming and allows the patient to preserve their natural dentition.^{1,4}

Post-Treatment Infection of the Root Canal System

DISEASE FACTORS

The treatment of chronic apical periodontitis has an unexpectedly high degree of success considering the fact that the root canal system is infected⁵⁻⁹ and that a high percentage of areas within the root canal system are neither touched by instruments nor effectively cleaned using mechanical and chemical antimicrobial strategies.¹⁰⁻¹² As a consequence of infection, endodontic treatment can fail when root canal treatment has not adequately eliminated or reduced the intraradicular bioburden. Failures occur even when the highest standards and the most conscientious procedures are adhered to because there are root canal complexities that cannot be cleaned and/or obturated with current technologies. Therefore, infection can persist or quickly reestablish itself.¹³⁻¹⁵ In rare cases, factors located outside the tooth within the inflamed periapical area can impede healing of apical periodontitis after a tooth has been treated endodontically. Nair¹⁶⁻¹⁹ has identified six biological factors that lead to recalcitrant asymptomatic radiolucencies: (1) continued intraradicular infection inside the root canal system; (2) extraradicular infection, such as periapical actinomycosis; (3) foreign body reaction due to extrusion of endodontic materials; (4) accumulation of endogenous cholesterol crystals that cause inflammation of periapical tissues; (5) true cysts with no connection to the root canal

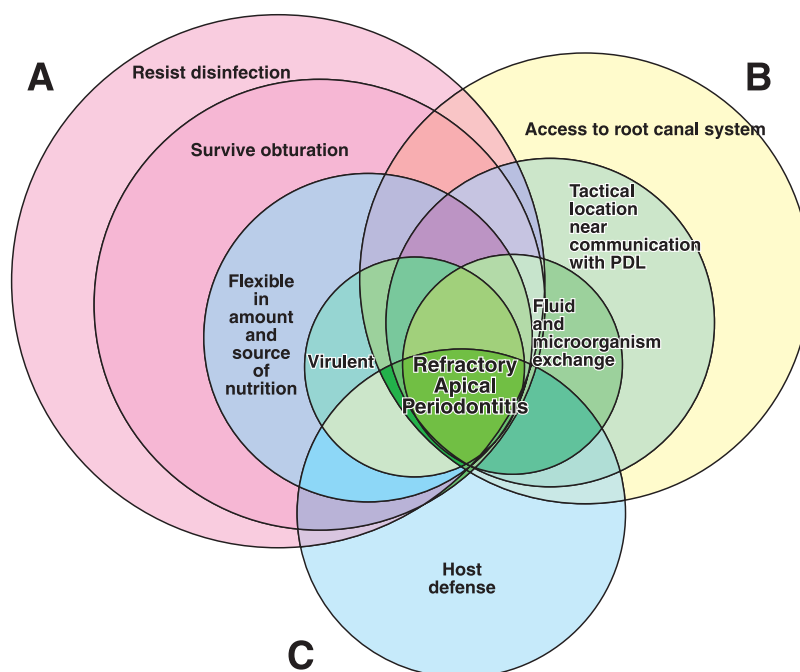

Figure 1 Interaction and characteristics of an endodontic infection. **A**, Microbial challenge. **B**, Location of the infection. **C**, Host defense in inflammation and persistence of disease after endodontic treatment. Adapted from Sundqvist G, Figdor D. Life as an endodontic pathogen. Ecological differences between the untreated and root-filled root canals. *Endod Topics* 2003;6:3–28.

space, and (6) scar tissue remaining after the healing of a lesion. Specific factors affecting the success of endodontic treatment are covered in Chapter 32, “Endodontic Treatment Outcome.”

PREVIOUS ROOT CANAL TREATMENT

In general, the fact that previously treated teeth have been instrumented and may have been subjected to procedural errors and unwanted changes in the original canal geometry, as well as possible contamination, results in lower success rates: healing of lesions in retreatment cases ranges from 56% to 84%, whereas initial treatment of apical periodontitis is 83 to 100%.^{20,21} In addition, when samples are taken from root canals during retreatment, there is a difference in the microbial flora between inadequately treated teeth and well-treated teeth that may contain microorganisms difficult to eradicate.²²

Case Selection Criteria: Risks versus Benefits

Root-filled teeth displaying apical periodontitis often embody multi-factorial difficulties over teeth with primary apical periodontitis and no prior treatment.²³

Ironically, in an effort to accomplish infection control and to prevent re-contamination, clinicians use methods, devices, and materials that may instigate and promote damage to periapical tissues.²⁴ When initial treatments do not lead to healing, a clinician may decide to retreat, to intentionally replant, to perform endodontic surgery, or to extract the tooth.²³

BENEFITS

While acknowledging extraction as valid treatment, albeit a terminal step, repeating root canal therapy offers benefits over apical surgery. Most cases that continue to display apical rarefactions are infected inside the root canal system. Retreatment presents an effort to eliminate microorganisms, while the focus of apical surgery is to restrict microorganisms from egress beyond the root canal system.²⁵ In the scenario of intracanal infection, retreatment has the benefit of potentially disinfecting the root canal. Due to a lack of higher evidence, the proof of a better retreatment outcome over a surgical outcome still needs to be determined.²⁵ Kvist and Reit²⁶ compared the results of surgical and non-surgical treatment. After 1 year, the surgically treated cases had healed more quickly, but after 4 years the slower healing of the non-surgical cases had “caught up” and there were some failures in the surgical group, resulting in no

difference. When directly compared to the sequelae of periapical surgery, there is significantly less discomfort and pain after retreatment. Only patients who received surgical treatment stayed home from work because of postoperative symptoms.

RISKS

Every treatment carries potential risks versus benefits. A significant complication leading to extraction of a tooth would be root fracture or an irreparable perforation.^{27,28} Mishaps such as instrument breakage or transportation of the center of a given root canal can also have a negative impact on the outcome of treatment.^{25,29} Spili³⁰ followed cases with fractured instruments for 1 year and found that prognosis was not significantly affected by the presence of a retained instrument fragment but rather by the presence or absence of a periapical lesion. The removal of a coronal restoration and buildup materials may render a tooth non-restorable. Al-Ali et al.³¹ conducted a survey among students about endodontic retreatment decision making. They noticed that cases of teeth with posts led the clinician to favor apical surgery over non-invasive measures. Post removal has become a predictable procedure if appropriate armamentarium is used with adequate skill. The risk of root fracture is very small. In Abbott's study³² of techniques used for post removal, only 1 of the 1600 teeth (0.06%) developed a root fracture during post removal. If a previously filled root canal is not accessible due to hard setting materials or other obstacles, the risk of perforating the root increases as the clinician approaches the apical portion of the canal. However, the use of materials with good marginal adaptation such as mineral trioxide aggregate (MTA) to repair root perforations has made this complication much more manageable.³³⁻³⁵

SPECIAL CONCERNS IN ENDODONTIC RETREATMENT

Although continuing periapical radiolucency is a clear sign of pathosis, many dentists do not automatically retreat the associated teeth.^{31,36} While Friedman²⁵ describes apical surgery as a compromise after unsuccessful or unfeasible retreatment, apical surgery appears to be more frequently preferred than non-surgical retreatment.^{25,37} Large and/or recently incorporated or expensive restorations may require replacement after retreatment. Obturation and restorative materials must be removed from the root canals, a step that may lead to procedural errors.³⁸ Technical problems due to previous treatment may be encountered.³⁹ Hence, patients and clinicians may be less willing to repeat the endo-

dontic treatment, especially when considering a less favorable prognosis when compared to initial treatment.^{38,40}

PATIENT CONSIDERATIONS

The indications for root canal retreatment are stated in a Consensus report of the European Society of Endodontology⁴¹:

- Teeth with inadequate root canal filling with radiological findings and/or symptoms
- Teeth with inadequate root canal filling when the coronal restoration requires replacement
- Teeth with coronal dental tissue that is to be bleached

During the decision-making process it may be decided that in the absence of apical pathosis, an endodontically treated tooth with inadequate obturation may only be monitored but not retreated. Further radiographic monitoring and non-intervention were favored by a majority of general practitioners.⁴² However, treatment is recommended in cases of periapical radiolucency and discomfort or pain.

A reliable and effective alternative to deal with a painful root-treated tooth is extraction of the tooth in question,⁴³ a step that might entail additional dental treatment and costs. Large non-healing lesions lead to higher frequencies of therapeutic intervention than do smaller persistent lesions.⁴⁴ Reit and Grondahl^{36,45} found large inter-individual variations among general dental practitioners in attitudes to treatment of asymptomatic periapical lesions. The important decision whether or not to retreat a tooth is further influenced by ethnic values and financial considerations, as well as by the technical quality of the primary treatment.⁴⁶ In cases where endodontic surgery is planned, orthograde retreatment should be attempted prior to surgery, because renewed disinfection and obturation improves the surgical success rate considerably.⁴⁷ Grung et al.⁴⁸ investigated 477 teeth that underwent apicoectomy and found that if teeth were retreated conventionally before periapical surgery, there was a 24% higher success rate than in teeth with periapical surgery alone.

The Praxis Concept theory according to Kvist et al.⁴⁶ hypothesized that dentists do not view periapical health and disease as two different entities, but rather as on a sliding scale. The investigators found that dentists regard the size of periapical lesions as corresponding to an increasingly more severe disease on a continuous scale. The personal threshold of each clinician seems to dictate when intervention is

Figure 2 Calculation of the “retreatment preference score” (RPS) between 0.0 and 1.0: Clinicians assessed five periapical conditions and chose a periapical situation as their cut-off point for retreatment. The mean score chosen was a cut-off point very close to “medium-sized lesion” (RPS = 0.38). Adapted from Kvist and Reit C.⁵⁰

considered necessary.^{44,49,50} In a study by Kvist et al.,⁴⁴ dentists reviewed six cases with five different periapical conditions. For each case, a cut-off point indicating that retreatment was necessary was identified. A “retreatment preference score” (RPS) was constructed to correspond to different cut-off points and to vary between 0.0 and 1.0 (Figure 2). The mean RPS was 0.38, representative of therapeutic intervention in cases of medium sized lesions. The decision to retreat a tooth was significantly more frequent if defective root fillings were present and in the absence of any

crown and post that would require removal. There were large variations between practitioners as to the cut-off point at which retreatment was felt to be appropriate. Differing cultural ethics and dental attitudes, prevailing level of educational background, and health care disparities may also play an important role in decision making.^{4,51-53}

Coronal Leakage and Prognosis for Healing

A significant factor in endodontic failures is coronal microleakage. As far back as 1961, coronal leakage was investigated to determine its role in the success of endodontics.⁵⁴ However, in recent years, the role of coronal leakage in restorative dentistry has now become a research niche in an attempt to account for endodontic treatment failures.⁵⁵⁻⁵⁸ In fact most of the emphasis today has been placed on the quality and integrity of the interface between the final restoration and dentinal surface sealing the root canal. Coronal leakage has become a clinical focus as a major factor in the overall success of root canal therapy.⁵⁹⁻⁶² Numerous studies have confirmed that sealing the coronal aspect of the tooth is of paramount importance for the overall success of root canal therapy.⁶³⁻⁶⁶ Coronal leakage has been shown to be responsible for a constant source of microorganisms and nutrients that can initiate and maintain periapical inflammation⁶⁷ (Figure 3). In addition, the fact that gutta-percha and root canal sealers are not effective barriers to the oral environment was

Figure 3 A, Postoperative radiograph of a completed root canal treatment on maxillary second molar with a bonded resin temporary filling. **B**, Three-month recall radiograph shows open crown margins that can result in bacterial invasion and eventual treatment failure.

shown in 1987.^{68,69} It has also been demonstrated that all crowns display some amount of leakage even though it may not be detectable clinically.⁷⁰

The microleakage associated with restorative materials has been studied in vitro as far back as 1990 for its role in failure rates of endodontic therapy. Root canals and pulp chambers of 69 extracted teeth were prepared and sealed using cold lateral condensation. Gutta-percha was removed from the pulp chambers of 3 of the groups of 15 teeth and filled with one of three materials. Results demonstrated that those teeth with no filling in the pulp chamber showed extensive leakage. The gutta-percha-filled-chamber group demonstrated greater leakage than did the groups in which other restorative materials had been employed. Therefore, it was recommended that the pulp chamber of molars be restored with a definitive restorative filling material following root canal treatment.⁷¹

Amount of leakage and percolation from saliva were evaluated to mimic the clinical setting. At 2, 7, 14, 28, and 90 days, salivary penetration was assessed in histological sections. The results strongly suggested that obturated root canals that have been exposed to the oral cavity for at least 3 months should be retreated due to the level of contamination.⁷² Leaking coronal restorations, and their relation to root canal failure rates, were further corroborated by investigations to determine the amount of time needed for bacteria in natural saliva to contaminate the entire length of sealed root canals. Observed results showed that all root canals were recontaminated in less than 30 days.⁷³ Similar tests results were obtained by other investigators that indicated specimens were contaminated in 30 and 60 days.⁷⁴ Attempts to evaluate amounts of bacteria present when coronal restorations were defective were also undertaken. Freshly extracted teeth were used for this study. Results demonstrated that the amount of bacteria present was just as important as the salivary contamination. A total of 252 bacterial strains were isolated from all the teeth. The predominant group of bacteria in root-filled teeth with persistent apical periodontitis and coronal leakage was Gram-positive facultative anaerobes of which staphylococci followed by streptococci and enterococci were the most prevalent.⁷⁵

Post-obturation bacterial contact was viewed to be of paramount importance for success of endodontics. One study reported that over 50% of unrestored and uncovered root canals in the test groups were completely contaminated after a 19-day exposure to *Staphylococcus epidermidis*. Furthermore, 50% of the root canals were completely contaminated when the coronal surfaces of their fillings were exposed to *Proteus vulgaris* for 42 days.⁷⁶ Similarly, Barrieshi

et al.⁷⁷ examined bacterial leakage of a mixed anaerobic community of organisms in obturated canals after post space preparation. They reported that 80% of the teeth demonstrating coronal leakage lost their seal between 48 and 84 days. In further investigations, results demonstrated that leakage reached the apex through the obturated canals of experimental teeth at the earliest in 17 days and at latest by 88 days.⁷⁸ This study was corroborated in the work performed by Hommez et al.⁷⁹ who investigated the effect of coronal restoration quality on the composition of the root canal flora of teeth with necrotic pulps and teeth with root fillings associated with apical periodontitis. They discovered that only in root-filled teeth did defective coronal restorations have a statistically significant influence on the mean numbers of detected bacteria in their samples.

Bacteria and their by-products have also been shown to penetrate root canal obturating materials and influence periapical tissues and outcomes for success. Endotoxin, a component of the cell membrane of Gram-negative bacteria, is a potent inflammatory agent that, due to its smaller size, may be able to penetrate obturating materials faster than bacteria. For that reason, the evaluation of bacterial endotoxin to pass through obturated root canals was also observed. Endotoxins demonstrated contamination in all teeth within 21 days.⁸⁰ A similar in vitro study examined the possible penetration of post-prepared canals by endotoxin and bacteria. Results showed that both bacteria and endotoxins were able to penetrate the obturating materials in post-prepared canals; however, endotoxin penetration was faster than bacterial. A conclusion was made that the need for an immediate and proper coronal restoration after root canal treatment was optimum.⁸¹

Several groups have reported that root canals with post space preparations only need 30 days to be recontaminated and that dowel-space preparations had a negative influence on the sealing ability of the remaining root canal-filling material.⁸²⁻⁸⁴ This finding was supported with a case report of a tooth that was restored coronally with a post space left empty, and 14 months later, pain and furcal radiolucency developed. Cleaning, shaping, medicating, and filling the post space resulted in the resolution of symptoms and healing of the radiolucency.⁸⁵

Early studies in coronal leakage were performed in vitro and only provided a sense of what was happening clinically. An in vivo study by Ray and Trope⁸⁶ evaluated the relationship of the quality of the coronal restoration and the root canal obturation on the periapical status of endodontically treated teeth. The

conclusion reported that the condition of the coronal restoration was more important than the quality of the endodontic treatment. It was observed that poor restorations in combination with good root canal therapy had negative results. The findings suggested that leakage of bacteria and their products along the margins of the restoration and the root filling will induce or maintain apical inflammatory lesions. When both the coronal restorations and endodontic fillings were inadequate, failure rates rose.

Tronstad et al.⁶⁵ found that the technical quality of endodontic therapy was significantly more important than the condition of the coronal restoration when the periapical status of endodontically treated teeth was evaluated. Their research highlighted the importance of the coronal restoration in cases where the endodontic treatment appeared satisfactory. However, if the quality of the endodontic treatment was poor, the quality of the restoration was of no significance. This study was corroborated when Hommez et al.⁶⁶ found that a good coronal restoration, as well as a good root canal filling, should be emphasized as the most influential factors on the periapical status. In another corroborating study, while the coronal restoration had a significant impact on periapical health, the quality of the root canal filling was found to be the most critical factor in this regard.²⁴

The majority conclusion appears to be that no matter what clinicians use to obturate root canal systems, if the coronal portion of the canal is left unsealed, dissolution of the cement will occur and bacterial by-products will migrate down the canal walls contributing to an endodontic failure.⁸⁷⁻⁹¹

While these studies have all concluded that sealing the interface of the coronal restoration and dentinal walls of the root canal system is of paramount importance, it is not clear if these studies measured the true interrelationship between the coronal restoration and periapical health. When inferior root canal therapy is present, the issue of coronal microleakage is a mute point.⁵⁵

Bergenholtz and Spångberg⁵⁵ evaluated the quality of root canal therapy as well as the quality of the coronal restoration with respect to endodontic failures. The data suggested that the problem of coronal leakage might not be of such a great clinical importance as implied by numerous *in vitro* studies, provided instrumentation and root fillings were carefully performed. There was however a 3-fold increase in the likelihood for radiographic periapical lesions to occur in teeth with a poor coronal seal or lack of a seal.⁹² This is in agreement with other researchers who support the premise that success stems from good endodontic therapy plus a good coronal restoration as an important secondary factor.^{64,65,93,94} Thus, it

appears to be the majority finding that once the endodontic therapy is complete, the best unequivocal recommendation to avoid re-infection of the root canal system is to restore the tooth immediately with either an immediate coronal restoration or a prefabricated post and composite system.^{81,83,95-98}

When sealing the coronal access opening after endodontic therapy, amalgam has been a material of choice. A bonded amalgam filling has been shown to produce significantly less leakage than non-bonded.⁸⁹ The technique has been shown to prevent re-infection of an endodontically treated molar through utilization of a bonded amalgam buildup.⁹⁹ Other long-term leakage studies have demonstrated resistance to salivary contamination improves by performing core buildups with adhesive materials.⁸⁹ Fabricating buildups with a glass ionomer base and an overlaying composite resin restoration demonstrated less leakage due to the composite resin protecting the glass ionomer from dissolution by saliva over time.¹⁰⁰

However, the clinician cannot always restore the tooth with a permanent restoration immediately following endodontic therapy. The restoring dentist and endodontist alike must be sure to communicate to the patient the need for a sealed temporary restoration and a minimum time interval prior to a permanent restoration. A major goal in restoration of the tooth after root canal treatment should be to prevent recontamination of the root canal system.⁹⁸ Grossman¹⁰¹ first emphasized the importance of achieving a bacteria-tight seal between visits with the use of temporary restorations. Lack of satisfactory temporary restorations during endodontic therapy ranked as the second leading contributing factor in continuing pain after commencement of treatment.⁴¹ Consequently, temporary restorative materials must then provide an adequate seal to prevent bacteria, fluids, and saliva from the oral cavity to recontaminate the obturated root canal system. To achieve effective temporization, it is essential to have adequate knowledge of the materials and their properties in order to select the proper temporary for the particular clinical circumstance.

TEMPORARY CORONAL RESTORATIONS

Temporary restorations have been available for decades, and manufacturers are continually developing new ones. The most common temporary restorations used in endodontics are zinc oxide-eugenol (ZOE) compounds such as intermediate restorative material (IRM) and zinc oxide and calcium sulfate mixtures such as Cavit. Adhesive dentistry has impacted endodontics,

and resin-based materials including composites such as TERM and modified glass ionomer materials such as Ketac, Vitrebond, and FUJI are increasing in popularity.¹⁰² Temporary restorations for use during and after non-surgical endodontic treatment have received a great deal of basic research and clinical evaluation (see Chapter 29, Root Canal Filling Materials). Studies have evaluated the materials for sealing ability, resistance to dissolution, radiopacity, and strength.^{98–142}

The placements of orifice plugs have also been suggested to augment the seal of conventional root canal fillings. Utilizing an *in vivo* model, the efficacy of white MTA plugs in preventing periapical inflammation subsequent to coronal inoculation of root-filled teeth was investigated. None of the roots revealed radiographic or histological evidence of severe inflammation after inoculation. Therefore, it was equivocal if MTA should be used as a barrier to improve resistance to leakage.²³ Further investigations evaluated gray and white MTA as well as Fuji II LC cement as coronal barriers to bacterial leakage. Results suggest that either gray or white MTA or Fuji II could be recommended as a coronal barrier for up to 3 months.¹⁴³ Glass ionomer cement was shown to prevent microleakage in teeth with post spaces when the

glass ionomer was used as a plug over the remaining gutta-percha.¹⁴⁴

THE TECHNOLOGY OF RETREATMENT

With so much potential for endodontic success, the fact remains clinicians are confronted with post-treatment disease.^{145,146} Before commencing with any treatment, it is wise to fully consider all the various treatment options.^{27,147} When the choice is non-surgical endodontic retreatment, then the goal is to access the pulp chamber and remove materials from the root canal space and if present address deficiencies or repair defects that are pathologic or iatrogenic in origin^{148,149} (Figure 4). Furthermore, endodontic access provides the opportunity to diagnostically evaluate teeth for coronal leakage, fractures, and missed canals.¹⁵⁰ Importantly, following disassembly procedures, the root canals can be re-shaped and disinfected and obturated in a manner that allows periapical healing.^{151–153}

This section of the chapter will focus on the science, strategies, techniques, and technology that can produce successful results in non-surgical retreatment. In the last decade alone, significant procedural refinements have led to more predictable results. Properly

Figure 4 **A**, Preoperative radiograph of an endodontically treated, non-healing maxillary central incisor. A gutta-percha point traces a sinus tract to a large lateral periapical lesion. **B**, Five-year recall radiograph demonstrates osseous repair following cleaning, shaping, and obturation. Note that the lateral lesion was associated with a lateral canal.

Figure 5 A, Preoperative radiograph shows a failing surgical treatment of a maxillary premolar with a laterally positioned lesion of endodontic origin. Note the “mineralized” canal and history of surgery. **B**, The tooth was successfully treated endodontically, and the 1-year recall radiograph demonstrates healing.

performed with advanced techniques, non-surgical endodontic retreatment is a strategic cornerstone of restorative and reconstructive dental procedures.

NON-SURGICAL VERSUS SURGICAL RETREATMENT

Endodontic revision must be carefully evaluated so a decision can be made among non-surgical retreatment (NSRCT), surgical retreatment (SRCT), or extraction.^{154,155} NSRCT are disassembly and corrective procedures which are performed to potentially enable the clinician to properly clean, shape, and seal the root canal system.¹⁵⁶ Historically, endodontic surgery has been selected as the primary approach in resolving treatment outcomes that do not heal and sometimes in situations in which root canals have been mistakenly assumed to be “mineralized” and not treatable (Figure 5). Even with the vast improvements achieved in surgical endodontics in recent years, surgical techniques are restricted in their ability to eliminate pulp tissue, microorganisms, and related irritants from the root canal system.^{157–159}

Infrequently, but on occasion after revision, surgery may still be necessary. However, higher success rates can be achieved if the root canal space has been adequately addressed prior to a surgical intervention. Consultation with the patient should be directed toward communicating the critical importance of retreatment, the cost of this approach compared to potentially less effective treatment choices, and the fact that this modality generally improves long-term results. Today, endodontic success can approach 100%.¹⁵² This significant improvement is related to a large number of factors. Clinicians now have a better

understanding of biological principles and a greater knowledge, appreciation, and respect for root canal system anatomy and the role it plays in success and healing. Better training, advanced techniques, relevant new technologies, and attention to restorative excellence improve the potential for long-term success.

CORONAL DISASSEMBLY

Clinicians typically access the pulp chamber through the existing restoration if it is judged to be functionally designed, well fitting, and esthetically pleasing. Endodontically, the decision to remove any restoration is based primarily on whether additional access is required to facilitate disassembly and retreatment.^{156,160} If the restorative is deemed inadequate and/or additional access is required, the restoration should be sacrificed. However, on specific occasions, it is desirable to preserve and remove the existing restorative dentistry.¹⁶¹ A variety of new technologies allow clinicians to more predictably eliminate coronal restorations.

FACTORS INFLUENCING RESTORATIVE REMOVAL

The removal of a restorative is dramatically enhanced when there is knowledge, respect, and appreciation for the concepts, materials, and techniques used in restorative and reconstructive dentistry. The safe dislodgment of a restorative is dependent on five factors that must be considered:

1. Preparation type: Preparations vary in retention depending on the total surface area of the tooth covered and the height, diameter, and degree of taper of the axial walls.

2. Restoration design and strength: The design and ultimate strength of a restorative is dependent on its physical properties, thickness of material(s), and the quality and techniques of the laboratory technician.
3. Restorative material(s): The composition of a restoration ranges from different metals to tooth colored restoratives such as porcelain. How these materials behave related to the stresses and strains required during removal must be appreciated.
4. Cementing agent: The retention of cements ranges from weak to strong, generally progressing from ZOE, polycarboxylate, silico-phosphate, zinc phosphate, glass ionomers, resin-modified glass ionomers to bonded resins.¹⁶² Clearly, the new generation bonding materials, in conjunction with well-designed and retentive preparations, have made restorative removal more difficult and, at times, unwise.
5. Removal devices: The safe and successful dislodgment of prosthetic dentistry requires knowledge in the selection and use of a variety of devices. Clinicians need to identify and become familiar with each device, its safe application, effectiveness, limitations, and costs.¹⁵⁶

A clinician must obtain a careful case history, confer with the original treating dentist if possible, and then consult with their patient to clearly define the risk versus benefit when entertaining the intact removal of an existing restorative.

CORONAL DISASSEMBLY DEVICES

Although there are many instruments available for coronal disassembly, the following represent a consensus of preferred instruments for the removal of various restorations. The tools used for disassembly have been arbitrarily divided into three categories. They can be used solely; however, it is useful to appreciate that they may be used in combination to synergistically attain removal success.¹⁶³

Grasping Instruments

In general, this class of hand instruments works by applying inward pressure on two opposing handles. Increasing the handle pressure proportionally increases the instrument's ability to grip a restoration. The actual grasping instrument selected should protect the restoration and provide a strong purchase while reducing dangerous slippage. These grasping devices are best used in removing temporary restorations and include K.Y. Pliers (G.C. America, Alsip, IL), the Wynman Crown Gripper (Miltex Instrument Company,

Figure 6 Removal of a crown using the K.Y. Pliers. Note the grasping pads have been dipped in emery powder to reduce slippage.

Lake Success, NY), and the Trident Crown Placer-Remover (Trident Dental Inc., Hendersonville, NC). An example of one of these grasping instruments is shown in (Figure 6).

Percussive Instruments

This method of prosthetic disassembly involves utilizing a selected and controlled, percussive removal force. This family of instruments delivers an impact either directly to a restorative or indirectly to another securely engaged prosthetic removal device. Although these devices are valuable removal instruments, caution must be exercised when considering the disassembly of tooth colored restoratives. Examples of percussive devices include Crown-A-Matic (Peerless International Inc., North Easton, MA) and the Coronaflex (Kavo America, Lake Zurich, IL), both of which are used to remove both temporary and permanently cemented prostheses.

Active Instruments

The instruments in this category actively engage restorations, enabling a specific dislodgment force to potentially lift off the prosthesis. These devices require a small access window to be cut through the restorative to facilitate the mechanical action of the instrument. In this method of removal, the downside of making and then repairing the access hole is significantly offset by the upside of saving the patient's existing restorative dentistry. Active devices among the most effective for removing permanently placed restorations intact are the Metalift (Classic Practice

Resources, Baton Rouge, LA), the WAMkey Removal Keys (Dentsply Maillefer, Ballaigues, Switzerland), the Kline Crown Remover (Brasseler, Savannah, GA), and the Higa Bridge Remover (Higa Manufacturing, West Vancouver, B.C.). An example of one of these active instruments is shown in Figure 7.

ARMAMENTARIA AND TECHNIQUES ASSOCIATED WITH MISSED CANALS

The etiology of endodontic failure is multi-faceted, but a significant percentage of failures are related to inadequate débridement of root canal systems. Missed canals contain tissue, as well as bacteria and other irritants that inevitably contribute to clinical symptoms and lesions of endodontic origin (Figure 8).^{164–166} Historically, and all too often, surgical treatment has been directed toward “corking” the end of the canal with the

Figure 7 Removal of a Poreelain fused to metal (PFM) crown using the Metalift. This system applies a force between the crown and the tooth.

Figure 8 **A**, Radiograph of a maxillary right second premolar reveals pins, a post, insufficient endodontic treatment and an asymmetrical apical lesion. **B**, Photograph ($\times 12$ original magnification) after removal of the post from the buccal canal. The palatal canal had not been treated. **C**, Photograph ($\times 12$ original magnification) of completed access and palatal canal preparation. **D**, Ten-year recall radiograph shows osseous repair, demonstrating the importance of correct endodontic treatment, and a well-designed prosthesis.

hopes that the retrograde filling material will incarcerate biological irritants within the root canal system over the life of the patient.^{156–159} Although this scenario may provide clinical success, it is not nearly as predictable for healing as non-surgical retreatment. Endodontic prognosis is maximized in teeth whose root canal systems are cleaned, shaped, and obturated in all their dimensions.^{160,167}

There are multiple concepts, armamentaria, and instruments that are useful to find missed canals, and the following represent the most important.

- **Anatomical familiarity.** It is essential before preparing the access cavity or re-entering a tooth that has had prior endodontic treatment.¹⁶⁸ For example, one can appreciate in the maxillary first molar that the second mesiobuccal canal (MB2) is almost never on the imaginary line between the MB1 and the palatal orifices. This canal is typically mesial to that imaginary line.
- **Radiographic analysis.** It is critical when evaluating an endodontic failure.^{169,170} Well-angulated periapical films should be taken with the cone directed straight-on, mesio-oblique, and disto-oblique. This technique oftentimes reveals and clarifies the three-dimensional morphology of the tooth. In teeth where complete endodontic treatment has been performed, obturation materials are seen radiographically as centered within the root regardless of the selected angle of the radiograph. Conversely, if the obturation materials appear positioned asymmetrically within the long axis of the root, a missed canal should be suspected (see Figure 8).¹⁷⁰ Digital radiography and other imaging technologies mentioned in this chapter afford a variety of software

features significantly enhancing radiographic diagnostics in identifying hidden, calcified, or untreated canals.

- **Vision.** It is enhanced with magnification glasses, headlamps, and transilluminating devices. A dental operating microscope affords extraordinary light and magnification and gives the clinician unsurpassed vision, control, and confidence in identifying or chasing extra canals.¹⁵¹ Operating microscopes typically have a range of magnification from about $\times 2.5$ to around $\times 20$. Magnification plus improved lighting equals significantly enhanced vision. Surgical length burs enhance direct vision by importantly moving the head of the handpiece further away from the occlusal table and improving the line of sight along the shaft of the bur.
- **Access cavities.** These should be prepared and expanded so their smallest dimensions are dictated by the separation of the orifices on the pulpal floor and their widest dimensions are at the occlusal table (Figure 9). The isthmus areas and/or developmental grooves are firmly probed with an explorer in an effort to find a “catch.” In general, access cavities should be expanded and finished to enhance vision, improve diagnostics, and provide straight-line access to the orifice(s).¹⁷¹
- **Piezoelectric ultrasonics.** It provides a breakthrough for exploring and identifying missed canals. The clinician should recognize that ultrasonic instruments perform optimally when they are designed, manufactured and tuned for a specific generator. Synergistically, a piezoelectric generator (P5, Dentsply International, Tulsa, OK) in conjunction with ultrasonic instruments (ProUltra ENDO Instruments, Dentsply International)

Figure 9 **A**, Magnified view into the access cavity in a mandibular first molar shows the four orifices to the root canal system. **B**, Photograph showing a third mesial orifice in another mandibular molar. It is important to explore the isthmus connecting the mesiobuccal and mesiolingual orifices.

are used to transfer energy and perform a variety of clinical procedures (Figure 10).¹⁷²⁻¹⁷⁴ Ultrasonic systems importantly eliminate the bulky head of the conventional handpiece that frequently obstructs vision. The working ends of specific ultrasonic instruments are 10 times smaller than the smallest manufactured round burs, and their abrasive coatings allow them to precisely prepare away dentin when exploring for missed canals.

- **Micro-Openers (Dentsply International).** These are flexible, stainless steel hand instruments that feature ergonomically designed off-set handles. Micro-Openers have limited length cutting blades which, in conjunction with their 0.04 and 0.06 tapers, enhance tensile strength, making it easier to locate, penetrate, and perform initial canal enlargement procedures. These instruments provide unobstructed vision when operating in difficult teeth with limited access.
- **Dyes.** Various dyes like methylene blue can be irrigated into the pulp chambers of teeth to aid in diagnosis. The chamber is subsequently rinsed thoroughly with water, dried, and visualized. Frequently the dye will be absorbed into orifices, fins, and isthmus areas and serves to “roadmap” the anatomy. This technique can aid in the identification and treatment of missed canals and enhance diagnostics, including the visualization of fractures.
- **Sodium hypochlorite (NaOCl).** NaOCl can aid in the diagnosis of missed or hidden canals.^{151,161} Following cleaning and shaping procedures, the access cavity is flooded with NaOCl and the solution is observed to see if oxygen bubbles emanate toward the occlusal table. A positive “bubble” reaction signifies that NaOCl is either reacting with residual tissue within a missed canal or with residual chelator still present within a canal being prepared.

Figure 10 Ultrasonic instruments. **A**, The Satellec P5 ultrasonic unit. **B**, The ProUltra ENDO 1-5 ultrasonic instruments have an abrasive zirconium nitride coating to improve efficiency, precision, and clinical performance. **C**, The ProUltra ENDO-6, 7, and 8 titanium ultrasonic instruments provide longer lengths and smaller diameters and are used when space is restrictive.

- **Transillumination.** It is accomplished by positioning a fiber optic wand either above or below the rubber dam and directing light buccal to lingual. Diagnostics are, at times, improved by turning off the overhead or microscope light source to achieve a different optical effect.
- **Explorer pressure.** It can help to identify a missed canal. Firm explorer pressure is used to punch through a thin layer of secondary dentin.
- **White line test.** Oftentimes, a shelf of dentin meets the pulpal floor and forms a groove. It is important to recognize that extra canals can be more readily identified by progressively preparing away this shelf of dentin with abrasively coated ultrasonic instruments. During ultrasonic procedures in necrotic canals, dentinal dust moves into available anatomical space, such as the isthmus, and forms a visible white line. The white line test is a visible road map that can be followed and diagnostically aid in identifying, as an example, an MB2 orifice/canal.
- **Red line test.** In vital cases, blood frequently moves into an isthmus area. Like a dye, blood absorbs into orifices, fins, and isthmuses, which serves to roadmap and aid in the identification of the underlying anatomy.
- **Restorative disassembly.** It provides better orientation to the underlying tooth structure and improves safe access to the pulp chamber.
- **Perio-probing.** It is another important adjunct for locating canals. Probing the sulcus can provide important information as to the relationship between the long axis of the clinical crown and the underlying root as well as indicate possible root fracture.
- **Symmetry.** It is an important visual test that can encourage looking for another orifice/canal or confirm that all canals have been properly identified. The rules of symmetry suggest that if any given root contains only one canal, then regardless of its anatomical configuration, the orifice should be positioned an equal distance from the external cavo-surface of the root.
- **Color.** Color changes indicate developmental grooves in the pulpal chamber floor. Oftentimes, a dark groove on the pulpal floor of a multi-canal tooth can be followed and will lead to another canal orifice. Additionally, orifices frequently appear a darker color than the surrounding dentin in teeth exhibiting mineralization.

If discovered, missed canals can usually be thoroughly cleaned, shaped, and sealed. However, if a missed canal is suspected but cannot be readily identified, then an endodontic referral may be prudent to avoid

further complications. Caution should be exercised when contemplating surgery due to the aforementioned concerns, but at times, surgery may be necessary in the hopes of salvaging the tooth.

Removal of Obturation Materials

The obturation materials most frequently found in the root canal space generally reflect a past era of knowledge, a current school of thought, or a personal philosophy of treatment. There are some commonly encountered materials found in obturated root canal systems: gutta-percha, carrier-based obturators, silver points, and paste fillers. In addition, new obturation materials based on resin fillers and sealers have recently been recommended for obturation of root canal systems. Resin-based materials can generally be removed using the same technique described for the removal of gutta-percha. Frequently, it is necessary to partially or totally remove an obturation material to achieve endodontic retreatment success or to facilitate placing a post for restorative reasons.

GUTTA-PERCHA REMOVAL

The relative difficulty in removing gutta-percha varies according to the canal's length, cross-sectional diameter, and curvature. Regardless of technique, gutta-percha is best removed from a root canal in a progressive manner to prevent inadvertent displacement of irritants periapically. Dividing the root into thirds, the obturation is initially removed from the canal in the coronal one-third, then the middle one-third, and finally eliminated from the apical one-third. In canals that are relatively large and straight, loosely fitting cones can, at times, be removed with one instrument in one motion. For other canals, there are a number of possible gutta-percha removal schemes. The techniques include rotary files, ultrasonic instruments, heat, hand files with heat or chemicals, and paper points with chemicals.¹⁷⁵ Of these options, the best technique(s) for a specific case is selected based on preoperative radiographs and clinically assessing the diameter of the orifices after re-entering the pulp chamber. Often, a combination of methods is required to achieve a safe, efficient, and potentially complete elimination of gutta-percha and sealer from the internal anatomy of the root canal system.

Rotary Instrumentation Removal of Gutta-Percha

Rotary instrumentation is the most efficient method for removing gutta-percha from a previously treated root canal (Figure 11). The ProTaper Retreatment Kit

(Dentsply International) is an example of a system that is useful in the retreatment of gutta-percha-filled root canals. However, to avoid instrument fracture, rotary instruments should be used with caution in under-prepared canals and are generally not selected for

removal of gutta-percha in canals that do not have a glide path that allows the instrument to cut passively. When attempting gutta-percha removal, it may be useful to divide the root into thirds and then select two or three appropriately sized rotary instruments that will fit

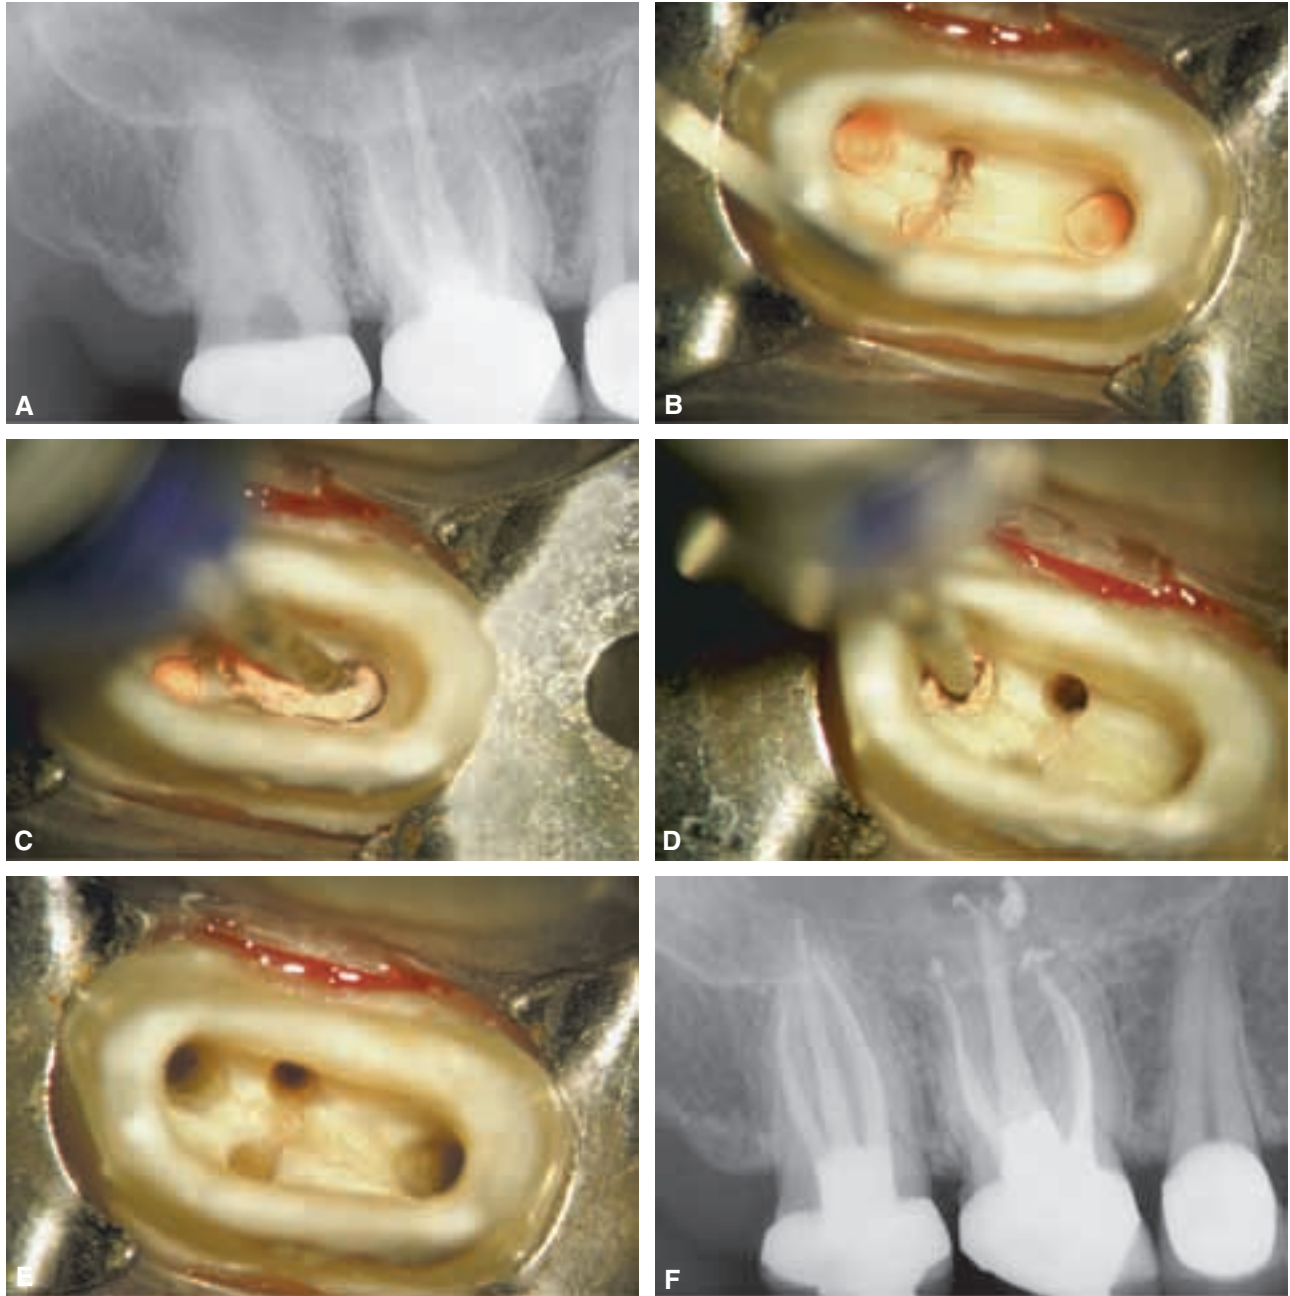

Figure 11 **A**, Radiograph of an endodontically treated, failing maxillary right first molar. Note the inadequate treatment resulting in an apical lesion. **B**, Photograph ($\times 15$ original magnification) after crown removal, adequate access, and the identification of an MB2 root canal orifice. **C**, Photograph ($\times 15$ original magnification) demonstrates the removal of gutta-percha from the palatal canal with a 0.06 tapered NiTi rotary profile. **D**, Photograph ($\times 15$ original magnification) demonstrates the removal of gutta-percha from the mesiobuccal canal with a smaller sized 0.06 tapered NiTi rotary profile. **E**, Photograph ($\times 15$ original magnification) shows the pulpal floor and orifices following canal preparation procedures. **F**, Postoperative radiograph after completion of retreatment.

passively within these progressively narrower regions. To mechanically soften and effectively remove gutta-percha, rotary instruments should turn at speeds ranging between 900 and 1200 rpm. Ultimately, the rotational speed has an effect on the amount of frictional heat generated to mechanically soften and effectively auger gutta-percha coronally. Coronal removal of gutta-percha allows the early introduction of solvents into the canal(s) and facilitates subsequent cleaning and shaping procedures.

Ultrasonic Removal of Gutta-Percha

The piezoelectric ultrasonic effect represents a useful technology to rapidly remove gutta-percha. The energized instruments produce heat that thermo-softens gutta-percha. Specially designed ultrasonic instruments may be carried into shaped canals and will displace gutta-percha coronally into the pulp chamber where it subsequently can be removed.

Heat Removal of Gutta-Percha

A power source in conjunction with specific electric heat carrier instruments may be used to thermo-soften and remove increments of gutta-percha from root canal systems.¹⁵² The cross-sectional diameter of the heat carrier limits its use in under-prepared canals and around canal curvatures; however, in larger canals, this method works quite well. The technique involves guiding a heated plugger into the most coronal aspect of the gutta-percha. The heated plugger is then deactivated and withdrawn, generally resulting in the removal of an attached portion of gutta-percha. This process is repeated as long as it continues to be productive.

Heat and Instrument Removal of Gutta-Percha

Another technique to remove gutta-percha employs heat and Hedström files. In this method of removal, a hot instrument is plunged into the gutta-percha and immediately withdrawn in order to only heat-soften the material. A size 35, 40, or 45 Hedström file is then selected and quickly and gently screwed into the thermo-softened mass.¹⁴⁸ When the gutta-percha cools, it will solidify on the flutes of the Hedström file. In poorly obturated canals, removing the file may eliminate the entire gutta-percha mass in one motion. This technique is recommended in canals where gutta-percha extends beyond the apical foramen. After removing as much of the gutta-percha as possible, the clinician must verify whether residual gutta-percha and sealer are entrapped within the canal system. Chemical removal techniques are then used in conjunction with the described technique.

File and Chemical Removal of Gutta-Percha

The file and chemical removal technique is best used to remove gutta-percha from small and/or more curved canals. Chloroform is the most frequently used solvent and plays an important role in chemically softening gutta-percha.¹⁷⁶⁻¹⁷⁹ This sequential technique involves filling the pulp chamber with chloroform, selecting an appropriately sized K-type file, and then carefully preparing the canal while removing the chemically softened gutta-percha. Initially, a size 10 or 15 stainless steel file is used to “pick” into the gutta-percha occupying the coronal one-third of the canal. Frequent irrigation with chloroform in combination with a “watch-winding” motion creates a pilot hole and sufficient space for the serial use of larger files to remove gutta-percha in this specific region of the canal. This method is continued until gutta-percha is no longer evident on the cutting flutes of the files when they are withdrawn from the solvent-filled canal. Only after gutta-percha has been removed from the coronal one-third of the canal should the clinician repeat the technique in the middle one-third and finally in the apical one-third. This progressive removal technique helps prevent the needless extrusion of chemically softened gutta-percha periapically. Once the “file and chemical” gutta-percha removal technique has been completed, the residual sealer and gutta-percha that remain in the irregularities of the root canal system need to be removed.

Paper Point and Chemical Removal of Gutta-Percha

Gutta-percha and most sealers are miscible in chloroform and, once in solution, can be absorbed and removed with appropriately sized paper points. Drying solvent-filled canals with paper points is known as “wicking” and should always be the final step during gutta-percha removal.¹⁴⁸ The wicking action is essential in removing residual gutta-percha and sealer out of fins, cul-de-sacs, and aberrations of the root canal systems. In this technique, the canal is first flushed with chloroform and the solution is then absorbed and removed with appropriately sized paper points. Paper points aid in removal of gutta-percha by drawing dissolved materials into and then out of the shaped canal. Chemical flushing and wicking procedures more effectively liberate residual gutta-percha and sealer from the root canal system. This process is repeated as long as it continues to be visibly productive.

Even when paper points come out of the canal clean, white, and dry, the clinician should assume residual gutta-percha and sealer are still present. At this point, the chamber is again flooded with

chloroform, but it is now introduced with more of an irrigation and vacuum “flushing action.” The irrigating canula is placed below the orifice and the solvent is passively and repeatedly irrigated, then aspirated. This alternating method of irrigating then aspirating creates a vigorous back and forth turbulence that will promote the elimination of the root canal filling materials. Following chloroform wicking procedures, the canal is liberally flushed with 70% isopropyl alcohol and dried to further encourage the elimination of chemically softened gutta-percha residues. Removal of all residual material in this manner enhances the efficacy of NaOCl when it is used during subsequent cleaning and shaping procedures.

REMOVAL OF RESILON

Recently, a new root filling material, Resilon (Resilon Research LLC, Madison, CT), was introduced. Derived from polymers of polyester, it contains bioactive glass and radiopaque fillers. It has the same handling properties as gutta-percha. The Resilon core materials, similar to gutta-percha cones, are available in ISO sizes with 0.02, 0.04 and 0.06 tapers. Additionally, pellets of this material (Epiphany Pellets; Pentron Clinical Technologies LLC, Wallingford, CT) are available for use with the Obtura II delivery system (Obtura Spartan, Fenton, MO). Resilon is recommended for use in combination with a new dual curable dental resin composite sealer Epiphany Root Canal Sealant (Pentron Clinical Technologies LLC). There have been only a few reports concerning retreatment of teeth filled using Resilon and Epiphany sealer. Often in these types of studies, the hypothesis is tested that root canals filled with these materials can be retreated using hand and rotary instrumentation combinations in the same manner as canals filled with gutta-percha and conventional sealer. In three recent studies of Resilon and Epiphany sealer, they were removed more effectively from treated root canal systems compared to gutta-percha.^{180–182} In two investigations, the most effective removal techniques involved a combination of rotary instrumentation and chloroform dissolution.^{181,182} When no solvent was used in retreatment, Resilon and Epiphany sealer was removed most effectively with Gates Glidden (GG) burs and Hedström files compared to rotary only instrumentation.¹⁸⁰

REMOVAL OF SILVER POINTS

The relative ease of removing failing silver points is based on the fact that chronic leakage and corrosion greatly reduce the seal, and hence, the lateral retention of the cone. Before any given silver point retrieval

technique is selected, it is useful to recall the canal preparation prescribed for this method of obturation. Typically, the apical 2 to 3 mm of the canal was prepared relatively parallel and then flared coronal to this apical zone. When clinicians evaluate silver point failures and subsequent retreatment strategies, they should recognize that the silver point is parallel over its length. In a coronally shaped canal, one may take advantage of this available space when approaching retreatment.¹⁸³

Many techniques have been developed for removing silver points primarily addressing their varying lengths, diameters, and positions within the root canal space.^{151,184,185} Certain removal techniques evolved to address silver points that bind in unshaped canals over a greater length. Other techniques have arisen to remove silver points with large cross-sections, resembling small diameter posts. Finally, other techniques are necessary to remove the split cone or intentionally sectioned silver points lying deep within the root canal space.

Access to Silver Points

Typically, the coronal portions of silver points are within pulp chambers and may be imbedded in cements, composites, or amalgam cores. Access preparations should be thoughtfully planned and prepared in order to minimize the risk of inadvertently shortening the silver points. Initial access is accomplished with high speed, surgical length cutting tools. Subsequently, ultrasonic instruments may be carefully used within the pulp chamber to “brush-cut” away restorative materials and progressively expose the silver point while avoiding direct contact of the silver point with the ultrasonic tip.

Pliers to Remove Silver Points

After completing access and fully exposing the coronal portion of the silver point inside the pulp chamber, a suitable grasping instrument (Stieglitz Forceps, Hu-Friedy; Chicago, IL) is selected. To identify the best removal strategy, a strong hold is obtained on the silver point and a gentle pull is exercised to confirm its relative tightness. A second lock on the grasping instrument by means of a hemostat can often enhance a tenuous grip.¹⁸⁴ Oftentimes, dentists make the mistake of over-manipulating the head of the silver point and needlessly shortening it, making subsequent retrieval efforts difficult, if not impossible. When grasping a silver point, rather than trying to pull it straight out of the canal, the pliers may be rotated and levered, using fulcrum mechanics, against the restoration or tooth structure to enhance removal efforts¹⁵¹ (Figure 12).

Figure 12 **A**, Preoperative radiograph of a failing endodontically treated maxillary central incisor bridge abutment; a gutta-percha point is tracing a sinus tract to a large lateral periapical lesion. Note the poorly filled root canal. **B**, Photograph ($\times 15$ magnification) reveals lingual access and restorative buildup around the coronal most aspect of the exposed silver point. **C**, Photograph ($\times 15$ magnification) demonstrates the ProUltra ENDO-3 ultrasonic instrument removing material lateral to the silver point. **D**, The left image shows the Stieglitz pliers used for grasping intracanal obstructions. The right image shows the “modified” Stieglitz pliers which working end has been altered to enhance access. **E**, Working radiograph during the down-pack phase of thermoplastic obturation reveals extensions apically and laterally. Note the thermosoftened and compacted gutta-percha is apical to the most coronally positioned lateral canal. **F**, Five-year review demonstrates that thorough endodontic treatment promotes healing.

Indirect Ultrasonics to Remove Silver Points

When a segment of a silver point is present below the canal orifice and space is restricted, an appropriate ultrasonic tip should be selected (e.g., ProUltra ENDO-3, 4, and 5, Dentsply International). These ultrasonic tips have parallel walls and provide progressively longer lengths and smaller diameters. The appropriate instrument is selected based on its anticipated depth of use and the available canal diameter. The ultrasonic instruments are used to trephine circumferentially around the obstruction, disintegrate the cement interface, and safely expose as much of the silver point as possible. Caution should be exercised not to use ultrasonic instruments directly on silver points because they rapidly erode during mechanical manipulation. Once the surrounding material is removed, ultrasonic energy may then be transmitted directly to the grasping pliers. This form of “indirect” ultrasonics advantageously transfers energy along the silver point, breaks up the interface deep within the canal, and enhances removal efforts.¹⁸⁴

Files, Solvents, and Chelators to Remove Silver Points

If grasping techniques and/or indirect ultrasonics are unsuccessful, then the clinician should make use of the fact that silver points are perfectly round and root canal systems are typically irregular in their cross-sectional shapes. This discrepancy provides the clinician with an opportunity to use solvents and a size 10 or 15 stainless steel file alongside the silver point. In a solvent-filled chamber, files are used lateral to the silver point to loosen cements and to undermine and loosen the point for removal. In under-prepared canals, chelators may be more effective than solvents by lubricating the instrument. If space exists or can be created between the silver point and the canal wall, a 35, 40, or 45 Hedström file can be inserted into this space. The Hedström instrument promotes the removal process as its positive rake angle engages and establishes a strong purchase on the soft silver.

MICROTUBE REMOVAL OPTIONS

Several microtube removal methods exist that are designed to mechanically remove an intracanal obstruction such as a silver point or separated instrument. However, it should be remembered that many of these microtube removal methods require excessive removal of dentin and may not be effective. For clinicians, the critical dimension when considering microtube removal methods is not the inside diameter of the device but, importantly, it is the outside dia-

meter, that defines how deeply it can be safely introduced into a given canal. The following list includes some of the various microtube removal methods and techniques.

- **Lasso and anchor:** In this removal method, an appropriately sized microtube is selected and a wire passed through the tube, then looped at one end and passed back through the tube. This loop can potentially lasso a coronally exposed obstruction and, when successful, form a purchase by pushing the tube apically while simultaneously pulling the wire ends coronally.¹⁸⁶ Although reported in the literature, this removal method has been essentially replaced with more practical techniques.¹⁸⁷
- **Tube and glue:** The Cancellier Extractor Kit (SybronEndo, Orange, CA) contains four different sized microtubes with outside diameters of approximately 0.5, 0.6, 0.7, and 0.8 mm. An ultrasonic instrument may be used to trephine around and ideally expose the coronal 3 mm of an obstruction. A microtube is prefit to ensure its internal diameter can just fit over the coronally exposed obstruction. The prefit microtube may now be bonded onto the obstruction with an adhesive, such as core paste^{148,161} or cyanoacrylate cement.¹⁸⁴ The diameters of Cancellier microtubes are safely scaled for progressively deeper placement into canals of posterior roots. This removal method may be effective for retrieving silver points, a fractured root canal instrument, or in cases of retrieval of a separated file that is already loose. Caution should be exercised to not use too much adhesive which could inadvertently block a canal.
- **Tap and thread:** The Post Removal System (PRS) kit (SybronEndo) contains five microtubular taps. The smallest PRS tap can be used to internally form threads and mechanically engage the most coronal aspect of any obstruction whose diameter is 0.6 mm or greater.¹⁴⁸ These microtubular taps contain a reverse thread and engage an obstruction by turning in a counterclockwise (CCW) motion. Because intracanal space is often restrictive, this system is generally used for removal of instruments or posts that extend into the pulp chamber (Figure 13). The PRS will be discussed in greater detail in the “Post Removal” section later in this chapter.
- **Masserann:** The Masserann kit (Micromega, Besançon, France) represents a time-honored method to remove a broken instrument.¹⁸⁸ Its smallest tubular extractors have outside diameters of 1.2 and 1.5 mm, limiting their safe use to larger canals in anterior teeth.

Figure 13 **A**, Radiograph of a mandibular right first molar with a silver point in the mesial root. **B**, Photograph ($\times 15$ original magnification) shows a ProUltra ENDO-3 ultrasonic instrument brush cutting the pulp chamber roof and improving access to the silver point. **C**, Microtubular tap from the Post Removal System kit. The tap may be used to engage an obstruction, and the rubber cushion protects the tooth during the extracting forces. **D**, Microtubular tap engages the silver point by turning the instrument counterclockwise. Care is exercised not to over-thread and shear off the point within the tap. **E**, Photograph ($\times 15$, original magnification) shows the elimination of the silver point. **F**, Postoperative radiograph shows non-surgical retreatment, including a filled third mesial canal.

- Spinal tap needle (STN): A STN (Ranfac, Avon, MA) in conjunction with its metal insert plunger or a Hedström file is another technique advocated to remove broken instruments.¹⁴⁸ With limitations,

this method of removal involves sizing the correct microtube so it can be placed over an ultrasonically exposed obstruction. Microtube sizes that are clinically relevant are 19-, 21-, and 23-gauge needles

Figure 14 **A**, Full-length spinal tap needle (STN) (top). The STN is shortened and placed over a coronally exposed object, and Hedström files are passed through the proximal end of the STN to engage an obstruction. **B**, Assembled STN with a #45 Hedström file to engage a fractured file segment.

corresponding to outside tube diameters of approximately 1.0, 0.8, and 0.6 mm, respectively. Because of their unique threading effect, smaller sized Hedström files may be selected and inserted into the coronal most aspect of the microtube.^{148,189} The Hedström is passed down the length of the tube until it wedges tightly between the obstruction and the internal lumen of the microtube (Figure 14). However, because ISO files increase by 0.32 mm over 16 mm of cutting blade, the taper of the file may restrict its placement through a smaller sized parallel microtube. In this instance, the STN's metal insert plunger may be used to potentially wedge the obstruction. This method is effective when removing obstructions from larger canals.

- **Endo extractor/Meisinger Meitrac:** The Endo Extractor System (Roydent Dental Products, Johnson City, TN) and the recently released Meisinger Meitrac Instrument System (Hager & Meisinger GmbH, Neuss, Germany) are techniques used for the removal of silver points or a separated instrument. However, the smallest Meitrac I trephine and extractor have outside diameters of approximately 1.5 mm. This diameter limits the practical use of this instrument to the coronal aspects of larger canals.
- **Instrument Removal System (iRS):** The iRS (Dentsply Maillefer) provides another mechanical method for the removal of intracanal obstructions such as silver points, carrier-based obturators, or broken file segments (Figure 15).¹⁴⁸ The iRS is indicated when ultrasonic efforts prove to be unsuccessful and may be used to remove fractured instruments that are lodged in the straight portions of the root

or partially around the canal curvature. For method of use of this device, see the “Fractured Instrument Removal” section later in this chapter.

CARRIER-BASED GUTTA-PERCHA REMOVAL

The techniques for removing carrier-based gutta-percha are the same methods previously described separately for gutta-percha and silver point removal. Carrier-based obturators were originally metal and file-like; yet over the past several years, they have been manufactured from easier-to-remove plastic materials. Metal carriers, although no longer distributed, are occasionally encountered clinically and are more difficult to remove than silver points because their retention flutes may engage dentin walls.¹⁹⁰

Following careful access and complete circumferential exposure of the carrier, suitable grasping pliers are selected and a grasp is obtained on the carrier. The relative tightness of the carrier within the canal can then be tested utilizing pliers. Successful removal in these cases is enhanced by recognizing that the carrier is embedded in gutta-percha. With this in mind, the following techniques are used to remove carriers:

- The carrier is grasped with the pliers and extrication is attempted using fulcrum mechanics rather than a straight pull out of the tooth.
- If enough canal width exists, an ultrasonic instrument can be used alongside the carrier to produce heat and thermo-soften the gutta-percha. The activated ultrasonic instrument is gently moved apically and the carrier may be displaced coronally.

Figure 15 **A**, The Instrument Removal System (iRS) is a set of devices used for removing fractured instruments or other intracanal obstructions. **B**, Each iRS instrument is comprised of a microtube and an internal screw wedge designed to mechanically engage and remove intracanal obstructions. **C**, Close-up of the assembled iRS.

- Indirect ultrasonics can be performed by grasping the exposed carrier with pliers and then placing an ultrasonic instrument against the pliers.
- Rotary instrumentation can be used to remove a plastic carrier out of a canal. This should only be attempted if there is sufficient space to passively accommodate the rotary instrument without engaging lateral dentin.
- The iRS, as previously mentioned regarding silver point removal, may be considered, in certain cases, to remove a carrier. This method of removal is especially appropriate if the core of the carrier is metal and has retention flutes engaging lateral dentin.
- Solvents will chemically soften gutta-percha and allow small files to work deeper, circumferentially and laterally, while loosening a carrier for removal.

If any of these efforts are successful, a carrier will be extracted from the canal. The canal can then be retreated using any of the gutta-percha removal

strategies followed by chemical solvents and paper point wicking procedures.

PASTE REMOVAL

A great variety of paste types exist. Originally, paste use was intended to simplify root canal treatment and reduce the cost to patients hoping to overcome deficiencies in the removal of tissue, bacterial by-products, and related irritants during canal preparation. This was often addressed by adding toxic ingredients and chemical formulations to the paste.

When evaluating a tooth obturated with paste for retreatment, it is useful to recall that pastes can generally be divided into soft, penetrable, and removable versus hard, impenetrable, and at times, non-removable formulations.^{150,191} Hard setting whitish-colored paste often used in Russia and the reddish-brown resin paste commonly used in Eastern Europe and the Pacific Rim is very difficult to remove.¹⁹¹ However, it is important to understand that, due to the

Figure 16 A, Maxillary premolar with the root canal system treated with a paste material. Note the large periapical lesion indicating bacterial contamination of the root canal system. **B**, Ten-year recall radiograph shows the result of complete endodontic treatment.

method of placement (e.g., packing or a rotary spiral), the densest portion of the paste in the canal is coronal and the material is progressively less dense moving apically. In addition, mineralization and resorption may be associated with paste-filled roots (Figure 16).

Ultrasonic Energy for Paste Removal

Ultrasonic instruments, in conjunction with the microscope, afford superior control in removing paste from the straight portions of a root canal.^{192–194} Specially coated ultrasonic instruments may be used below the orifice to remove brick-hard resin-type pastes. To remove filling materials apical to a curvature, small-sized hand files should be used first to negotiate this region of the canal. Once a glide path has been created, then an appropriately sized precurved file may be attached to a specially designed adapter (File Adapter 11, SybronEndo) that mounts on, and is activated by, the ultrasonic handpiece.

Heat for Paste Removal

Certain resin pastes soften with heat. Heat carriers can be selected if this modality of removal is chosen.

Rotary Instruments for Paste Removal

Stainless steel 0.02 tapered hand files may be used to negotiate paste-filled root canals. These files are used to create a pilot hole for safe-ended NiTi rotary instruments which do not cut at the tip to follow and effectively remove the material coronally. At times helpful are end-cutting NiTi rotary instruments to penetrate paste. These instruments are more active apically and hence more prone to preparation error should they be used too aggressively.

Solvents and Hand Files for Paste Removal

Reagents like Endosolv “R” and Endosolv “E” (Endoco; Memphis, TN) may be helpful in chemically softening hard paste.¹⁹¹ The “R” designates the solution of choice for the removal of resin-based pastes and the “E” is the solution for the softening of eugenol-based pastes (Figure 17). These solutions may be placed between appointments against a paste-type material via paper points or cotton pellets to promote subsequent removal.

Micro-Debriders for Paste Removal

After removing the paste filling and shaping the root canal, it should be remembered that residual paste will still be contained within the irregularities of the root

Figure 17 Endosolv “E” is a solvent for eugenol-based pastes whereas Endosolv “R” is for resin-based pastes.

canal system. Micro-Debriders (Dentsply International) are specially designed instruments to remove residual paste materials from a root canal system. These stainless steel instruments enhance vision due to their offset handles, have tip diameters of 0.2 and 0.3 mm, and are available in 0.02 tapers with 16 mm of efficient Hedström-type cutting blades.

Solvents and Paper Points for Paste Removal

Following paste removal, chemical dissolution with solvents in conjunction with paper point wicking is a possibility to further remove material from the irregularities of the root canal system.

Post Removal

It is common to encounter endodontically treated teeth containing posts. When endodontic treatment fails to achieve healing, the need may arise to remove a post in order to gain access and allow retreatment. In other instances, the endodontic treatment may be judged successful, but restorative needs require the removal of an existing post to improve the design, mechanics, or esthetics of a new restoration. Over time, many techniques have been advocated for the removal of posts and other large intracanal obstructions.^{37,188,195}

FACTORS INFLUENCING POST REMOVAL

There are many factors that influence post removal such as operator judgment, training, experience, and choice of technologies and techniques.^{148,184} Furthermore, clinicians should have knowledge of the anatomy of the teeth being treated and be familiar with the typical range of variation associated with each tooth type.¹⁹⁶ As an example, it is helpful to know tooth morphology, including the length, circumferential dimension, and curvature of any given root, including, if present, the depth of an external concavity. This information is best appreciated by obtaining three well-angulated preoperative radiographs. These radiographs also assist the clinician in visualizing the length, diameter, and direction of the post and aid in determining if it extends coronally into the pulp chamber.¹⁷²

Other factors influencing post removal are the post type and cementing agent.^{197,198} Posts can be catalogued into parallel versus tapered shapes, active versus non-active, and metallic versus non-metallic materials.^{199,200} Posts retained with the classic cements such as zinc phosphate can generally be removed more predictably; however, posts bonded into the root canal

space with composite resins or glass ionomers may be more difficult to remove.¹⁷³ Additional factors that impact post removal are the available inter-occlusal space, existing restoration, and whether the most coronal aspect of the post is supracrestal or subcrestal. In general, post removal becomes more challenging moving from anterior to posterior teeth. The difficulty in removing a post substantially increases in furcated teeth containing multiple posts joined coronally with single or multiple interlocking keyways.

When evaluating a tooth for post removal, the clinician must weigh risks versus benefits before proceeding with this procedure.³² As an example, the relative radiodensity between titanium or a titanium alloy post can appear very similar, or even identical, to gutta-percha when viewed radiographically. As such, when considering non-surgical retreatment, clinicians need to be familiar with the radiographic characteristics of these metallic and non-metallic posts.²⁰¹ A root can be structurally weakened, perforated or fractured during any phase of retreatment ranging from radicular disassembly to subsequent shaping and filling procedures. In some instances, it may be wise to consider a surgical approach to resolve an endodontic failure.

TECHNIQUES FOR ACCESS FOR POST REMOVAL

Successful post removal requires eliminating all circumferential restorative materials from the pulp chamber. Once straight-line access into the pulp chamber is established, the restorative materials circumferential to the post are removed. Surgical length burs are useful to section and eliminate cores because their added lengths improve vision during re-entry into the pulp chamber. Removing the greatest bulk of restorative materials that commonly surround various post head configurations will expose the coronal aspect of a post.

Ultrasonic energy in conjunction with appropriate ultrasonic instruments provides important advantages when performing access refinement procedures. Advantageously, small-sized ultrasonic instruments afford continuous and improved vision into the field of operation (see Figure 10). On the contrary, a rotating bur in a dental handpiece is oftentimes difficult to see because even a small handpiece head may block the line of sight. Strategically, contra-angled, parallel-sided, and abrasively coated stainless steel ultrasonic instruments enhance access, vision, and cutting precision when progressively removing various materials. In general, ultrasonic instruments are used at the lowest power settings that will efficiently accomplish the

clinical task. Thinner and more parallel-sided ultrasonic instruments are designed to work in smaller spaces, such as between a post and an axial wall. Importantly, a parallel-sided ultrasonic instrument may be safely used below the orifice and lateral to a post, especially in an irregularly shaped canal.¹⁵⁶

If space is restrictive within the field of operation, then an appropriately sized titanium ultrasonic instrument may be selected and is generally used at a lower intensity. These instruments provide the clinician with thinner diameters and longer lengths as compared to abrasively coated or non-coated stainless steel ultrasonic instruments (see Figure 10C). Ultrasonic instruments are best used with a light brush-cutting motion and on the peripheral edge of a sectioned core to chip, break up, and “sand away” materials such as cement, composite, or amalgam. Eliminating these materials from the pulp chamber serves to undermine the retention of a post. To optimize vision, virtually all non-surgical ultrasonic procedures are performed under air stream. When an abrasively coated ultrasonic instrument removes dentin or a restorative material, the by-product of this ultrasonic action is dust. The dental assistant may use compressed air to clear the field of vision by utilizing the Stropko three-way adapter with the White Mac tip (Ultradent, South Jordan, UT) to direct and control a continuous stream of air into the field. Debris is blown away and, importantly, allows the clinician to maintain visual contact with the energized tip of the instrument.¹⁴⁸

Water port technology in non-surgical ultrasonic instruments is not recommended for four important reasons: (1) water flowing through an ultrasonic instrument dampens movement and decreases tip performance; (2) small diameter ultrasonic instruments are weakened and more predisposed to expensive breakage when they are machined for internal water flow; (3) there is an undesirable aerosol effect regardless of where the water port is positioned on an ultrasonic instrument; (4) and most important, water in combination with dentinal dust, creates mud, reduces vision, and increases the potential for iatrogenic outcomes. In summary, clinical experience supports the strategy that the vast majority of all non-surgical ultrasonic procedures may be performed under air stream and at the lowest power setting that will safely accomplish the clinical task. However, if ultrasonic procedures are performed at higher energy levels, for longer periods of time, and against larger, conductive objects, such as a metal post, then it is critically essential that the dental assistant use a triplex syringe with an intermittent water spray to reduce heat buildup and heat transfer to the periodontal tissues.²⁰² Fortunately, heat

does not conduct well through dentin and is further rapidly dissipated due to the moisture content in the attachment apparatus.^{203–205} However, later in the section titled “Thermal Injury with the Use of Ultrasonics,” the sequelae of inappropriate heat transfer to the attachment and bone through vibratory energy to metallic posts will be discussed.²⁰²

TECHNIQUES FOR POST REMOVAL

Once straight-line access into the pulp chamber has been accomplished, all core materials eliminated, and the post has been fully exposed, then a variety of techniques have been advocated to finally remove a post.^{174,195,206,207} No single method always produces a successful result. It is important to be familiar with a variety of techniques to maximize success.

Rotosonic Vibration for Post Removal

Rotosonics is a method to potentially loosen and remove a fully exposed post. The Regular Tip Roto-Pro bur (Ellman International, Hewlett, NY) is a high-speed, friction grip bur whose six sides utilize six edges which when rotated in one revolution produce six vibrations per revolution. When the instrument is rotated at 200,000 rpm, it produces 1.2 million vibrations per minute or 20,000 vibrations per second. This instrument provides an inexpensive method to remove certain posts especially those secured with zinc phosphate cement. The bur is kept in intimate contact with the obstruction and is generally moved CCW around the post.

Ultrasonic Energy for Post Removal

The active distal end of an appropriately designed ultrasonic instrument may be kept in intimate contact with the post to maximize energy transfer and promote cement/bond failure (Figure 18A). The selected ultrasonic instrument is energized and moved around the post circumferentially and up and down along its exposed length.²⁰⁸ Again, it must be stressed that the by-product of ultrasonic energy is heat (see Figure 18B). When performing ultrasonic procedures for extended periods of time in cases of larger conductive metal posts, the operating field should be cooled with water to decrease heat buildup and the potential for dangerous heat transfer to the periodontal tissues (see Figure 18C).^{202–204} Experience suggests that after removing all circumferential restorative materials, the majority of posts can be safely and successfully removed within approximately 10 minutes (see Figure 18D).^{197,209} Certain posts resist removal even after ultrasonic efforts using the

Figure 18 **A**, The ProUltra ENDO-1 is activated and used to vibrate against all aspects of the exposed post. **B**, Illustration of how ultrasonic procedures generate heat, particularly when removing larger, more conductive metal posts. **C**, A graphic representation demonstrating the importance of using an external water source to reduce temperature and eliminate heat transfer. **D**, Following post removal, an ultrasonic instrument loosens intracanal cement and a White Mac Tip collimates air and blows out debris.

“10-Minute Rule.” Caution is important for safe and efficient alternative strategy to loosen these posts.²¹⁰

MECHANICAL DEVICES FOR POST REMOVAL

Many of the available mechanical devices, such as the Masserann kit (Micromega) and the Post Puller (Braseler), have had limited success because they may frequently require excessive removal of tooth structure, which predisposes to ledges, perforations, or root fractures. The Gonon post extractor (EFDM-Pneumat, Bourge, France) represents a definite improvement over the Masserann and the Post Puller devices in that it is less invasive and requires less removal of tooth structure.^{37,195} The PRS kit (Sybron-Endo) (Figure 19) was designed to mechanically engage and remove different kinds of post types or other intracanal obstructions whose cross-sectional diameters are 0.6 mm or greater.¹⁴⁸ The PRS kit con-

tains extracting pliers, a transmetal bur, five trephines of varying internal diameters, five corresponding

Figure 19 The Post Removal System is a kit designed to mechanically engage and remove many different types of posts.

tubular taps whose internal diameters range from 0.6 to 1.6 mm, a torque bar, tube spacers, and a selection of rubber cushions. The preparatory procedures before utilizing the PRS require straight-line access

and complete circumferential visualization of the post within the pulp chamber.

A transmetal bur is used to round-off or taper the coronal most aspect of the post (Figure 20A).

Figure 20 **A**, Graphic representation depicting a transmetal bur efficiently doming the post head. **B**, The no. 3 trephine has precisely machined down the coronal 3 mm of the post. **C**, The tubular tap is turned counterclockwise to form threads, draw down, and strongly engage the post. **D**, Once the tap is securely engaged to the post, then the rubber bumper is seated against the occlusal surface to protect the tooth. **E**, Graphic representation of the mounted and activated Post Removal System extracting pliers. Note the energized ProUltra ENDO-1 may advantageously be placed against the post-engaged tap to synergistically facilitate the removal effort. **F**, Completed post removal.

“Doming” the head of the post will serve to effectively guide subsequent instruments over the post. A chelator, such as RC Prep, Glyde or ProLube, may be placed on the head of the post to act as a lubricant to facilitate the machining process. In order to ensure circumferential milling, the largest trephine that will just engage the post is selected. The latch-type trephines should rotate at approximately 15,000 rpm in a clockwise (CW) direction, in a slowspeed, high torque handpiece. The trephine is used with a “peck” drilling motion to maintain revolutions per minute and to keep the head of the post cooler so it does not work harden and become more difficult to machine. The trephine is used to prepare down a 2 to 3 mm length of the most coronal aspect of the exposed post (see Figure 20B). If the chosen trephine fits loosely, then a sequentially smaller size trephine is selected to ensure proper circumferential milling. In some instances, the configuration of the coronal aspect of the post, such as a cast post/core, dictates the use of a transmetal bur or diamond to grind down the head of the post to create a relatively round cylinder. The trephine can then machine a precisely round cross-sectional diameter on the post.

In general, trephines used for machining the post dictate the subsequent selection of a correspondingly sized tubular tap. An appropriately sized protective rubber cushion is selected and inserted over the distal end of the tap. The cushion serves to act as a bumper, evenly distributing the loads to protect the tooth during the removal procedure. The tubular tap is pushed against the head of the milled down post and is manually turned CCW to form threads (see Figure 20C). Firm apical pressure and small quarter-turn CCW motions will generally draw down and securely engage the tap to the post. The tap can be screwed over the post as little as 1 mm or, more optimally, up to a maximum of 3 mm. Caution should be exercised so that the tap is not drawn down too far over the post because its maximum internal depth is 4 mm. If the tap bottoms out against the post head, it can predispose to stripping the threads, breaking the wall of the tap, or shearing off the post inside the lumen of the tap. When the tubular tap has snugly engaged the post, the protective rubber cushion is pushed down onto the occlusal surface of the tooth (see Figure 20D).

The post removal pliers are then selected and the extracting jaws are mounted onto the tubular tap. The instrument is held securely with one hand, while the fingers of the other hand begin opening the jaws by turning the screw knob CW. As the jaws slowly begin to open, increasing pressure will be noted

on the screw knob. The clinician should repeatedly verify that the compressing rubber cushion is properly protecting the tooth. Furthermore, when utilizing this removal method, the clinician should visually confirm the post is being safely withdrawn along the long axis of the root canal. If turning the screw knob becomes increasingly difficult, the clinician should either hesitate a few seconds before continuing and/or use the indirect ultrasonic technique to vibrate on the post-engaged tubular tap (see Figure 20E). In combination, the PRS and indirect ultrasonic techniques enhance post removal, allow the screw knob to be turned further, and work synergistically.²¹⁰ Ultimately, the PRS provides clinicians with an alternative post removal method that can be safely employed when ultrasonic techniques are unsuccessful (see Figure 20F).

Actively engaged threaded posts sometimes require removal. The PRS is useful in such situations because each tubular tap turns in a CCW rotation. In instances where threaded posts are encountered, the use of the extracting pliers is contra-indicated because of the active engagement. Typically, the clinician backs the post out of the canal using a CCW rotation with finger pressure. If the post is strongly anchored, an ultrasonic instrument may be used to vibrate on the tap and, if necessary, the torque bar may be inserted into the handle port to increase leverage (Figure 21).

Fractured Instrument Removal

Every clinician who has performed endodontics has experienced a variety of outcomes ranging from a case well done to a procedural accident such as the separation of an instrument. During root canal preparation procedures, the risk of instrument breakage or fracture exists. When instrument breakage occurs, it provokes considerable stress to the clinician.²¹¹ In fact, the fractured instrument dilemma has caused such emotional distress that this event is frequently referred to as a “separated” or “disarticulated” file.

Many clinicians associate a “broken instrument” with a separated file, but the term could also apply to a sectioned silver point, a segment of a Lentulo instrument, a GG drill, a portion of a carrier-based obturator, or any other device obstructing the canal.^{212,213} With the advent of rotary NiTi files, there has been an increase in the occurrence of fractured instruments.^{214,215} The prognosis of leaving, versus removing broken instruments from the canal have been discussed in the literature.^{39,216} Over the years,

Figure 21 **A**, Radiograph of a mandibular right first molar with a crown, a screw post, and inadequate endodontic treatment. **B**, Clinical photograph demonstrates a tap forming threads and being drawn down to tightly engage the post. **C**, Postoperative radiograph of completed retreatment.

a variety of approaches for managing broken instruments have been presented.^{42,188,217}

Today, separated instruments can usually be removed due to technological advancements in vision, ultrasonic instrumentation, and microtube delivery methods.^{148,218} Specifically, the increasing integration of the dental operating microscope into clinical practice allows clinicians to visualize the coronal portion of most fractured instruments.²¹⁹ In combination, the microscope and ultrasonic instrumentation have created “microsonic” strategies which have greatly improved the potential and safety of removing broken instruments.^{148,220,221}

FACTORS INFLUENCING FRACTURED INSTRUMENT REMOVAL

The factors influencing non-surgical access and removal of a fractured instrument include the dia-

meter, length, and position of the obstruction within a canal.^{184,222} Additionally, the chosen approach to safely remove a broken instrument is guided by anatomy, including the diameter, length, and curvature of the canal. Limiting factors include the circumferential dimensions and thickness of dentin and the depth of an external concavity.^{223,224} In most instances, if one-third of the overall length of an obstruction can be exposed, it can usually be removed. Instruments that lie in the straight, more coronal portions of the canal can be removed more readily than separated instruments that lie partially around canal curvatures. In these cases, an attempt to establish straight-line access to their most coronal extents may prove successful.^{148,221,225} If the fractured instrument segment is apical to the curvature of a canal and access without compromising the structural integrity of the root cannot be accomplished, then removal is not feasible, and in the

presence of signs or symptoms, surgery or an extraction may be required.

The type of material comprising an obstruction is another important factor to be considered. As an example, stainless steel files tend to be easier to remove because, in general, they do not disintegrate during the removal process. Separated nickel-titanium instruments may break again, albeit deeper within the canal, during ultrasonic efforts. This may be due to heat buildup.¹⁶¹ Perhaps, the most important factors central to successful instrument removal are knowledge, training, and competency in selecting the best contemporary technologies and techniques. Importantly, no one removal method will always produce the desired result. As such, successful removal often-times requires patience, perseverance, and creativity. However, no removal method should be attempted until access has been made to the head of an intracanal obstruction.

CORONAL AND RADICULAR ACCESS FOR INSTRUMENT REMOVAL

Prior to the initiation of efforts to remove a fractured instrument, the clinician should thoughtfully observe different horizontally angulated preoperative radiographs. Coronal access is the first step in the removal of a fragment. Surgical length burs are selected to create straight-line access to all canal orifices. Flaring the canal wall alongside the instrument aids in efforts to provide space for subsequent treatment steps.

Radicular access is the next step in the attempted removal of a broken instrument. However, before commencing with radicular access, some basic morphological data must guide one's clinical actions. With exceptions, the vast majority of teeth range from 19 to 25 mm in overall length. Most clinical crowns are about 10 mm and most roots range from 9 to 15 mm in length. If the root is divided into coronal, middle, and apical one-thirds, then each third is between 3 and 5 mm in length. An important concept in retreatment strategy is how wide a canal can be optimally flared without creating a problem. The answer is to review the dimensions of a typical preparation in a longer, thinner, and more curved root form.^{152,226} An ISO size 20 apical preparation in conjunction with 1/2 mm increment stepback technique leads to a taper of 10%. In this specific example, the diameter of the canal 4 mm coronal to the apical end point of the preparation would be equivalent to a 60

file or 0.60 mm. This analogy is useful and can serve to safely guide the limits of preparation in the apical one-third and the coronal two-thirds of a canal when there is a separated instrument.²²⁷ The majority of broken files separate toward their terminal extents at between D₃, D₄, or D₅.^{228,229} Files most frequently break in the apical 3 to 5 mm because this is the region where a canal usually has its smallest diameter and exhibits its greatest degree of curvature or propensity to divide.²³⁰ Even if a file fracture occurs at the working length, the position of the cross-section of the instrument typically lies at the junction of the middle and apical one-thirds. Fortunately, straight-line radicular access can generally be created through the coronal two-thirds of a canal to the head of a broken instrument.^{148,225}

A number of different techniques may be employed to flare the canal coronal to an intracanal obstruction. A predictable way to create safe radicular access is to initially use hand files, small to large, coronal to the obstruction. Hand files create sufficient space to accommodate NiTi rotary files or, preferably, GG drills (Dentsply International). GG sizes 1 to 4 are most typically employed in the coronal one-third of root canals and have maximum diameters of 0.50, 0.70, 0.90, and 1.10 mm, respectively. In many cases, GGs are used to create radicular access and a uniform tapering funnel to the obstruction. GGs are more safely rotated at speeds of about 750 rpm and, importantly, are safely used with a "brushing motion" to create a tapered shape and maximize visibility.²²⁵ Increasingly, larger GGs are uniformly stepped out of the canal to create a smooth flowing funnel that is largest at the orifice and narrowest at the obstruction. To avoid strip perforations, GG drills should be limited to the straightway portions of the canal. However, in the case of a fractured instrument, a GG-1 or GG-2 can be carried to the depth of the head of a separated instrument. The GGs are used cautiously approximating the obstruction with attention to brush-cutting out of the canal and away from the furcal direction. Deliberately relocating the coronal one-third of a canal away from the furcation maximizes remaining dentin, produces a more centered preparation, and improves straight-line radicular access.²²⁵ The GG-3 is carried short of the level where the GG-2 was used and, in furcated teeth, the GG-4 is confined to a depth of no more than one length of the cutting portion below the orifice. Ideally, radicular access would be performed in a way that the canal is pre-enlarged and shaped to the same diameter than it would

otherwise be prepared if there was no broken instrument obstructing the canal.

CREATING A STAGING PLATFORM

When the canal has been shaped, microsonic techniques are usually the first step selected to remove a broken file segment. When an ultrasonic instrument is introduced into a pre-enlarged canal, often its activated tip does not have enough space, lateral to the broken file segment, for the amplitude of vibration to effectively trephine. If more lateral space is required, then the cutting head of a GG can be modified and used to create a circumferential “staging platform”.^{148,161} The staging platform is made by selecting a GG drill whose maximum cross-sectional diameter is slightly larger than the visualized instrument. The cutting portion of the GG drill is altered by cutting it perpendicular to its long axis at its maximum cross-sectional diameter (Figure 22). This modified GG drill is carried into the pre-enlarged canal, rotated at a reduced speed of approximately 300 rpm, and directed apically until it lightly contacts the most coronal aspect of the obstruction. This clinical step creates a small platform that facilitates the introduction of an ultrasonic instrument. If properly performed, straight-line coronal and radicular access, in conjunction with magnification and lighting, should enable the clinician to fully visualize the coronal most aspect of a broken instrument. To facilitate excellent vision to the intra-radicular obstruction, the canal should be thoroughly irrigated and thoroughly dried prior to beginning ultrasonic procedures.

TECHNIQUES FOR REMOVING FRACTURED INSTRUMENTS

A number of devices, technologies, and techniques have been reported to remove an intracanal obstruction such as a separated instrument.^{231–233} However, many of the removal techniques described in the early literature did not make use of the operating microscope. Today, most fractured instruments can be retrieved if straight-line access can be safely made to the coronal most extent of a broken instrument.^{148,221,225} The most predictable and safe removal schemes utilize a microscope in conjunction with optimally designed ultrasonic instruments and/or a microtube method.^{161,225,234}

ULTRASONIC TECHNIQUES FOR REMOVING FRACTURED INSTRUMENTS

Prior to performing any radicular removal techniques, it is wise to place cotton pellets into other canal orifices, if present, to prevent the nuisance re-entry of the fragment into another canal. The first option to remove a broken instrument is to utilize piezoelectric ultrasonic technology and specific ultrasonic instruments. An ultrasonic generator should provide a broad range of power, precise adjustment within the lower settings, and electrical feedback to regulate amplitude and safe tip movement. Ideally, ultrasonic instruments should have a contra-angled design to provide access into all regions of the mouth, parallel-sided walls to create a line of sight between the instrument and the tapered canal, and non-aggressive coatings, such as zirconium nitride, to precisely remove dentin during trephination. Furthermore, an ultrasonic instrument of appropriate length should be chosen that allows contact with the

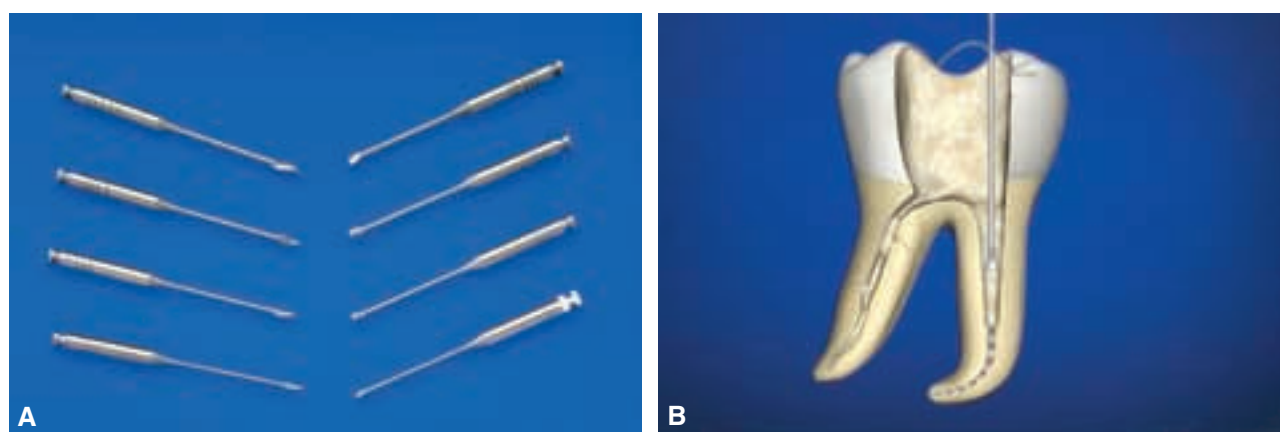

Figure 22 **A**, Selected Gates Glidden drills (left) and their subsequent modification (right). **B**, Graphic representation of a staging platform.

instrument fragment and affords an unobstructed line of sight into the canal. The tip of this ultrasonic instrument is placed in direct contact with the obstruction and is activated within the lower power settings (Figure 23A). One should choose the lowest power setting that will efficiently and safely accomplish the clinical task. All ultrasonic preparation below the orifice is conducted with a compressed air stream so visualization of the energized tip against the broken instrument is possible. To maintain vision, the dental assistant may utilize a Stropko three-way adapter with an appropriate luer lock tip to collimate and direct the continuous stream of air and water to remove dentinal dust. Microsonic techniques during removal of fractured instruments do not generate sufficient heat to become harmful to the attachment apparatus if they are used correctly and are cooled using water and air.

The selected ultrasonic instrument is moved lightly, in a CCW direction, removing dentin around the

obstruction. An exception is made when removing a file that has a left-handed thread in which case the direction would be CW. This ultrasonic action trephines, precisely prepares dentin, and thus exposes the coronal millimeters of the obstruction (see Figure 23B). Often, during ultrasonic use, the obstruction begins to loosen, unwind, and then spin around its long axis. Gently wedging the energized tip between the tapered file and canal wall may cause the broken instrument to suddenly move in the coronal direction.

In the circumstance where a separated file tip is located further apically in a slender root morphology, ultrasonic procedures are then restricted to a smaller space. A longer length and smaller diameter, abrasively coated, ultrasonic instrument may be useful in promoting safe retrieval. In longer roots, or when space is even more restrictive, an appropriately sized titanium instrument may be chosen. Titanium instruments provide a less aggressive cutting action when trephining

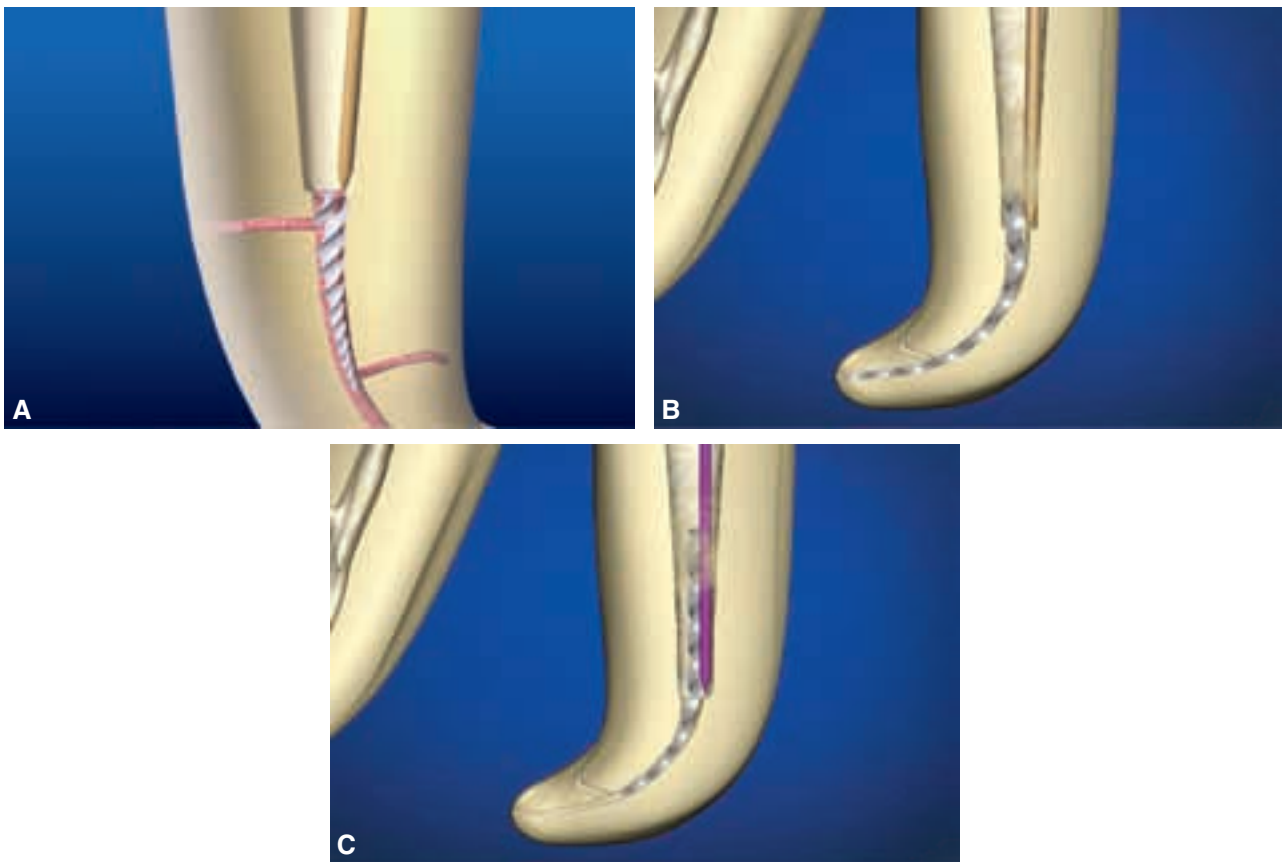

Figure 23 **A**, Illustration of the importance of coronal and radicular access, the staging platform, and the ultrasonic instrument just lateral to the fractured file. **B**, The ultrasonic instrument maintains contact with the fractured file, precisely removes dentin, and progressively exposes the coronal aspect of the fractured file. **C**, Longer length and smaller diameter titanium instrument is selected to conserve dentin and successfully displace the fractured instrument.

deeper within a canal (see Figure 23C). At times, weighing risk versus benefit, ultrasonic trephining procedures may have to be aborted. In these instances, manual use of the sharp cutting edges of a hypodermic needle may allow further exposure of the head of a file fragment.²³⁵ Exposing 2 to 3 mm of the coronal most aspect of an obstruction, or about one-third of its overall length, will generally produce the desired result. On occasion, despite sufficient coronal and radicular access, exposure of the separated instrument and ultrasonic trephining procedures, it may be impossible to loosen and extract the instrument from the canal. Lack of vision or anatomical restrictions may render further efforts unsafe. In this instance, small hand files may be used with an aqueous or viscous chelator, to partially or completely bypass or remove an instrument fragment. Even when this tedious removal method is unsuccessful, space can be created along a portion of the overall length of a retained instrument. To maximize efficiency and success, the handle from a stainless

steel hand file can be removed intentionally and the shaft of the instrument inserted into a special device, for example, a File Adapter. The File Adapter attaches to the ultrasonic handpiece and its chuck will retain a 0.02 tapered hand file. Small, stainless steel hand files can be precurved, and if indicated, inserted into available space, and used at low power in an ultrasonic effort to remove a broken instrument. This technique may be useful when the root is thin or a portion of the file lies apical to a canal curvature.²³⁶ Another clinical challenge is encountered when trying to remove a broken NiTi file that lies partially around a canal curvature. In these situations, the mechanical reality is that the head of a broken NiTi file will always lie against the outer wall even after optimal ultrasonic trephining procedures. Even when loose, the angle formed between the coronally flared canal and the head of the broken instrument oftentimes precludes its removal. This situation is best managed using a micro-tube removal method (Figure 24).^{148,225}

Figure 24 **A**, Preoperative radiograph of a mandibular left first molar with a fractured instrument in the apical one-third of the mesial root. **B**, After refining access and completing ultrasonic procedures, photograph shows the head of the fractured NiTi file leaning against the outer canal wall. **C**, Radiograph confirms straight-line access and removal of the separated file. **D**, Post-treatment radiograph demonstrates a furcal canal and that the distal system bifurcates apically.

REMOVAL OF FRACTURED INSTRUMENTS USING A MICROTUBE SYSTEM

As previously mentioned in the section concerning “Silver Point Removal,” there are several microtube removal methods designed to mechanically engage an intracanal obstruction. The iRS provides a conservative advantage in the retrieval of broken instruments lodged deep within the root canal space. The iRS is composed of variously sized microtubes and insert wedges that are scaled to fit and work deep within the root canal space (see Figure 15A). The iRS is indicated when ultrasonic efforts prove to be unsuccessful and may be used to remove broken instruments that are lodged in straight portions of the root or partially inside a canal curvature. The black instrument has an outside diameter of 1.00 mm and is designed to work in the coronal one-third of larger canals, whereas the red and yellow instruments have outside diameters of 0.80 and 0.60 mm, respectively, and may be placed deeper into more narrow

canals. Each complete instrument is comprised of a color coordinated microtube and screw wedge (see Figure 15B). Each microtube has a small-sized plastic handle to enhance vision during placement, a side window to improve mechanics, and a 45° beveled end to “scoop up” the coronal end of a broken instrument. Each screw wedge has a knurled metal handle, a left-handed screw mechanism proximally, and a solid cylinder that transitions into 0.02 tapered K-type file blades toward its distal end to facilitate engaging an obstruction.

As has been emphasized for any removal technique, straight-line coronal and radicular access is required to expose and subsequently visualize the coronal most end of the broken instrument. However, ultrasonic instruments can only circumferentially trephine dentin and expose the portion of the obstruction that lies in the straight portion of a canal. Therefore, in order to create the potential for instrument retrieval, the goal is to expose 2 to 3 mm, or about one-third of the total length, of a separated instrument (Figure 25A).

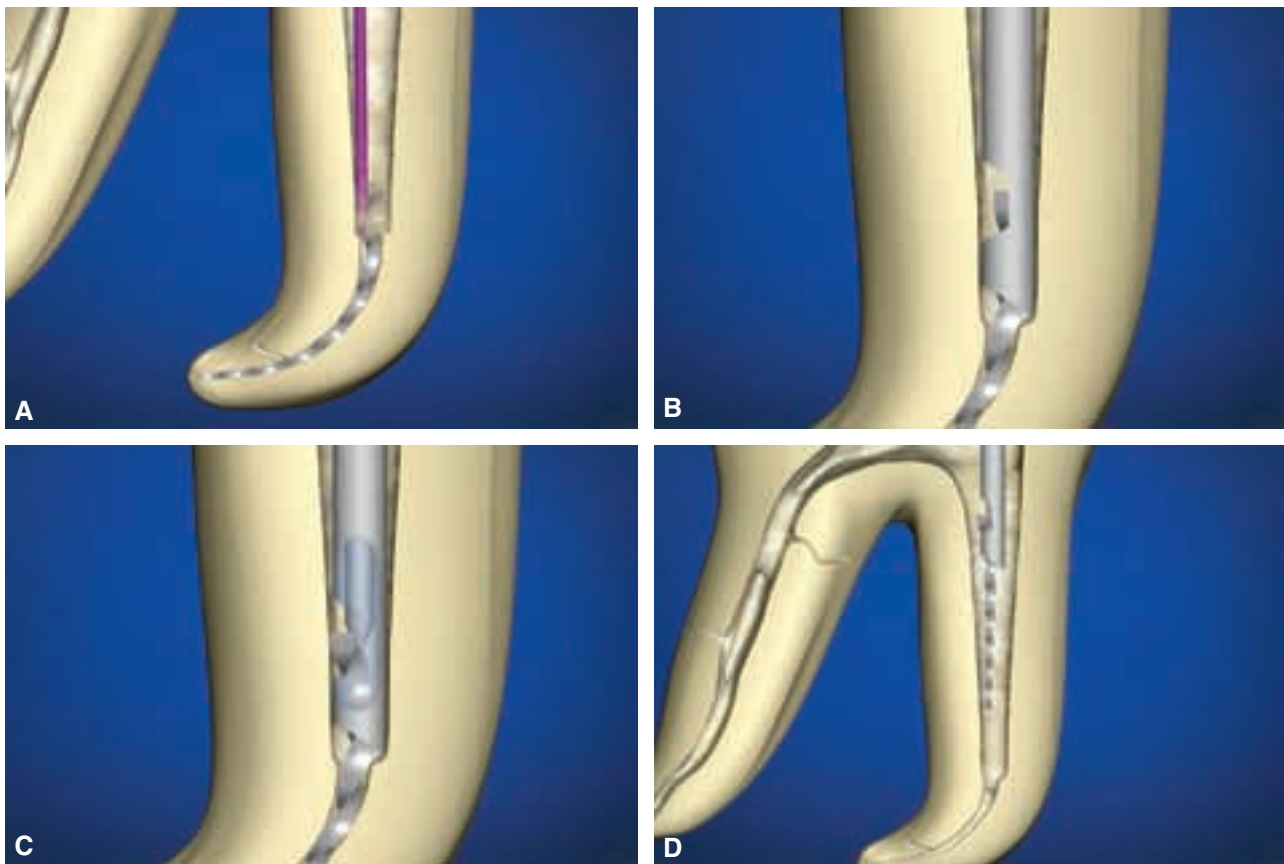

Figure 25 **A**, Graphic representation demonstrates a titanium ProUltra ENDO-6 tip trephining deep around the coronal aspect of the fractured file. **B**, When ultrasonic procedures prove ineffective, the beveled end of an Instrument Removal System (iRS) microtube is designed to “scoop up” the head of a fractured file. **C**, Illustration shows the introduction of the screw wedge which is rotated counterclockwise to engage and potentially displace the head of the file out the side window. **D**, The iRS can strongly grip, unwind, and remove a fractured instrument.

An iRS microtube is selected that can passively move through the pre-enlarged canal and over the exposed broken instrument. As previously mentioned, in a curved canal, the head of a fractured file will usually lay against the outer dentin wall. In these instances, the microtube is inserted into the canal with the long part of its beveled end oriented to the outer wall of the canal to scoop up the head of the broken instrument and guide it into the microtube (see Figure 25B). Once the microtube has been positioned, the same color-coded screw wedge is inserted through the microtube's length until it contacts the obstruction. The obstruction is engaged by gently turning the screw wedge handle CCW. A few degrees of rotation will serve to tighten, wedge, and, often-times, displace the head of the obstruction through the microtube window (see Figure 25C). Several color-coded screw wedges may be tried to improve engagement and successful removal. When engaged, the obstruction can be potentially unwound and removed by rotating the microtube and screw wedge assembly CCW (see Figure 25D). The removal direction of rotation, in the instance of a broken file, is generally CCW, but ultimately should be appropriate to the thread design of the obstruction. If difficulty is encountered when rotating the microtube and screw wedge assembly CCW, then proceed with a limited

CW rotation of 3° to 5° that will promote continued engagement, followed by turning the assembly CCW as feasible. This repeated reciprocating handle motion will serve to loosen and facilitate the removal process. Placing an activated ultrasonic instrument on the engaged assembly is another adjunct that will possibly facilitate removal. If a microtube cannot be placed over a broken instrument such that the head of the obstruction lies within the side window, then, in these instances, the microtube's beveled end may be reduced or eliminated to achieve better mechanics. A clinical case utilizing the iRS option is shown in Figure 26.

The best way to avoid a fractured file is prevention. Adhering to proven concepts and utilizing safe techniques during root canal preparation procedures will eliminate most instrument fractures.^{148,227} Prevention may also be facilitated by using negotiating and shaping instruments as single-use items. Simply discarding all instruments after the completion of each endodontic case will reduce fractures, lost clinical time, and stress for clinician and patient. However, on occasion, an instrument may break and the treating dentist must decide on the best treatment strategy.¹⁵⁵ Weighing risk versus benefit, certain broken file segments may not be retrievable. In these cases, and in the presence of clinical symptoms and/or radiographic pathosis, surgery or extraction may be the best treatment option.

Figure 26 **A**, Preoperative radiograph of a maxillary cuspid with an instrument fractured deep into the apical one-third of the canal. **B**, Working radiograph shows that the 21-gauge Instrument Removal System has successfully engaged and partially elevated the deeply positioned file segment. **C**, Postoperative radiograph.

Blocks, Ledges, and Apical Transportations

It is important to understand the biological and mechanical objectives for shaping canals and cleaning root canal systems.^{227,237} Failure to adhere to these objectives predisposes to needless complications such as blocks, ledges, apical transportations, and, potentially, perforations. Regrettably, these events are clinically encountered. Perhaps, the most overlooked and unstated method to negotiate a blocked canal, bypass the ledge, or manage transportation is determination, perseverance, and patience.

TECHNIQUES FOR MANAGING BLOCKED CANALS

When encountering a blocked canal, the canal should not be dry but irrigated with NaOCl as a lubricant. Well-angulated radiographs are necessary to determine the root curvature and apical pathosis. The clinician should appreciate that disease flow in a root canal system occurs in a coronal to apical direction. Consequently, lesions of endodontic origin form adjacent to portals of exit from the canal system onto the root surface. As such, and if applicable, files are directed toward apical lesions.

Generally, when managing blocked and/or ledged canals, the shortest file to reach working length should be chosen. Shorter instruments provide more stiffness and move the clinician's fingers closer to the tip of the instrument, resulting in greater tactile control. Appreciate that canals are frequently more curved than the roots that hold them. An ISO (0.02) size 10 file is precurved to simulate the expected curvature of the canal, and a marked rubber stop is oriented to match the file curvature. An attempt is then made to gently slide the file to length. If unsuccessful, the canal should be pre-enlarged above the stopping point to facilitate moving it to length. If an obstruction is encountered, the precurved file is used in an apically directed, gentle pecking action. During this procedure, the rubber stop should be continuously re-oriented which will redirect the apical aspect of the precurved file in the attempt to negotiate the remainder of the canal.

A small-sized file should be used with very short amplitude, light pecking strokes in efforts to negotiate the canal terminus. Short amplitudes of this motion ensure safety, carry irrigant deeper, and increase the possibility of canal negotiation of a file's handle whose tip is engaged, should never be excessively rotated. The torsional loads over length will predispose the instrument to separation. If the apical extent of the

file "sticks" or engages, then the handle motion should be a minimal back and forth reciprocating movement. If a #10 file begins to move apically, it may be useful to move to a smaller instrument whose tip diameter is 0.08 or 0.06 mm. A working radiograph or frequently removing the file helps to verify if its curve is following the expected root canal morphology. Depending on the severity of the blockage, these efforts may allow the clinician to passively reach the foramen and establish patency.

If no progress is made after diligent efforts over a time frame of approximately 2 to 3 minutes, then the NaOCl is removed from the root canal system and replaced with a viscous chelator, such as RC Prep, Glyde, or ProLube. The same techniques as described above are then used, recognizing that it takes a few minutes for the chelator to penetrate deep into the canal and soften superficial dentin. If a #10 file does not negotiate through the debris, then a smaller instrument such as a #08 file may be appropriate.

When the instrument reaches working length, its tip is gently moved to and minutely through the foramen. Pushing the instrument to length carries more chelator deeper into the canal, keeps debris into suspension, and lubricates the file so it will more readily reach the desired length. The clinician should continue with short amplitude push/pull strokes and move the file gently and subtly over a range of 1 to 2 mm. When the instrument moves freely, slightly longer 2 to 3mm amplitude strokes are taken. Finally, strokes of 3 to 4 mm are used until the file can be moved to the terminus with ease and predictability. These steps require time and patience.

Occasionally, clinical situations arise where the aforementioned techniques have been carefully attempted, but either the file is not progressing apically or is not maintaining the true pathway of the canal. Corrective steps require a thoughtful treatment decision. If the tooth is asymptomatic and symptoms are not masked by a pharmaceutical, and if the periodontium is healthy and there are no lesions of endodontic origin, then the preparation may be finished to the level of the obstruction and obturated. The patient must be informed of this less than ideal outcome, the importance of monitoring the situation with follow-up appointments, and the possible need for future surgery.

If a blocked canal is not negotiable and if clinical symptoms, periodontal breakdown, and/or a lesion of endodontic origin are present, then the root canal system should be treated and obturated as efficiently as possible, for at times postoperative radiographs may demonstrate that the hydraulics of a thermoplastic

obturation has moved material into untreated areas of the root canal. The patient needs to be advised of the importance of follow-up visits and that future treatment options may include surgery, replantation, or extraction.

TECHNIQUES FOR MANAGING CANAL LEDGES

An internal transportation of the canal is termed a “ledge” and is a result of over-enlarging a curved canal and working short of full canal length. Many ledges may successfully be bypassed using the techniques described for blocks.¹⁴⁸ Once the tip of an instrument is apical to a ledge, it is moved in vertical amplitude utilizing very short push-pull movements while remaining apical to the defect. When the file moves freely, slightly longer push-pull strokes are used to reduce the ledge and confirm the presence or absence of any residual internal canal irregularities. Once the file reaches working length easily, it is turned CW upon withdrawal in an effort to rasp, reduce, smooth, or eliminate the ledge, which is typically on the outer wall of a canal curvature. During these correcting procedures, the file should be kept coronal to the full working length in order to prevent enlargement of the apical foramen. Once a ledge can be predictably bypassed, then efforts are directed toward establishing patency with a #10 file. Gently passing a 0.02 tapered #10 file 1 mm through the foramen increases its diameter to 0.12 mm and paves the way for the #15 file.

Root canal enlargement after ledge management may be accomplished by using nickel-titanium hand files, for example, ProTaper (Dentsply International). The major advantage of using NiTi files with larger taper to remove a ledge is their tapers are three to six times larger than conventional 0.02 tapered files, and thus, their ability to shape the canal more efficiently. Once a precurved NiTi hand file has been inserted into the canal and its precurved tip has successfully bypassed the ledge, then its larger taper oftentimes eliminates or reduces the extent of the ledge while using a minimum number of files.

NiTi files should not be introduced into the canal until the ledge has been bypassed, the canal negotiated, and patency established. Bypassing the ledge and preparing the canal up to a size 15, and if necessary a 20 K-file, creates a glide path that allows the tip of the NiTi instrument to passively reach the desired length. To move the apical extent of a NiTi file past a ledge, the instrument must be precurved, preferably with Bird Beak Pliers (Hu-Friedy). To successfully

pre-curve a NiTi instrument, the working end of the NiTi file is securely grasped between the jaws of the pliers and the handle is pulled through a radius of between 180 and 270°. Nickel titanium has shape memory, and efforts to bend it must be exaggerated so that when the instrument is released from the pliers, it will have the desired curvature in its apical extent. A rubber stop on a manual NiTi instrument is oriented in a way that allows control of the file's precurved working end to bypass and move apical to the ledge. Following the use of NiTi hand files, the 10 file is used to verify ledge reduction or elimination. The canal then needs to be further enlarged to its final size and taper.²³⁴

In difficult cases and based on preoperative radiographs, a clinician occasionally must make a decision whether to continue shaping procedures in hopes of eliminating the ledge or to abort if continued efforts will weaken or perforate the root. Not all ledges can or should be removed. Clinicians must weigh risk versus benefit and make every effort to maximize remaining dentin.^{227,237}

In cases where a ledge cannot be removed, fitting the master gutta-percha cone may be difficult. In these cases, a master cone is cut back from the tip so that its narrowest diameter equals the D₀ diameter of the file that fit tightly at length. The cone can then be precurved to simulate the curvature of the canal and its tip placed in a dampen dish of 70% isopropyl alcohol. The master cone is removed after a few seconds and the clinician will notice a significant increase in its rigidity. An orientation mark can be placed on the end of the master cone to identify working length and the direction of the cone's curvature. This technique greatly facilitates the placement of the master cone during obturation.

TECHNIQUES FOR MANAGING APICAL TRANSPORTATIONS

Moving the position of the canal's physiologic terminus to a new iatrogenic location on the external root surface equates to a transportation of the foramen.¹⁵³ Apical zipping or tearing is caused by using progressively larger and stiffer files to working length.^{153,238} If apical transportation has occurred, then the canal exhibits a so-called elbow preparation with a reversed apical shape. This shape fails to provide a resistance form to condense gutta-percha. This leads to poorly packed cases that are vertically overextended but at the same time internally underfilled.^{145,152} In general, apical transportations can be categorized into three types, each differing in the specific treatment strategy.

Type I Transportation

A Type I transportation represents a minor movement of the position of the physiologic foramen, resulting in its iatrogenic relocation. In this instance, the clinician must select the right technique trying to create positive apical canal architecture. Generating the correct shape coronal to the foramen will require additional removal of dentin and could predispose to root weakening or to a lateral strip perforation. If sufficient residual dentin can be maintained and the preparation above the foramen can be corrected, then some of these initially transported cases may be thoroughly cleaned, shaped, and filled.¹⁴⁸ Regrettably, many canals whose foramina have been significantly transported are not amenable to a Type I-related treatment approach and will require additional steps.

Type II Transportation

A Type II transportation represents a moderate movement of the physiologic position of the foramen, resulting in a considerable iatrogenic relocation on the external root surface. Apical zipping or tearing is more pronounced than in a Type I transportation. In these cases, a larger communication with the periapi-

cal space exists, and attempting to create additional coronal shape would risk weakening and/or perforating the root. In treating these canals, a barrier is selected to control bleeding and provide a matrix to condense against during subsequent obturation procedures.¹⁴⁸

The barrier of choice for a Type II transportation is MTA (ProRoot, Dentsply International) (Figure 27A).^{239–241} MTA is a biocompatible material for managing radicular repairs and can be used in canals which exhibit apical transportation as well as in immature roots and in Type II transportations. Additionally, MTA is used for non-surgical and surgical perforation repairs or as a surgical root end-filling material. Remarkably, cementum grows adjacent and onto this non-absorbable and radiopaque material, thus allowing for a normal periodontal attachment apparatus.²³⁹ Although a dry field facilitates visual control, MTA is apparently not compromised by slight moisture and typically sets hard within 4 to 6 hours with slight expansion, creating a marginal adaptation as good as or better than the best materials used today.^{34,239,240} A more comprehensive discussion of MTA will occur in the section “Perforation and Prognosis for Healing.”

Figure 27 **A**, ProRoot, or mineral trioxide aggregate (MTA), is packaged in a powder form and then mixed with sterile water to a heavy “cake-like” consistency. Photo shows gray MTA; white MTA is also available. **B**, The MAP System (Micro-apical placement, Produits Dentaires SA, Vevey, Switzerland) offers one of many options to place MTA at the apex or within the canal space. **C**, The West Perf Repair Instruments provide thin, flexible trowels angled at different orientations.

MTA powder is mixed with anesthetic solution, or sterile water, to a heavy viscous consistency. Fiberless 2×2 gauze may be used to absorb surplus moisture and achieve the ideal viscosity. A small aliquot of the MTA is introduced into the prepared canal with a microtube carrying device or on the side of a West Perf Repair Instrument (SybronEndo) (see Figure 27B,C). MTA is then gently tamped down the canal to approximate length using a customized non-standard gutta-percha cone as a flexible plugger. The gutta-percha cone should be trimmed apically to have sufficient diameter to effectively condense MTA. In straighter canals, MTA can be vibrated and moved into the defect and to length with an ultrasonic tip. The instrument chosen should be selected according to the length and diameter of the canal, inserted into the MTA mixture, and activated at the lowest energy. Direct ultrasonic energy will vibrate and generate a wave-like motion which facilitates moving and adapting the cement into the apical extent of the canal. Prior to initiating subsequent procedures, a dense 4- to 5-mm zone of MTA in the apical one-third of the canal should be confirmed radiographically.

In case the defect is located apical to a canal curvature, a 4- to 5-mm column of MTA is first pushed apically beyond the curvature with a flexible gutta-percha plugger. A precurved #15 or #20 stainless steel file is then inserted past the canal curvature, into the MTA and to within 1 to 2 mm of the working length. Indirect ultrasonics with an ultrasonic tip is then used on the shaft of the file. This vibratory energy will cause MTA to liquefy, move, and adapt to the configurations of the canal laterally as well as control its movement toward periapical tissues. Again, a dense 4- to 5-mm fill zone of MTA in the apical extent of the canal should be confirmed radiographically.

MTA sets when it comes into contact with moisture. Fluids present in periapical tissues external to the canal will provide sufficient moisture for the apical aspect of the positioned MTA to set. In addition, a pre-sized cotton pellet moistened with water must be placed against the coronal most aspect of the MTA within the canal. The tooth is then temporized and the patient dismissed. At a subsequent appointment, the temporary filling is taken out and the wet cotton pellet removed. The MTA cement is probed with a sharp explorer to determine its hardness. Typically, the material has set hard and the clinician can then obturate against this barrier. If the material is soft, it should be removed, the area irrigated, dried, and a new mix of MTA placed. Upon subsequent re-entry, a hard barrier should exist which will provide a matrix against which to condense the root canal filling. The clinical steps for managing a Type II transportation are illustrated in Figure 28.

Type III Transportation

A Type III transportation represents a severe movement of the physiologic position of the canal, resulting in a significant iatrogenic relocation of the physiologic foramen. In this situation, a barrier technique is usually not feasible and hence, thermoplastic obturation is impossible. If a tooth with a Type III transportation is to be retained, it requires obturation as best as possible followed by corrective surgery. Severe foramina transportations that cannot be treated surgically result in tooth removal as the only alternative.

Perforation and Prognosis for Healing

Because endodontic therapy can often be complex and challenging, some procedures carry an inherent risk for complications or procedural accidents. The access opening to initiate therapy and the shaping and debridement steps are unquestionably those types of procedures.

An endodontic perforation is an artificial opening in the tooth or its root, created by the clinician during entry to the canal system or by a biologic event such as pathologic resorption or caries that results in a communication between the root canal and the periodontal tissues.²⁴² A furcation perforation refers to a mid-curvature opening into the periodontal ligament space and is a worst possible outcome in root canal treatment.²⁴³ A post space perforation is defined as a communication between the lateral root surface and the surrounding periodontal structures due to misdirection or an excessively large post enlargement.²⁴⁴ Except for resorptive defects or caries, furcation or root perforations are iatrogenic in nature and are a key cause of endodontic failure. It has been reported that root perforations were the second greatest cause of failure accounting for 9.62% of all unsuccessful cases.²⁴⁵ Seltzer et al.²⁴⁶ also attributed 3.52% of all endodontic failures to perforation. However, these perforations were often created without the knowledge of the clinician.

TIMING OF PERFORATION REPAIR

The main complication arising from perforation is the potential for secondary inflammation of the periodontal attachment with eventual infection and ultimately tooth loss if untreatable.^{28,242,246-251} When aseptic perforations were induced in dog canine teeth, attachment reactions were observed with granulation tissue formation, resulting in epithelialized polyps at the gingival margin.²⁵² In 1925, Euler²⁵² demonstrated that infected perforations would lead to marked

Figure 28 **A**, Preoperative radiograph of a maxillary right central incisor bridge abutment with a post and an apparently empty apical root canal system. It appears that the apical opening has been transported. **B**, Photograph ($\times 8$ original magnification) confirms post removal. The apical foramen is visible following cleaning and shaping procedures. **C**, Photograph shows tamping mineral trioxide aggregate (MTA) into the apical one-third with a gutta-percha cone used as a flexible plunger. **D**, Photograph shows the ProUltra ENDO-5 ultrasonic instrument vibrating MTA densely into the apical one-third of the canal. **E**, Photograph taken on a subsequent appointment shows set MTA. **F**, A 6-year recall radiograph demonstrates a new bridge, a post, non-surgical treatment, and osseous repair.

inflammation, poor organization of fibrous connective tissue, and abscess formation with subsequent proliferation of the crevicular epithelium. Similar results were observed when periodontal tissue reactions were investigated after aseptic and septic perforations in humans and dogs. In later stages, some repair and regeneration of the bone occurred in aseptic perforation sites whereas the infected perforations resulted only in abscess formation.²⁵³ Similarly, aseptically induced perforations that were left open to the oral cavity would result in progressive destruction of the periodontal tissues.²⁵⁰

In consideration of the declining nature of an open perforation defect, repair of the unintended communication between the root canal system and periodontal attachment was strongly advocated.²⁵⁴ Endodontic perforations in humans were examined by Kauffman²⁵⁵ in 1944. Results showed formation of granulation tissue in most cases; yet on occasion, there was a closure of the defect with cementum. Favorable healing of the periodontal tissues occurred when the defects were closed as compared to those left open.²⁵⁰ This also corroborated others findings, demonstrating that sealed perforations result in less inflammation than unsealed ones, even when those perforations were not immediately repaired.²⁵⁶

Therefore, the time lapsed between seal of the perforation and its inception plays an important role in determining the prognosis of periodontal repair. The timing of repair was categorized into immediate or delayed. The literature strongly advocates immediately closing the communication between the periodontal tissues and the root canal system to promote a superior healing potential.^{241,246,248,257-261} Benenati et al.²⁶² evaluated perforation defects in dogs created under aseptic conditions and repaired either immediately or after 1 to 230 days postoperatively. Their results demonstrated favorable healing in response to immediate repair of the perforation. However, even in the delayed repair, a favorable prognosis was possible in aseptic perforations.

LOCATION OF PERFORATION

In addition to time intervals prior to repair, another criterion that strongly influences the prognosis of the perforated tooth is the location of the defect. Periodontal status is therefore a major contributing factor that determines the success or failure of perforation repair. Once perforations exhibit the formation of osseous defects, the prognosis is compromised significantly.^{249,263} A study evaluating human root perforations indicated decreased success in cases where furcation perforations occurred. In those cases, epithelial

proliferation and periodontitis increased, markedly influencing the prognosis of the tooth.²⁶⁴ Many studies have identified that the position of the defect, with respect to the marginal gingival or junctional epithelium, is a definite determinant in the healing potential. Any perforation located near the gingival sulcus promoted inflammation and loss of epithelial attachment, resulting in periodontal pocket formation.^{241,242,246,265,266} This was further corroborated by the fact that a perforation located away from the gingival sulcus in an otherwise healthy periodontium usually offers a fair prognosis.²⁶⁷ Accordingly, perforations encountered clinically, well within the bony structures, were much more predictable following repair, than those in close proximity to the crestal bone.²⁴⁸ Similarly observed were apical and midroot perforations without communication to the oral cavity. These had a good prognosis provided an immediate seal was obtained.²⁵⁰ In a clinical assessment of perforation in humans, only 4 out of 48 perforations failed due to epithelial migration and communication with the oral cavity.²⁵¹

Perforations can be categorized by location: subgingival, midroot, or apical.

Subgingival perforations occur most often during the access cavity preparation and the search for canal orifices. Careful attention should be paid to the three-dimensional spatial orientation of the tooth to be accessed. Three clear preoperative radiographs, two periapical views and one bitewing, should be taken to aid in proper access. Accurate film images reveal a wealth of pre-access information, such as the degree of cervical constriction, coronal asymmetry, disparities between the long axis of the root and the crown, and the presence of extra roots, canals, or both. A bitewing radiograph provides even more accurate information about the vertical dimension of the pulp chamber than a periapical projection.²⁶⁸ With the advent of three-dimensional cone beam imaging and a surgical operating microscope, more accurate information is available to evaluate any tooth in all three spatial dimensions. Valuable clinical information can also be obtained before access. Palpation and periodontal probing of the root surfaces provides localization of the long axis of the root. This is most helpful when accessing through prosthetic crowns and in the presence of malposition of the teeth. Also, probing the cervical areas to provide the width and circumference of the furcation areas tells the clinician where the narrowest areas of invaginated tooth structure exist.

Midroot perforations occur mainly during post space preparation as well as during aggressive cleaning and shaping the midroot area of the canal. Careful preparation of the post space must follow the long

axis of the root. Safe removal of coronal gutta-percha with heat and hand instruments provides a pilot track that keeps post drills centered in the canal.²⁵⁰ This reduces their aggressive cutting nature and prevents the instruments from making their own canal. Post size selection is also an important factor. The post size should be no larger than one-third the mesial distal width of the tooth and should follow the canal anatomy.²⁶⁹

Apical perforation usually occurs during instrumentation, as a result of using large inflexible files in curved canals and by violating the apical constriction.^{249,268} These perforations are often managed with the obturation material or by surgical correction.

SIZE OF PERFORATION

After duration and location, another criterion impacting the successful repair of perforations is the size of the defect. Small perforations of the canal space promote a direct and immediate restoration of the defect.²⁷⁰ This offers fewer chances for periodontal breakdown and epithelial proliferation within the perforation site. Investigators have demonstrated that perforation size has a clinical significance for the success of perforation repairs.²⁴⁹ A clinical report evaluated 55 root perforations and found that 12 of those cases were too large to repair and had to be extracted.²⁸ The smaller defect was also less likely to result in an overfill of repair material.²⁶⁷ Conversely, the larger the perforation the more difficult to place a well-condensed properly shaped, uncontaminated seal.²⁷¹ In addition, prognosis is uncertain due to the large contact surface area of the restorative material with the periodontium that can allow inflammatory irritants to continuously diffuse into the surrounding vital tissues. Marginal adaptation also decreases with increased defect circumference.²⁷²

PERFORATION REPAIR MATERIALS

A final influencing criterion and one receiving the most investigative scrutiny in recent years is the material used to restore a perforation defect.^{249,272,273} If the clinician's only criterion is adequate sealing of the perforation margins alone, a fair to poor prognosis for the repair will be the result.²⁷¹⁻²⁷³ The ideal repair material for furcation and root perforations should be antimicrobial, non-toxic, capable of providing an adequate seal, non-absorbable, radio-opaque, non-carcinogenic, and promote osteogenesis and cementogenesis. It should also be easily attainable and relatively inexpensive. Additionally, it should be stable during the repair process to allow new bone to repair against it and act as a matrix, against which, root canal obturating or restorative materials can be condensed.^{249,267}

Many different restorative materials have been developed and used for non-surgical and surgical repair of iatrogenic perforation defects. Chloroform-rosin and gutta-percha cones with phosphate cement were first introduced in 1967.²⁵⁰ ZOE cements were also used to repair perforations. This, however, always resulted in a chronic inflammatory response indicating a continuous destructive process.²⁴⁶ Calcium hydroxide was introduced into the perforation defect in the hope of a positive attachment response and a possible hard tissue barrier to form. The root canal obturating materials could then be placed into the canals.^{248,258} Calcium hydroxide was further investigated and reported to form a physical barrier to prevent overfilling of obturation materials into the defect and periodontal ligament space.²⁵⁹ Beavers et al.²⁵¹ showed calcium hydroxide prevented in-growth of granulation tissue into the perforation defect. Root perforations repaired with calcium hydroxide were also compared with ZOE. These data demonstrated necrosis of the periodontal tissues adjacent to the perforation repair with calcium hydroxide. ZOE produced inflammatory reactions with abscess formation and resorption of the alveolar crest.²⁶⁶ In a clinical and radiographic study, Cavit was investigated as a restorative material for endodontic perforations. In one study, there was a favorable response in approximately 89% of cases.²⁷⁴ However, when Cavit was used in restoration of furcal perforations in dogs, a mild to moderate inflammatory response was seen histologically.²⁴² ElDeeb et al.²⁷³ compared Cavit, calcium hydroxide, and amalgam as furcal repair materials. The conclusions followed that amalgam was the material of choice when assessing healing potential. Amalgam was also found to be superior to gutta-percha when reevaluating iatrogenic root perforations.^{262,275}

Super EBA was introduced in 1985 to restore endodontic perforations after first being used as a retrograde filling material.^{276,277} This material, however, provided a poorer seal than amalgam in root perforations.²⁷⁸ In other investigations, Super EBA adapted better to the perforation site than amalgam and did not expand.²⁷⁹⁻²⁸¹ Several investigators have shown that Super EBA had a success rate of 95% from a period of 6 months to 10 years when used as a retro filling material.^{282,283}

Glass ionomer cements were introduced in 1990 to restore lateral root perforations.²⁸⁴ The sealing potential of glass ionomers and amalgam had no statistically significant difference.²⁸⁵⁻²⁸⁸ Glass ionomers provoked an inflammatory response that was less severe than gutta-percha.^{289,290}

MTA FOR PERFORATION REPAIR

MTA was introduced in the 1990s and investigated for repair of furcal perforation defects.²⁴¹ The composition of MTA includes calcium and phosphorus ions with a pH of 10.2.²⁹¹ MTA was reported to be the least toxic repair material when compared with amalgam Super EBA and IRM²⁹² a fact corroborated by several studies of the new material. For the first time, this material had demonstrated a biologic compatibility, growth of a cementum-like substance on the surface of the material that was either calcified or in its immature matrix form.^{33,293–303} It was also noted that over time, MTA provoked less inflammatory infiltrative cells than other materials. Further investigations evaluated its marginal adaptation to dentin demonstrating a better adaptation to surrounding dentin than amalgam, Super EBA, or IRM.^{240,304,305} Moreover, MTA was shown to leak significantly less than amalgam in the repair of lateral root perforations in extracted molars.^{73,306} Clinically, the material leaked significantly less than glass ionomers.^{307,308} MTA is technique sensitive. The consistency of the material and delivery are difficult. However in the presence of blood contamination, MTA was reported to be superior to amalgam, Super EBA, and IRM in resisting leakage.³⁰⁹ This is a desirable property for a material, as placement often occurs in contact with periradicular fluids.

MTA has been used for the past 8 to 10 years with promising success. MTA has been reported to be the material of choice for furcal and root perforations.³¹⁰ In *in vivo* studies with patient follow-up, MTA demonstrated normal tissue healing and no pathologic changes adjacent to perforated sites.^{35,311} Further studies have identified MTA as an excellent material for repair and reconstitution of the supporting structures.^{312,313}

However, as no currently available material meets all the requirements of an ideal restorative material, improvements continue to enhance the properties of MTA, for example, to be more radiopaque and seal better against fluid leakage as well as bacterial contamination, be less technique sensitive, but still maintain all the biologic qualities that the original material has shown. MTA is currently the material of choice for perforation repair.^{303,314–317}

CLINICAL CONSIDERATIONS INFLUENCING PERFORATION REPAIR BASED ON EVIDENCE

When evaluating a perforated tooth, the four variables mentioned above must be considered individually and collectively to properly guide treatment and understand how each of these entities critically affects treat-

ment selection and prognosis.¹⁴⁸ Microscopes, paper points, electronic apex locators, and a diagnostic radiopaque contrast solution (e.g., Hypaque, available through pharmaceutical companies) are useful in determining the level, location, and extent of a perforation and the potential for successful management.¹⁴⁸ The following four defining characteristics of a perforation always occur in combination, which synergistically complicates treatment outcomes.

- **Level:** Perforations may occur in the subgingival, middle, and apical one-thirds of roots. Furcal perforations have similar considerations as coronal one-third perforations. Perforations at this level threaten the sulcular attachment and pose different treatment challenges than more apically occurring perforations due to communication with oral flora.
- **Location:** Perforations may be on the buccal, lingual, mesial, or distal aspects of roots. The location of the perforation is less important when non-surgical treatment is selected, and more so if surgery is considered.
- **Size:** Perforation size greatly affects the clinician's ability to establish a biologic seal. The area of a circular perforation can be mathematically described as πr^2 . Therefore, doubling the perforation size increases the surface area to seal four-fold. Many perforations are ovoid in shape due to the nature of occurrence and represent large surface areas to effectively seal.
- **Time:** Regardless of etiology, a perforation should be repaired as soon as possible to discourage further loss of attachment and prevent periodontal pocket formation. Chronic perforations exhibiting a loss of sulcular attachment pose treatment challenges that potentially require surgical correction and efforts directed toward guided tissue regeneration procedures.^{159,318,319}

PERIODONTAL CONDITION AND PERFORATION REPAIR

Teeth that have been perforated must be thoroughly examined periodontally. The sulci of these teeth must be carefully probed.^{320,321,322} If the attachment apparatus is intact, then timing is critical, and the treatment is ideally directed toward non-surgical repair of the defect. However, if there is periodontal disease with resultant loss of attachment, then interdisciplinary consultations, including orthodontics, periodontics, endodontics, and restorative, should guide treatment planning, sequencing, and prognosis. In these instances, a decision must be made between a non-surgical repair and surgical correction, recognizing

that at times combined treatment may be required to retain the tooth. Importantly, extraction may be a wise decision in some cases and a fixed bridge or restored implant considered.

ESTHETICS AND PERFORATION REPAIR

Perforations in the anterior region can undeniably impact esthetics. Patients that exhibit a high lip line may be esthetically compromised by soft tissue defects such as clefts, recessions, or discrepancies in the incisio-gingival dimensions of a crown as compared to the adjacent teeth.^{322–324} Tooth colored restorations are chosen in areas that demand esthetics.¹⁶² In the past, certain traditional materials have contributed to tooth discoloration, soft tissue tattoos, and a compromise in esthetics.

VISION AND PERFORATION REPAIR

Magnification loupes, headlamps, and transilluminating devices along with the dental operating microscope and Oroscope facilitate vision and are important adjuncts in addressing perforations (see Chapter 25E). They may be used to more predictably repair perforation defects non-surgically, thus reducing the need for surgical intervention and its associated risks.¹⁵¹

TREATMENT SEQUENCE FOR PERFORATION REPAIR

When there is a perforation and the canal has not been fully prepared, the defect should be repaired prior to proceeding with definitive endodontic treatment. Repairing the perforation will allow control of bleeding into the canal, confine irrigation, and facilitate obturation. However, any given perforated canal should be optimally enlarged and prepared, when necessary, to improve access to the defect, enhance visualization, and to minimize post-repair instrumentation. When repairing a perforation, it is necessary to maintain the pathway to the canal because the barriers and restorative materials used could inadvertently block the canal. A gutta-percha segment or a collagen plug may be placed apical to the defect to prevent canal blockage during the perforation repair procedures. In failing endodontic cases exhibiting a perforation, the existing obturation material may be used to hold the position of the canal. This allows the clinician to first repair the perforation before proceeding with endodontic retreatment efforts. However, in this sequence of treatment, caution must then be exercised not to disrupt the perforation repair material during subsequent disassembly, canal preparation, and obturation procedures.

HEMOSTATICS FOR PERFORATION REPAIR

Many perforation defects exhibit considerable hemorrhage due to granulomatous tissue in situ upon re-entry. Clinicians need to be familiar with a few hemostatic agents and materials that can predictably arrest bleeding.³²⁵ A dry field enhances vision while creating an environment for the predictable placement of a restorative agent. Calcium hydroxide, a well-regarded material, may be passively syringed into the canal, hydraulically moved to place, and allowed to remain in the canal/defect for 4 to 5 minutes or longer. The calcium hydroxide is then flushed from the field using NaOCl. Two or three applications of placing and then removing calcium hydroxide usually control the bleeding. When hemostasis cannot be obtained, calcium hydroxide can be advantageously left in the canal until a future appointment.³²⁶ Other increasingly important materials that can be used to achieve hemostasis by various mechanisms include collagen, calcium sulfate, freeze-dried bone, and MTA.^{318,319,325,311} Other hemostatics exist but they are not generally selected due to factors such as cost, ease of handling and placement, or their by-products. Ironically, some of the most effective hemostatics, like ferric sulfate, leave a coagulum behind which may promote bacterial growth, compromise the seal at the tooth-restorative interface, and jeopardize the prognosis.³²⁷

BARRIER MATERIALS FOR PERFORATION REPAIR

The two main challenges a clinician faces when attempting to repair a perforation are hemostasis and the controlled placement of a restorative material. Barriers help produce a “dry field” and also provide an internal matrix or “back stop” against which to condense restorative materials.¹⁴⁸

In general, barriers may be divided into absorbable and non-absorbable; however, it is important to note that the restorative material used oftentimes dictates the barrier that is selected.

Absorbable Barriers

Hemorrhage into the tooth must be arrested in order to successfully manage perforations. Hemostasis may be accomplished by introducing an absorbable barrier non-surgically through the access cavity, internally through the perforation defect, and ideally into a three-walled osseous defect.¹⁴⁸ Absorbable barrier materials are intended to be placed within the bone and not left inside tooth structure. The barrier should conform to the anatomy of the furcation or root surface involved. Although a variety of absorbable barriers exist, collagen and calcium sulfate materials are

best employed due to supporting research, ease of handling, and observed clinical results.

- Collagen materials, such as CollaCote (Sulzer/Zimmer Dental, Carlsbad, CA), exhibit working properties that provides complete hemostasis.³²⁵ CollaCote is biocompatible, supportive of new tissue growth, absorbable in 10 to 14 days, when left in situ.^{311,318,328} Based on the size of the defect and the available access, pieces of CollaCote are cut to appropriate sizes and carried into the access cavity. The material is incrementally placed through the tooth and into the osseous defect until a solid barrier is established at the cavosurface of the root. Hemostasis is typically achieved in 2 to 5 minutes. Collagen barriers have been widely used in conjunction with amalgam, Super EBA, and other non-bonded restoratives.³²⁸ CollaCote is contraindicated as a barrier if adhesion dentistry is contemplated as it absorbs moisture and will contaminate the restorative material.
- Calcium sulfate, marketed as Capset (Life Core Biomedical, Chaska, MN), can be used as both a barrier and hemostatic material in perforation management.^{319,328,329} Calcium sulfate creates a tamponade effect, mechanically plugging vascular channels once it sets. Capset is biocompatible, does not promote inflammation, and is absorbable in 2 to 4 weeks. This material is syringed through the tooth and into the osseous defect utilizing a microtube delivery system. During its placement, calcium sulfate will fill the osseous defect and a portion of the space within the root defect. Calcium sulfate rapidly sets hard and may be prepared flush to the external root surface with ultrasonic instruments. Calcium sulfate is the barrier of choice when utilizing the techniques of adhesive bonding.^{162,328,330} Importantly, the perforation defect can be rinsed of contaminants in preparation for adhesion dentistry.

Non-absorbable Barriers

MTA exhibits superior tissue biocompatibility and can be used both as a non-absorbable barrier and restorative material.³³¹ MTA has many clinical applications and represents an extraordinary breakthrough for managing radicular repairs.^{239–241} MTA is the barrier of choice when there is potential moisture contamination or when there are restrictions in access and visibility. Furthermore, MTA can be used as the sole radicular filling material or as a barrier against which to condense another material. The mixing and use of MTA was previously discussed in the sections “Perforation and Prognosis for Healing” and “Techniques for Managing Apical Transportations”.

RESTORATIVE MATERIALS IN PERFORATION REPAIR

Central to success when repairing a perforation is to select a restorative material that is easy to use, non-absorbable, biocompatible, esthetically pleasing, and one that provides a fluid-tight biologic seal. The materials widely employed to repair perforations include amalgam (no longer recommended), Super EBA resin cement (Henry J. Bosworth, Skokie, IL), composite bonded restoratives (Geristore, DenMat Corporation, Santa Maria, CA), calcium phosphate cement, and MTA.^{306,281,332} The choice of the restorative repair material is based on the technical access to the defect, the ability to control moisture, and esthetic considerations.

TECHNIQUES FOR PERFORATION REPAIR

The barrier material and restoration selected to seal a perforation site should be based on sound research, judgment, experience, training, esthetics, ease of handling, and the advantages or disadvantages of a particular material in a specific clinical application. This section describes the armamentarium, materials, and techniques required to repair perforations.

Management of Coronal One-third and Furcal Perforations

The major difference between coronal one-third and furcation floor perforations is the shape of the resultant root defect. Mechanical perforations that occur in the furcal floor are generally round while those occurring in the lateral aspects of roots are ovoid by nature of occurrence. When managing these perforations, the clinician must first isolate the perforation site. Generally, if the perforation is mechanical and has just occurred, it is non-infected and hence clean. In this situation and if hemostasis is achieved, the defect should be repaired immediately. However, if the perforation is longstanding and exhibits microleakage, then the defect needs to be disinfected and prepared before receiving the restorative. Ultrasonic instruments are ideal for preparing perforation sites because of their geometries and coatings and because they afford direct vision.

Once the defect has been properly prepared, an appropriate barrier material and restorative are selected based on the following considerations:

- In a coronal one-third perforation where esthetics is a concern, a calcium sulfate barrier in conjunction with adhesive dentistry and a tooth-colored restoration is generally used.³³⁰
- Historically, amalgam and more recently Super EBA have been used to repair coronal one-

third perforations when esthetics was not an issue. Presently, MTA is rapidly becoming the barrier/restorative of choice for repairing non-esthetic coronal one-third defects because of its many desirable attributes. The choice to use MTA

should only be made when there is no sulcular communication.

Following perforation repair, the tooth may be cleaned, shaped, and obturated if this has not already been accomplished (Figure 29).

Figure 29 *A*, Preoperative radiograph showing periapical pathosis associated with a mandibular left second molar bridge abutment. Note the previous access and possible pulp chamber floor perforation. *B*, Photograph shows the canal orifices and an open furcal floor perforation. *C*, Photograph showing pieces of CollaCote sponge protecting the canal orifices and calcium sulfate being introduced into the perforation. *D*, The absorbable barrier is finished flush to the external root surface. *E*, The photograph shows the perforation repair with a dual cured composite material. *F*, A 5-year recall radiograph shows a new bridge and osseous repair in the furcation and apically.

Management of Perforations in the Middle One-third

Iatrogenic perforations in the *middle one-third* of roots are often caused by endodontic files, GG drills, or large misdirected post preparations. By the nature of their occurrence, these defects are ovoid in shape and typically represent relatively large surface areas to seal.

Middle one-third or strip perforations have the same technical considerations as coronal one-third perforations except the clinician is now dealing with defects located deeper and further away from the occlusal table. The factors that must be addressed in order to successfully treat these more apically positioned perforations are hemostasis, access, utilization of micro-instrumentation techniques, and the selection of suitable materials in a difficult environment. When managing deeper defects that are positioned on the lateral walls of canals, vision is enhanced when direct access exists or can be safely created. In some instances, direct access may not be possible without irreversibly compromising the structural integrity of the tooth and indirect repair techniques are required. Generally, perforations that occur secondary to overzealous canal instrumentation are sterile and do not require further modification. These should be sealed immediately. However, failing endodontic cases are associated with microleakage and microbial infection and may require ultrasonic instrumentation to clean and modify the defect in preparation for repair.

When the middle one-third perforation is a small defect, if the hemorrhage can be arrested and a dry working field obtained, then the perforation can be sealed and repaired during obturation. However, if the defect is large and the canal cannot be definitively dried, then the perforation must be repaired first before obturation. It is wise to finish the root canal preparation prior to initiating the perforation repair procedures. To prevent obstructing the root canal space during repair procedures, any readily retrievable material is placed in the canal as a space holder apical to the defect, before the perforation is repaired.

In these teeth, due to the difficult access, limited visibility, and the uncertainty of a moisture-free environment, the restorative/barrier material of choice is MTA. MTA is mixed and placed into the perforation site in accordance with the techniques discussed earlier in this chapter. After 4–6 hours, MTA will set hard and the clinician can proceed with the required treatment (Figure 30).

Management of Perforations in the Apical One-third

Perforations occurring in the apical one-third of roots primarily result from iatrogenic shaping procedures. Blocks and ledges lead to apical perforations and result from inadequate irrigation, inappropriate instrumentation, and failure to maintain patency. It is quite common that a root perforated in its apical one-third contains a canal that is both blocked and ledged. Recognizing the etiology of this type of perforation has led to surgical correction utilizing apicoectomy and retrograde-type procedures. However, it is generally recommended to first attempt non-surgical retreatment to enhance the existing endodontic treatment and, if present, to identify and treat missed canals.

The clinician should attempt to negotiate the full length of the root canal system with the concepts, instruments, and techniques previously discussed under “Techniques for Managing Blocked Canals” and “Techniques for Managing Canal Ledges.” Occasionally, the apical extent of the file will engage the original canal path and the instrument will begin to track along the true canal position. The file is gently rotated to negotiate the physiologic pathway, establish patency, and pave the way for the next successively larger instrument. The next sequentially larger pre-curved file is then inserted and carried apical to the perforation, but not necessarily to length. This “holding file” maintains the pathway of the true canal and prevents it from being blocked during subsequent repair.

MTA is the material of choice for repairing deep perforations, especially when a dry environment is not possible. MTA is placed as has been previously described. To prevent the “holding file” from being cemented into MTA as it hardens, the instrument is grasped with Stieglitz pliers and moved up and down in short, 1- to 2-mm amplitude strokes. The loosened holding file is then sectioned so its coronal most aspect is below the occlusal table but well above the canal orifice. A radiograph should be taken to confirm the position of the MTA and the quality of the repair. A moist cotton pellet is placed within the pulp chamber and in contact with the MTA and the tooth is closed with a temporary filling until the following visit. Upon re-entry, the holding file is removed, and if the MTA is hard, copiously irrigated, and the preparation finalized. A gutta-percha master cone is then fit and the root canal system is obturated. It is wise to monitor these cases periodically to observe healing before placing a

Figure 30 **A**, Preoperative radiograph of a mandibular left first molar with a periapical lesion. Note the previously over-enlarged mesial root canals. **B**, Photograph taken upon re-entry shows significant bleeding from the mesial root canals. **C**, The photograph demonstrates hemostasis and identifies the existence and position of a strip perforation. **D**, Gutta-percha cones in the mesio Buccal (MB)/mesio Lingual (ML) root canals prevent their blockage. Mineral trioxide aggregate is being vibrated ultrasonically to make the material flow into the perforation defect. **E**, Photograph at a subsequent visit shows removal of the gutta-percha cones, perforation repair, and the canals ready to be obturated. **F**, Postoperative radiograph shows the repair of the perforation.

definitive restoration. It is also important to acknowledge that not all perforations can be corrected non-surgically, even when the best technologies are used in the hands of the most skilled practitioners. Some teeth will still require surgical treatment or extraction.

Mishaps and Serious Complications of Endodontic Therapy

THERMAL INJURY WITH THE USE OF ULTRASONICS

As described earlier, the use of vibratory energy has evolved as a highly efficient method for removal of obstructions and cements within the root canal space when retreatment or rehabilitation of that space is planned. In less than a decade, ultrasonic therapies have gained rapid and widespread acceptance within the community of practitioners as an adjunctive technique in overcoming a heretofore, formidable challenge. This has occurred because the ultimate goal in recovery of the root canal space is to ensure that the remaining dentin is sound and able to structurally support the subsequent restoration providing a restorative complex that is functionally healthy.¹⁸⁴ The use of ultrasonic devices has allowed dentists to embrace this important strategy.

Because conventional retreatment is the choice a prudent practitioner would first consider before turning to a surgical option, more and more clinicians are finding that ultrasonic technology is becoming indispensable in a modern dental practice. Ultrasonic energy is derived from one of two sources: magnetic resonance such as that used by devices such as the Cavitron or Cavi-endo units, or piezoelectric energy, such as that used by the Enac, Satelec's Suprasson P5 Booster, Analytic's MiniEndo II, and the Spartan MTS from Obtura Spartan. While it is recognized that piezoelectric devices operate in energy ranges that are higher than magneto-restrictive devices, most units used for post removal are within the higher ranges of operation.

Only a small number of investigators and authors have cautioned that ultrasonic energy can be harmful as intense heat can be generated within a metallic object that has its distal end millimeters away from any cooling effects created by the operator or the device itself.^{204,203,333} The use of heat and the potential for injurious heat transfer to dentin and bone has been investigated for a number of different devices used in endodontics and associated restorative proce-

dures.³³⁴⁻³³⁹ It is generally accepted that external root temperature increases that exceed 10°C produce irreversible bone and attachment damage as well as dehydration effects on dentin often resulting in resorption.³⁴⁰ Investigations of this kind have been in the literature for over two decades, and many investigators have used the 10°C threshold to examine devices that produce heat in dentistry. Heat transferred to the pulp through conventional cavity preparations and restorative procedures have been well documented in the literature.^{341,342} Newer technologies such as laser use on dentin have also been investigated for intrapulpal heat transfer. Lasers may jeopardize pulp vitality through heat transfer. In recent research, temperature elevations between 0.5 and 32.0°C were registered in an energy- and time-dependent manner. Thinner dentin in the site of laser usage resulted in higher temperature elevations within the pulp. The time of application was a critical variable that mandated a "Caveat" to monitor time limits in usage.³³⁹

When investigating devices that create heat within the root canal space, the System B obturation system, when used according to the manufacturer's specifications, produces heat transfer to the attachment that falls below the critical threshold for irreversible injury.²⁰⁴ Other researchers investigating different thermoplasticizing techniques have found similar results. Specifically, that generated temperature increases on the root surface are not sufficiently high to cause damage to the tooth-supporting tissues or exceed the critical 10°C.^{336,337} In an assessment of heat transfer to the root surface during post preparation with Peeso reamers and Parapost drills, large temperatures were generated on the root surface by these engine-driven drills through frictional heating.^{335,338}

There is very little evidence in published research for the considerable heat transfer that occurs during ultrasonic vibratory motion of devices during removal of posts, pastes, and separated instruments in teeth. A number of studies over the past few years have cautioned the practitioner regarding adequate coolant and the need to counter heat buildup.^{203,333} There are far less published recommendations for how to accomplish this goal. Often, even the manufacturers are generic in their admonitions for usage and methods for cooling. Research studies of time intervals for application of energy consistently recognize that temperatures can rise to destructive levels within a few minutes without adequate and sufficient coolant.^{203,333-344}

The general recommendation from this research is that care should be taken not to continue ultrasonic

vibration over prolonged time periods. In addition, clinical protocols are needed to safely remove posts without causing thermal damage to the adjacent periodontal tissues. A recent study of ultrasonic heat transfer through ceramic and metallic posts reported that 75% of samples in both ceramic and stainless steel groups showed external root temperatures that exceeded the critical 10°C threshold of samples within the first 5 minutes. All samples were vibrated with a water spray coolant directed to the ultrasonic tip. There were no significant differences comparing the effects of heat generated by ceramic or stainless steel posts during removal.²⁰³

These authors cautioned against extrapolating in vitro data of root temperature rises to the in vivo clinical situation of a circulatory system within the attachment apparatus capable of dissipating heat. However, the results of this study showed temperature rises that would have greatly exceeded the dissipation effects of the periodontal vasculature. Accordingly, the authors warn the reader to maximize coolant and minimize application time.

The safe usage of ultrasonic devices is paramount. Thus, expediency should not compromise proper procedural design to protect the patient's safety and welfare. Because dentists are taught to be cautious with heat-generating devices contacting hard and/or soft tissue, a reasonably careful (and prudent) dentist should always be mindful of excessive heat potential with ultrasonic devices despite water coolants. Ultrasonic device usage should be coupled with monitoring intervals to assess overheating and to permit post cooling (Figure 31).

FACTORS INFLUENCING POST REMOVAL AND HEAT TRANSFER

Many factors that influence successful post removal were discussed in prior sections of this chapter. Individually and in combination, these factors should be carefully considered before commencing with any treatment.¹⁴⁵ There are several factors that serve to influence heat transfer and the potential for thermal injury. Specifically, there is virtually no research information available quantifying the optimal magnitude of energy, for any given ultrasonic device, that maximizes clinical efficiency yet mitigates dangerous heat transfer. Additionally, at any given ultrasonic power setting, little is reported regarding the length of time an instrument can vibrate against a post without causing thermal injury. Furthermore, protocols need to be developed to measure heat transfer based on the length, diameter, and configuration of a post

Figure 31 **A**, Preoperative radiograph of a maxillary left central incisor with a metal post. Ultrasonic vibration was used to remove the post. **B**, Postoperative appearance of the burn after post removal. The tooth was later extracted and the bone loss was severe.

and the type of material from which it is constructed. Another factor influencing heat transfer, when attempting to remove a post using the ultrasonic option, is the thickness of the remaining dentin. As an example, many posts observed radiographically to be centered within a root are often-times extremely close to the external root surface

due to surface concavities. A recent investigation showed that when a #4 GG drill is used to prepare a post space in the distal root of mandibular molars, in 82% of cases the residual dentin thickness was less than 1 mm.³⁴⁵

Fortunately, adequate water coolant can safely reduce heat transfer and virtually eliminate the risk of thermal injury. However, the literature does not provide sufficient guidelines for how often a clinician should irrigate the tooth to dissipate the heat, how long ultrasonic energy should be applied and whether cool-down intervals are necessary to prevent cumulative damage. Also unknown is what volume of coolant is effective in maintaining a safe physiological temperature. Additional research needs to be performed and data gathered and published to clarify how each factor, or combination of factors, influences heat transfer.

Based on the best available evidence, the following recommendations can be made to provide safe and effective therapy using ultrasonic devices in intraradicular obstruction removal.

- Attempt to radiographically image residual dentin thickness for the working level within the root. This will help judge heat transmission rates to the attachment. Thicknesses below 1 mm in combination with metallic or ceramic posts will transmit heat rapidly.
- Use devices that allow water to reach the working end of the ultrasonic tip. This provides maximum cooling effect.
- Use copious water spray and effective suction at a continuous rate. There is ample evidence that when the working end of any ultrasonic device is deep within the root, heat generation occurs rapidly.
- Monitor the post temperature at 1- to 2-minute intervals. This seems to be the most prudent standard given the evidence that extreme temperatures on the root surface, even while using coolant, can be reached in 5 minutes.
- Where possible, monitor heat buildup in the post by touching it. A gloved finger will be able to sense a post overheating.
- Allow reasonable intervals between applications of ultrasonic energy. If post removal attempts are continued beyond 10 minutes, rest intervals between ultrasonic device applications should be at least 2 minutes. Timers with beepers should be considered to monitor time intervals; heat buildup appears to be dissipated in stages and recovery of physiologic temperatures occurs very slowly.

- Incorporate refrigerants (ethyl chloride or Endo Ice) applied to a cotton swab or ice sticks to cool the post down if necessary. The expansion/contraction effects of this strategy are minimal compared to the severe outcomes of a burn injury.
- Use post pullers and other vise-like devices as adjuncts to ultrasonic energy.

Each dental procedure has a variable degree of inherent risk. The practitioner is required to avoid unreasonable risks that may harm the patient. Treatment is deemed negligent when a reasonably careful clinician should have foreseen and prevented unreasonable risk of harm to the patient. Failure to follow the dictates of sound biologic practice increases the risk of negligently induced deleterious results.

Obturation and Irrigation Mishaps

Unfortunately, there are numerous examples reported in the literature that cite and document many disabling complications to the alveolar bone, neurovascular bundle, and maxillary sinus following inadvertent overextension of root canal filling materials and irrigants. These injuries require a thoughtful strategy for prevention during endodontic procedures as well as a responsible systematic approach to management, should the outcome of endodontic therapy produce an injury.

It is important to focus on measures that can prevent and/or minimize accidents that can occur under the most vulnerable of circumstances. The identification of those principal factors that can affect prognosis after injury will also be an important consideration in the remainder of this chapter. Many of the root-filling materials used today are either chemically neurotoxic or can be mechanically destructive to surrounding structures via compression injury. In addition, overinstrumentation errors in shaping root canal spaces may produce an abnormal over-enlargement of the apical constriction allowing overfill or instrument damage to structures through direct manipulation or rotation that severs susceptible tissues. With the use of rotation during instrumentation and heated obturation devices becoming increasingly available to all practitioners in the last decade, the introduction of endodontic filling materials into periapical tissues is quite common. This is of major concern when the teeth being treated are in close proximity to anatomically important structures such as the maxillary sinus or inferior alveolar canal. Overextension of the root canal-filling materials and/or irrigants risk injurious

Figure 32 Extreme overfill into the sinus resulting from the combination of an over-instrumented apex and an automated thermoplastic technique.

consequences if the underlying inferior alveolar nerve or sinus structures are initially penetrated with files. A pathway of entry into the inferior alveolar nerve or sinus space can more likely result when the pathway is created by over-instrumentation or an open apex (Figure 32).

THE IMPORTANCE OF ACCURATE RADIOGRAPHIC IMAGING

While this is a common admonition by educators to many students in the medical sciences, as they are learning the principles and practice of diagnostic assessment, it is a fundamental truth. “You don’t know ... what you don’t know.” For the practitioner embarking on endodontic therapy for a molar or premolar tooth in the anatomical vicinity of the maxillary sinus, mental foramen, or inferior alveolar nerve, this caveat is critical. It is a common understanding that both large and small pathoses as well as anatomic entities are routinely missed in radiographic surveys both by the operator and by the limitations of the technology when encountering differences in anatomic variation.³⁴⁶

ANATOMIC AND IMAGING CHARACTERISTICS OF THE MAXILLARY SINUS

The maxillary sinus or antrum is an air-filled cavity lined by respiratory mucosa. The inferior border of the sinus lies in the alveolar process of the maxilla and is situated above or often between the apices of the

maxillary posterior teeth. The sinus may also be separated by bony walls into several compartments. Proper visualization of the maxillary sinuses is critical for interpretation of location and distances of root apices from the sinus space³⁴⁷ (see Chapter 17).

A standard panoramic projection provides very good information about the dimensions of the sinus space notwithstanding the superimposition of the nasal and zygomatic structures in a panographic image. The size and configurations of the sinuses vary greatly; in some individuals, there is considerable bone between the apices of the teeth and the sinus cavity, whereas in others the roots directly project into the sinus with minimal or no bony covering.^{348–352} Information derived from cone beam computed tomography (CT) was reported very useful in a case involving surgical access to a maxillary molar. The course of the sinus and its relationship to the roots of the first molar as well as potential sinus pathology were assessed.³⁵³

Neural distribution to the sinus is diagnostically important. The nerve supply is from the maxillary division of the trigeminal nerve, with branches coming from the posterior, middle, and anterior–superior portions. The inflammatory effects of overfilled endodontic materials as well as dental sepsis can affect the differential diagnosis of pain localized to the sinuses. High-contrast three-dimensional CT will greatly facilitate the evaluation of the sinuses and determine the position of foreign materials and their relation to the apices of teeth.³⁴⁷ The inflammatory effects induced by irrigants, medicaments, and endodontic filling materials will extend a pathway to the sinus if proximity allows; great caution and care in the use of these products is indicated in root canals that adjoin the sinus.^{348,349}

ANATOMIC AND IMAGING CHARACTERISTICS OF THE INFERIOR ALVEOLAR CANAL

The inferior alveolar canal starts at the mandibular foramen on the inner aspect of the ramus and passes in a downward and forward direction through the mandible. As it passes forward, it also moves from the lingual side of the body of the mandible in the third molar area to the buccal side in the premolar area. In traditional radiography and panographic films as well as digital images, it appears as a narrow, radiolucent ribbon between two radiopaque lines representing the canal walls. It has been reported that CT imaging was highly reliable when attempting to

determine the relation between periapical lesions and the mandibular canal prior to endodontic surgery.³⁵⁴

In the region of the mental foramen, the mandibular nerve bifurcates into its two branches, the incisive and mental nerves. The exact location of the inferior alveolar canal and its mental branch is important in the placement of implants, surgical extractions, and endodontic therapy of roots within close proximity.³⁵⁵ In a series of investigations on 75 human skulls to identify the radiographic position of the mental foramen on periapical and panoramic film, the authors found that the foramen could be seen on only 75% of the horizontal periapical radiographs.³⁵⁶ Visualization of the mental foramen was increased and enhanced when a panoramic radiograph was available due to a 23% magnification factor that occurs in a panoramic film.³⁵⁷

Interruptions in the protective wall of the canal by dental manipulations can have serious and calamitous effects on the patient's sensibility in the distribution of the nerve.^{358,359} In research that assessed the spatial relationship between the posterior teeth and the mandibular canal using 22 mature dried human skulls accounting for 264 specimen sections, second premolars and second molars had the closest distances to the canal with a mean distance of 4.7 and 3.7 mm respectively. The mandibular canal was directly inferior to the root apices of the posterior teeth 5% of the time. The data also determined that as the mandibular height decreased, the distance between the canal and root apices also decreased.³⁶⁰ In prior studies, investigators have found that 60% of mandible specimens contained canals while 40% of the dissection samples had no distinct canals. Often, branches of the nerve showed significant morphologic variability and occupied only a space in the bone as opposed to residing within a distinct tunnel-like structure.³⁶¹ These findings have significant implications regarding the effects of endodontic medicaments, sealers and materials on bone, connective tissue, and specifically the neurovascular elements found in the antrum and inferior alveolar canal.

Endodontic filling materials and sealers are reviewed in Chapter 25. Biocompatibility of endodontic obturation materials have been investigated in great detail.³⁶²⁻⁴⁰³ Biocompatibility studies have included tissue and cell culture studies,³⁶⁶⁻³⁶⁸ bone and soft tissue reactions to set and unset implanted materials in experimental animals,³⁶⁹⁻³⁷¹ experimental and clinical studies on animals and humans,³⁷²⁻³⁷⁴ and new assessments involving histochemical analysis and X-ray microanalysis.³⁷⁴⁻³⁷⁶

Length Determination Controversies in Endodontics

One of the major controversies in root canal treatment is the apical end point of the working length. It is a paradigm in modern endodontics that instrumentation beyond the apical foramen should be avoided because it is so often associated with a reduced success rate⁴⁰⁴⁻⁴⁰⁸ and exposes the patient to the potential for injury.⁴⁰⁹

Generally, as discussed in here and prior chapters, most clinicians prefer to end the biomechanical instrumentation at the apical constriction (narrowest point in the canal at approximately the dentin-cemental junction),⁴¹⁰ where the contact between root canal filling material and the apical tissues is minimal. In addition, many dentists practice apical patency with small files in order to maintain communication with the apical tissues and prevent canal blockage and ledging coronal to the determined end point.

Despite the limited three-dimensional information provided by a conventional radiograph, a periapical radiograph remains the commonly used standard for working length determination.^{411,412} However, the acceptance of apex locators is widely increasing with the introduction of devices well into their fourth generation. In addition, many clinicians use paper points to help determine the juncture of the canal confines from the serum of periapical tissues. Generally, a distance of 0 to 2 mm between radiographic apex and the obturation material marking the end point of root canal instrumentation has been designated as acceptable when evaluating postoperative radiographs. Accordingly, in a retrospective study that investigated the influence of the level of apical obturation on the treatment outcome,⁴⁰⁶ a root canal filling was considered satisfactory, if among other factors its apical level was 0 to 2 mm short of the radiographic apex, this apical level contributing to the highest success rates.

Stein and Corcoran⁴¹³ discussed the possibility of unintentional over-instrumentation when radiographs alone were used for working length determination. They reported that the position of a file placed for working length determination appeared radiographically 0.7 mm shorter than its actual position. The results of another investigation suggest that a working length that ends radiographically 0 to 2 mm short of the radiographic apex does not guarantee that instrumentation beyond the apical foramen will be avoided in premolars and molars. The authors conclude that radiographic measurements should be combined

with electronic working length determination using modern apex locators to better help identify the apical end point of root canal preparation and avoid over-instrumentation.⁴¹⁴

In a recent review of the literature on the role of apical instrumentation in root canal treatment, Baugh and Wallace⁴¹⁰ concluded that because the apical dimensions of root canals range from very large to very small, the clinician should seek instruments and techniques that can help determine when instrumentation to the correct apical size has been achieved and that additional research was necessary given the controversy that still lingers regarding final apical size. Other researchers have shown the importance of combining therapies such as rotary instrumentation using larger apical sizes with the use of calcium hydroxide to reduce the numbers of bacteria in root canals and increase long-term success.⁴¹⁵ In a recent meta-analysis of studies done over the last three decades on optimal obturation length, the results demonstrated that obturating materials extruding beyond the radiographic apex correlated with a decreased prognosis for repair.⁴¹⁶ When faced with the possibility of inadvertent over-instrumentation into neurovascular anatomy, the research provides a substantial number of appropriate caveats.

Techniques for Obturation Control When Neurovascular Proximity Exists

There are a number of contributions to the literature that assess techniques for apical control of obturation materials. Tronstad⁴¹⁷ assessed the apical plug of dentin chips in monkeys and showed that a plug of clean dentin fillings could provide an apical matrix that was well tolerated by the tissues and would provide an apical barrier that would allow the canals to be well sealed yet protected against impingement of filling materials on the periodontal tissues. Others have found that a dentinal plug serves as an effective means of preventing extrusion when using thermoplasticized techniques^{418,419} or to confine irrigating solutions.⁴²⁰ In a comprehensive study comparing the apical plugs of dentin versus calcium hydroxide to prevent overfilling, when the apical foramen had been intentionally over-instrumented in cats, the investigators found plugs of calcium hydroxide or dentin to work equally well.⁴²¹ However, the calcium hydroxide plugs were less durable and produced foramina mineralization that was less complete than the dentinal plugs. Periapical healing

was similar for both calcium hydroxide and dentin. In another study that looked at foramen size as it affected apical extrusion of thermoplasticized gutta-percha, it was noted that overfills and the extrusion of material occurred proportionately to the area of the apical opening. An opening the size of a #40 file (0.40 mm diameter) was found to be twice as likely to allow extrusion of material than an apical diameter sized at #20 (0.20 mm).⁴²² When the sealing ability of laterally condensed gutta-percha was compared to injection molded thermoplasticized gutta-percha in straight and curved canals, only the thermoplasticized technique produced overextensions.⁴²³ It has also been shown that great differences in flowability exist between gutta-percha brands when used in a thermocompaction technique.⁴²⁴ The recommendation to consider a hybrid technique when using thermoplasticized materials has often involved a cold condensation of gutta-percha apically followed by a thermomechanical compaction, providing a safer barrier for limiting the extrusion of material.⁴²²

Thermoplasticized Gutta-Percha and the Effects of Heat

Previously discussed in this chapter were a series of investigations in vitro⁴²⁵ and on dogs,⁴²⁶ wherein the heat of thermoplasticized gutta-percha was assessed for its potential injurious effects. Levels of heat generated by the plasticized gutta-percha did not appear to be at clinically deleterious levels and no apparent irreversible tissue destruction was evident.⁴²⁶ Similar results have been obtained in other in vitro and in vivo studies when manufacturers' protocols for usage have been followed.^{204,336,337,427,428} Where deleterious effects are seen either experimentally or in clinical situations, the lessons require heeding. Bailey et al.³³³ in a study utilizing ultrasonic condensation of gutta-percha found that the combination of a high power setting and a 15-second application of activation energy resulted in temperature rise on the root surface beyond the recognized deleterious threshold of 10°C. Clinical case reports involving overfill with heat softened gutta-percha are increasing in the literature.^{429,430} The current practice of maintaining apical patency and the popularity of thermoplastic gutta-percha filling techniques have increased the likelihood that overfills can involve the neurovascular anatomy. Fanibunda et al.⁴³⁰ warn of the lesser known danger of thermal and mechanical insult from chemically "safer" materials

other than paraformaldehyde, being extruded into the inferior alveolar canal. They report a case of thermally compacted gutta-percha having a severe affect on patient sensory loss after gross overfill into the mandibular canal. In this case, they identified a mechanical (compression), chemical (calcium hydroxide sealer), and thermal insult (molten gutta-percha) to the nerve.⁴³⁰ A similar outcome for thermoplastic overextension was reported by Blanas et al.⁴³¹

Carrier-Based Gutta-Percha

Carrier-based gutta-percha was first introduced as Thermafil (Dentsply Tulsa Dental Specialties).⁴³² The Thermafil obturator currently consists of a plastic carrier and is covered in a uniform layer of gutta-percha. The carrier is constructed from a special radiopaque plastic similar to a manual or rotary endodontic instrument. The obturator is heated in a special oven where the gutta-percha it carries assumes a softened state with unique adhesive and flow characteristics. The ideal canal preparation for a carrier-based obturator must allow sufficient space for the flow of cement and gutta-percha.⁴³³ Carrier-based obturators use techniques that caution against the use of excess cement because of the increased likelihood of overfilling due to the piston-like effect of the obturator during placement. Because the risk of overfilling is considered the only true limitation of carrier-based obturators, authors and manufacturers caution against the following major errors in technique:

- Incorrect canal preparation including over-instrumentation and laceration of the apical terminus.
- Excessive cement or gutta-percha.
- Excessive force and velocity during insertion.
- Improper obturator selection.⁴³³

Damage to the Neurovascular Anatomy: Causes and Outcomes

Reports in the literature involving serious injury to the inferior alveolar nerve have included paresthesia or anesthesia associated with overfill of N2 and similar paraformaldehyde pastes,^{385,386,388–391} (Figure 33), Endomethasone,^{387,399} AH26,^{434,435–437} calcium hydroxide,^{430,438} ZOE, and gutta-percha.^{409,436} There is almost no current obturation material that has not been reported in the literature to produce paresthesia when overfilled into the neurovascular anatomy. If a

Figure 33 A, Postoperative radiograph of a paraformaldehyde paste overfill of a mandibular left second molar. The patient developed paresthesia that prompted surgical intervention weeks later. **B**, After extraction and removal of the extruded paste material, the patient continued to have a burning pain and anesthesia.

new material is not currently cited, it is almost assured the mishap of overfill will eventually find itself in the literature.

Ørstavik et al.³⁷⁴ described 24 published cases of paresthesia involving the mandibular nerve. It was reported that there was no indication of healing in 14 of the 24 patients during the observation periods which ranged from 3 months to 18 years after initiation of the injury. They described the characteristic deficits of the inferior alveolar nerve as unilateral loss of sensitivity of the lip and gums, numbness, a tingling sensation, and dryness of the affected mucosa, often preceded by intense pain in the affected area.³⁷⁴ All of the reported cases were molars or involved the lower second premolar. There were numerous materials involved, all of which are cited in here. Paraformaldehyde pastes were well represented in the materials cited but were not exclusive. They concluded that neurotoxic and compressive effects are the most frequent causes of paresthesia after endodontic overfill into the mandibular canal and that the use of syringes and rotary paste fillers should not be used to insert root-filling pastes or cements in teeth in areas susceptible to neurovascular damage.

A serious case of calcium hydroxide overfill has been reported through a lower second molar causing severe vasospasm and a resulting facial ischemia.⁴³⁹ The ischemia caused cyanosis and necrosis on the face as well as a total absence of function in the mandibular and mental nerve. Again, the authors cautioned in this case report against the use of a syringe in applying the calcium hydroxide with a known level of toxicity and a high pH (12.4).⁴³⁹

It is difficult to ascertain with absolute certainty the primary etiology for paresthesia when assessing the sequelae and future prognosis for repair from overfill into neurovascular tissue. The clinician, therefore, must consider the following critical factors in all cases of overfill: the chemical neurotoxicity of the materials involved, the possibility of direct damage of files (crushing and mechanical injury),^{386,436} the compression damage of solid materials such as gutta-percha (the pressure on the nerve bundle is directly proportional to the amount of material pushed into the canal),^{430,436} and the possibility of epineural fibrosis resulting in neuroma.³⁸⁸ In a clinical report that suggests the use of corticosteroids may be helpful in countering the injurious compression effects resulting in epineural and intraneural edema, Gatot and Tovi⁴⁴⁰ have reported that prednisone therapy may limit the severity of injury as well as aid in the prevention of fibrosis. Others also report the pharmacologic use of corticosteroids in the treatment of paresthesia related to overfill.⁴⁴¹

Inflammatory edema with resulting ischemia, that compresses and compromises blood supply to soft

tissues and nerves in confined spaces such as the inferior alveolar canal, is termed compartment syndrome.⁴⁴² Compartment syndromes are a group of conditions that result from increased pressure within a limited anatomic space, acutely compromising the circulation, and ultimately threatening the function of the tissue within that space. Compartment syndrome occurs from an elevation of the interstitial pressure in a closed osseous compartment that results in microvascular compromise. The pathophysiology of compartment syndrome is an insult to normal local tissue homeostasis that results in increased tissue pressure, decreased capillary blood flow, and local tissue necrosis caused by oxygen deprivation. Compartment syndrome is caused by localized hemorrhage or post-ischemic swelling resulting in fibrosis that obstructs axonal regeneration. The clinician should have a high index of suspicion whenever a closed bony nerve compartment has the potential for bleeding or swelling. Compartment syndromes are characterized by pain beyond what should be experienced from the initial injury. Also, diminished sensation may be noted in the distribution of the nerve within a compartment that is being compressed.⁴⁴²

DIAGNOSIS AND MANAGEMENT OF INFERIOR ALVEOLAR NERVE INJURY

Nerve recovery subsequent to an endodontic mishap is unpredictable. Because of this unpredictability, the clinician is responsible for making a timely diagnosis and monitoring neurosensory changes. Careful follow-up evaluations and appropriate referral is our responsibility to the patient.⁴⁴³⁻⁴⁴⁶

Neurosensory function can be divided into two basic categories based on the specific receptors that are either stimulated or injured: mechanoreceptive and nociceptive. The mechanoreceptive aspect of sensory perception can be further divided into two-point discrimination and brush directional stroke. The nociceptive path can be subdivided into pinprick and thermal discrimination. Each type of nerve fiber varies with respect to diameter, conduction speed, and physiologic function. Each afferent nerve end offers a distinct receptor terminal that is specific for warmth, cold, pain, and touch. The first phase of any peripheral nerve regeneration is the degeneration of the axon and its myelin sheath along the nerve fiber at the site of injury. These changes along the nerve are known as Wallerian degeneration and lead to degeneration of the entire axon terminal over several weeks following a severe injury. Neural injuries are most commonly classified using the Seddon classification

system.⁴⁴⁷ Seddon's classification is derived from the extent of nerve injury. Neurotmesis is the most severe nerve injury because conduction is completely disrupted resulting in the loss of anatomic integrity of the endoneurium, perineurium, and epineurium. Axonotmesis, a less severe injury, results in damage to the axons, but the endoneurial and epineurial sheaths are preserved. Neuropraxia occurs when a nerve is injured and conduction is blocked, but this does not lead to Wallerian degeneration.

Clinically, neurotmesis leads to anesthesia with a loss of feeling or sensation. It can also produce dysesthesia, an abnormal unpleasant sensation often burning in character. Recovery is unlikely or limited. Axonotmesis causes paresthesia, an abnormal altered sensation that can show some degree of sensory recovery after several months. Neuropraxia is usually a transient paresthesia where recovery is complete from days to weeks.

The clinical evaluation of a patient who suffers a sensory loss in the oral or maxillofacial region subsequent to an endodontic obturation should begin by identifying the patient's subjective assessment of these alterations. The clinician should distinguish between anesthesia, dysesthesia, and paresthesia. Often considerable variability will exist within the descriptions outlined above, and few patients will fit perfectly within the Seddon categories.⁴⁴³ However, it is important that any patient with anesthesia or a painful dysesthesia be evaluated in a systematic fashion.^{443,444} The dentist should assess the chronologic history of the area even if that history has only been in the last several hours and note the patient's chief complaint—the nature, frequency, and severity of the symptoms and how they might be changing for better or worse as well as the loss of function that is occurring. If the initial symptom is anesthesia, the area of anesthesia should be mapped and placed in the patient's record. Any return of sensation should be noted.⁴⁴⁵

The physical evaluation should also include pinprick for deep pain (small myelinated A-delta fibers), brush stroke for directional discrimination (mediated by large myelinated A-alpha nerve fibers), and two-point discrimination for proprioception (large myelinated A-alpha fibers). The small myelinated fibers of the A-delta group and the smaller unmyelinated axons of the C group are responsible for sensations of temperature.⁴⁴³

Should anesthesia and painful dysesthesia be consequences of overfilling, the practitioner must understand when the referral to a surgeon (oral-maxillofacial or neurosurgeon), who is experienced in the surgical therapies for relief and healing, may be required to resolve the patient's problem.⁴⁴⁶ The final management of such a

case depends on several factors. Even the most acceptable materials can cause serious injury if extruded in large volumes into sensitive structures. Pastes and sealers that contain paraformaldehyde or known safer materials are difficult to control and may moreover create injuries to the maxillary division of the trigeminal nerve when extruded through maxillary teeth or into the sinus membranes.⁴⁴⁸ In addition, maxillary root-treated teeth with overextensions of the root canal sealer or solid materials such as gutta-percha or silver cones into the sinus might be the main etiological factor for aspergilliosis of the maxillary sinus in healthy patients. Root-filling materials based on ZOE are considered to be a growth factor for aspergillus.^{449,450}

While paraformaldehyde-containing materials should never be used because of the dangers of chemical injury they present, all obturation materials should be used with extreme caution in all circumstances, especially in teeth intimately related to the inferior alveolar canal.

When presented with the extrusion of endodontic obturation materials into the neurovascular tissues, and after careful and systematic assessment of the nature and course of the injury and its effects, a decision to intervene surgically or delay and observe has to be made (Figure 34).

MANAGEMENT OF INFERIOR ALVEOLAR NERVE INJURIES

The oral surgery literature describes most inferior alveolar nerve injuries as neuropraxias and thus they resolve spontaneously within a 6-month time frame. These are often lingual nerve injuries as well as mandibular trauma subsequent to tooth removal. It is reported that inferior alveolar nerve injuries heal better than lingual nerve injuries due to the guidance provided by the bony mandibular canal.⁴⁴⁵ This fact has relevance if oral surgical procedures are likely and decortication procedures and removal of overfill are contemplated. The clinical examination that results in a diagnosis of anesthesia or increasing painful dysesthesia unresponsive to non-surgical therapy should help guide this decision.^{443,444} It is suggested that the decision to intervene surgically should include the high suspicion of injury resulting in the loss of conduction within the nerve due to suspected chemical toxicity and mechanical compression.

There are several recent reports in the literature of surgical intervention to provide decompression and removal of chemically toxic materials that demonstrate successful outcomes.^{451,452} However, when the practitioner takes a "wait and observe"

Figure 34 **A**, Radiograph shows zinc oxide–eugenol sealer extruded into the mental foramen from the canal of a mandibular second premolar. The patient experienced anesthesia in the distribution of the mental nerve 24 hours after injection of the sealer, and the decision was made to remove as much material as possible through the root canal space in an attempt to reduce the pressure on the neurovascular bundle. **B**, Patient exhibited signs of anesthesia for approximately 30 more days. After 60 days, the first signs of recovery appeared. The patient was symptom-free after 6 months.

approach, the favorable potential for long-term spontaneous recovery requires thoughtful consideration. When a peripheral nerve is injured, a non-surgical management that supports spontaneous neurosensory recovery and promotes patient tolerance of the sensory loss is a viable option.⁴⁴⁵ The most compelling reason to wait is that a majority of injuries are known to recover spontaneously to some degree. Higher levels of recovery can also be expected when the patient is young and healthy. In addition, a “recovering patient profile” with improving levels of function, detection abilities, and sensory symptoms argues for restraint in management.^{443,445}

In the final analysis, the decision of whether and when to intervene surgically in the removal of overfill should be based on objective criteria and a comprehensive assessment of each individual patient. The current guidelines for intervention are unfortunately not based on satisfactory evidence-based science, and this leaves a troublesome vacuum in our knowledge of effective therapies, making prevention of this injury critical to treatment planning prior to initiating root canal therapy.

Prevention of Obturation Mishaps

This chapter has offered a number of remedies to provide a safe and prudent approach to the obturation of posterior teeth in close proximity to the vul-

nerable tissues of the sinus or inferior alveolar nerve. In summary, the following recommendations are made.

- It is essential to image and identify radiographically the sensitive neural structures of the jaws and the sinuses in order to clearly understand the proximal risk.
- It is critical to use obturation materials that are well tolerated by the body after therapy, rather than paraformaldehyde formulations that can cause irreversible sensory nerve damage and should not be used in the good and safe practice of endodontics.
- The clinician must practice careful and judicious shaping strategies that use multiple confirmations of working length and take serious precaution against over-instrumentation.
- It is important to use “resistance form” in controlling overfills. This “resistance form” can be imparted during canal preparation by producing funnel-form, tapered preparations and by selecting gutta-percha cones to match those canal shapes that will resist the obturation forces which promote extrusion.
- When using thermoplastic techniques, it is important to respect the flow characteristics of the materials and the heat energy used.
- The use of paste fillers and syringes for applying endodontic sealers should be cautioned when there is close proximity to neural structures and control is compromised.

- In cases of extreme proximity to the neurovascular anatomy, the importance of creating a clean dentin plug or material barrier at the patent apical terminus should be carefully planned when the risk of extrusion is considerable.

NaOCl Accident

Accidental injection of NaOCl into the periapical tissues is an experience that neither the patient nor the practitioner will soon forget. The literature contains numerous case reports describing the morbidity associated with such occurrences.^{453–457} A NaOCl accident refers to any event in which NaOCl is expressed beyond the apex of a tooth and the patient immediately manifests some combination of the following symptoms:

- Severe pain, even in areas that were previously anesthetized for dental treatment.
- Swelling.
- Profuse bleeding, both interstitially and through the tooth.

CAUSES OF NAOCL ACCIDENT

- Some of the reasons that a hypochlorite accident may occur include forceful injection of the irrigating solution, having an irrigating needle wedged into a root canal, and irrigating a tooth that has a large apical foramen, apical resorption, or an immature apex. Considering its excellent tissue-dissolving properties, a large volume of the irrigant under pressure will lead to immediate strong reactions.⁴⁵⁸ Some patients have several days of increasing edema and ecchymosis, accompanied by tissue necrosis, paresthesia, and secondary infection (Figure 35). Although most patients recover within 1 to 2 weeks, long-term paresthesia and scarring have been reported,^{456,457} as well as an incident that described the injection of NaOCl into the maxillary sinus resulting in hospitalization and surgical intervention.⁴⁵⁹

MANAGEMENT OF NAOCL ACCIDENT

- Recognize that a hypochlorite accident has occurred. NaOCl has immediate toxic effects on vital structures resulting in hemolysis, ulceration, and necrosis.^{454,458}
- Attend to the immediate problem of pain and swelling. Administer a regional block with a long-acting

Figure 35 The situation several hours after 2.5% sodium hypochlorite solution was expressed through the roots of a maxillary premolar. The patient experienced immediate severe pain and swelling subsequent to the accident.

anesthetic solution. With the irrigant spreading rapidly over a wide region, pain management is difficult because symptoms from distant anatomic structures will continue to cause discomfort. This also explains the extreme pain felt during the accident despite establishment of adequate local anesthesia before treatment was begun. A reported incident describes flushing the palatal canal of a maxillary molar with sterile water to dilute the effects of the hypochlorite that was expressed into the sinus through the same route.⁴⁶⁰

- Reassure and calm the patient. The reaction, although alarmingly fast, is still a localized phenomenon and will resolve with time. If available, nitrous oxide sedation can help the patient cope throughout the remainder of this emergency.
- Monitor the tooth over the next half an hour. A bloody exudate may discharge into the canal. This bleeding is the body's reaction to the irrigant. Remove the fluid with high-volume evacuation to encourage further drainage from the periapical tissues. If drainage is persistent, consider leaving the tooth open over the next 24 hours.
- Consider antibiotic coverage. If the treated tooth is pulpless and cleansing and shaping procedures have not been completed, consider prescribing amoxicillin, 500 mg, four times a day, over the next 5 days.
- Consider administering an analgesic. Because of possible bleeding complications with aspirin and

other nonsteroidal anti-inflammatory drugs, an acetaminophen-narcotic analgesic combination may be more appropriate. If swelling is extensive, it is best to caution the patient to expect bruising or pooling of blood as it subsides.

- Consider prescribing a corticosteroid or antihistamines which can help minimize the ensuing inflammatory process.^{453,458}
- Give the patient home care instructions. For the first 6 hours, the patient should use cold compresses to minimize pain and swelling. Subsequently, warm compresses should be used to encourage a healthy healing response.
- Consider referring the patient. If the patient continues to be apprehensive or needs additional reassurance or develops complications, referral to the endodontist or oral surgeon is appropriate. Informing the specialist about the patient and the nature of the problem will ensure a smooth transition between offices for the patient.

PREVENTION OF NAOCL ACCIDENT

A hypochlorite accident is completely avoidable. As an endodontic irrigant, hypochlorite solution is meant to flush debris from the root canal system. Part of the efficacy of hypochlorite depends on the volume of irrigation and the depth of penetration of the irrigating needle. Even so, the solution must be delivered in a passive manner to avoid apical extrusion. Because root canals are coronally flared during the cleansing and shaping process, the irrigating needle can penetrate deeper into the canal and still not bind against the walls.

The following measures are recommended to prevent a hypochlorite accident:

1. Side-vented needles will add a measure of safety to prevent binding and decrease intracanal pressures.⁴⁶¹
2. Bend the irrigating needle as needed to confine the tip of the needle to higher levels in the root canal and to facilitate direct access to all teeth regardless of angulation.
3. Never place the needles so deeply into the canal that it binds against the walls.
4. Oscillate the needle in and out of the canal to ensure that the tip is free to express irrigant without resistance.
5. Express the irrigant slowly and gently.
6. Stop irrigating if the needle jams or if there is any detectable resistance when pressing against the plunger of the syringe.

7. Check the hub of the needle for a tight fit to prevent inadvertent separation and accidental exposure of the irrigant to the patient's eyes.

Although a hypochlorite accident requires immediate management, the definite assessment and accurate identification of this dental emergency must follow a prioritized process of recognition and response.

Air Emphysema

The dangers of air emphysema from compressed air are well known. Subsequent to surgical procedures in dentistry, there are reports of impingement on the airway as well as vision affects and cardiac complications.⁴⁶²⁻⁴⁶⁴ Additionally, air introduced into periapical tissues during invasive root canal therapy has the potential to do great harm. While this phenomenon is a rare occurrence during endodontics, the risk is present and has been reported in animals to cause serious clinical complications.⁴⁶⁵ Shovelton⁴⁶² reviewed 13 reports of air emphysema and found their etiology to range from pressurized air forced into the root canal to oxygen gas emphysema caused by irrigation past the apex with hydrogen peroxide. The patients in his review demonstrated signs of emphysema in the face, the neck, and suborbital regions. In an animal study in dogs, Rickles and Joshi⁴⁶⁵ could not rule out air emphysema as the cause of death in four of seven dogs. When air dissects along fascial planes to produce emphysema, there may be impingement upon critical anatomical structures. Moreover, infection can be carried deeper into tissue spaces. The main symptom of emphysema is a crepitus of the swollen tissues (Figure 36).

In a study done on pigs, the investigators detected significant pressures during air-drying beyond the apex of the roots especially with apical root diameters of file sizes larger than #20. The authors concluded that compressed air should never be a component in the drying of a root canal that is open to the periapical tissues.⁴⁶⁶

The mishaps described in this chapter that could potentially cause permanent injury to a patient are disconcerting for any practitioner to consider. We recognize that knowledge of these injuries must encourage reflection on the safe and prudent practice of endodontics. Our ethical obligation to protect patients from harm is met when we as a profession can provide advanced and sophisticated therapies in a controlled manner with patient welfare as an overriding priority.

Figure 36 **A**, Radiograph of a lower left canine. The tooth was perforated during an attempt to locate the root canal space. An air emphysema complication occurred when air was blown into the access in an attempt to improve vision. **B**, The patient immediately experienced swelling and the characteristic air crepitus of the swollen tissues.

CHAPTER 32

TREATMENT OUTCOME: THE POTENTIAL FOR HEALING AND RETAINED FUNCTION

SHIMON FRIEDMAN

Definitions and Classification

When attempting to review the outcome of studies on nonsurgical endodontic treatment (*initial* root canal treatment,¹⁻³⁰ orthograde *re-treatment*,^{1,2,6,16,34,41,43,50,57,81-92}) and surgical endodontic treatment (apical surgery,^{82,84,88,89,93-151} intentional *replantation*¹⁵²⁻¹⁶¹), it quickly becomes apparent that outcome definitions and classification have been inconsistent. This has resulted in considerable variability of the reported “success” rates.¹⁶² Much of the confusion is created by the definition of outcomes using nonspecific ambiguous terms, such as “success” and “failure.” The frequent lack of calibration in outcome assessment, particularly differences in observer strategies for recording of radiographic findings, has amplified the inconsistency of reported outcomes.

In the majority of endodontic outcome studies, the outcome assessment is based on clinical and radiographic measures. Nevertheless, in many studies on nonsurgical treatment,^{3,11,12,16,22,28,37,41,45,47,48,52,54,56,58,60,66,71,75,163} and in at least one apical surgery study,¹²¹ the radiographic appearance is used as the only outcome measure. This strategy may overstate the “success” rate by not noting teeth that could be radiographically normal but symptomatic.¹⁶⁴

Radiographic Outcome Assessment

Assessment of radiographic images has been shown to be highly inconsistent.¹⁶⁵⁻¹⁶⁹ The consistency of assessment can be significantly improved when structured observer and calibration strategies are applied, as suggested for endodontic treatment.^{167,169-175} However, the suggested strategies have not been frequently applied in endodontic outcome studies.

To improve consistency of radiographic assessment, the Periapical Index (PAI)¹⁷⁶ has been used with increasing frequency. The PAI system includes a calibration kit of 100 radiographic images of root-filled teeth for determining a level of sufficient consistency. Assessed radiographs are compared with a set of five radiographic images (see Figure 1 in Chapter 16, “Radiographic Interpretation”) derived from Brynolf’s histologic–radiographic correlation study,¹⁷⁷ representing a healthy periapex (scores 1 and 2), and increasing extent and severity of apical periodontitis (scores 3 to 5). Radiographs are assessed independently in a “blind” manner, by assigning a score according to which of the five reference images it appears to match. This results in improved reproducibility and sensitivity of the assessment.^{72,176} The PAI has been used mainly for outcome assessment after nonsurgical treatment.^{48,52,54, 56,66,67,70-72,75,76,78,79,90} Although it has not been validated for outcome assessment after apical surgery,¹⁴⁴ the PAI was used in one apical surgery study¹⁴⁸ to assist in unbiased outcome assessment and to promote comparisons with studies on nonsurgical endodontic treatment reported by the same group of researchers.^{67,70,78,90} Results obtained with the PAI scores cannot be directly interpreted as measures of “success” or “failure”; however, PAI scores have been dichotomized with scores 1 and 2 representing “healthy” periapical tissues and scores of 3 and above representing “disease.”^{54,56,66,67, 70,71,76,78,90,178-180}

AMBIGUITY OF OUTCOME DEFINITION AS “SUCCESS” AND “FAILURE”

The main confusion in reported outcomes results from differences among studies in the definition of a successful outcome when using “strict” or “lenient” classifications of “success.”

Strict Definition of "Success"

In the majority of the studies, a successful outcome is strictly defined by complete absence of radiolucency and absence of clinical signs and symptoms. After nonsurgical treatment, complete normalcy has been named "success." However, a small radiolucency may be accepted around extruded root filling materials,^{1,6,43,53,86} but any other remaining radiolucency is excluded, even if its size is decreased; unchanged radiolucencies represent "failure". A smaller radiolucency, in the presence of clinical normalcy, is usually considered as "incomplete healing."⁵⁰ This combination is not considered as a successful outcome, but rather as an interim outcome requiring further observation.

In studies on apical surgery, complete normalcy is often named "complete healing" and occasionally "success." A typical radiographic appearance of a periapical scar (Figure 1), named "incomplete healing" or "cicatrice," has also been considered a successful outcome.^{96,174,181-183} A reduction in size of a radiolucency coupled with clinical normalcy is usually considered "uncertain healing." It appears that the "complete" healing category has been subject to considerable observer variation,¹⁷³ whereas the "incomplete healing" category has been subject to interpretation errors.¹⁸³

Lenient Definition of "Success"

In some studies of nonsurgical treatment, "success" is defined as the absence of clinical signs and symptoms. Clinical normalcy may be accompanied by a residual radiolucency, either decreased^{3,16,29-31,36,47,59,60,85} or unchanged in size,^{11,33,42} but not increased. These lenient definitions contrast sharply with the strict one outlined above.

In studies on apical surgery, further confusion has been caused by misinterpretation or misuse of the "incomplete healing" category. Although teeth classified as "incomplete healing" are originally defined as healed by scar formation, researchers may erroneously include teeth with persistent disease in this category.¹⁸³ Furthermore, "incomplete healing" has been used to describe decreased radiolucency rather than scars, yet still considered a successful outcome. A successful outcome is occasionally defined primarily by the normal clinical presentation, even if it is accompanied by different degrees of residual radiolucency.^{113,131}

Clearly, use of "lenient" outcome criteria that do not require radiographic normalcy increases the "success" rate in comparison with use of "strict" criteria that do require radiographic normalcy. Friedman et al.⁵⁰ reported 78% complete healing and 16% incomplete healing after nonsurgical treatment. This would be 94% by the "lenient" criteria. The discrepancy would be even larger if unchanged radiolucencies were

included in the criteria for success. Wang et al.¹⁴⁸ reported that 74% of the teeth healed after apical surgery using "strict" criteria. However, they also report that 15% of the teeth presented with a decrease in size of the radiolucencies and only 9% had clinical signs and symptoms. By the "lenient" criteria, their success would be 89% if reduction of radiolucency was required or 91% if only clinical "normalcy" was required.

The debate regarding the use of strict versus lenient criteria for outcome assessment after endodontic treatment is specific to teeth affected by preoperative apical periodontitis. It is noteworthy that apical periodontitis is frequently asymptomatic, both before treatment and when persisting after treatment.^{34,55,62,65,67,70,77,78,90,184-187} Notwithstanding the frequent absence of symptoms, apical periodontitis is universally considered a disease requiring therapy. Thus, persisting apical periodontitis after therapy cannot be regarded as "success" only because it is asymptomatic, and treatment is still indicated.

Outcome Definition as "Uncertain," "Questionable," "Doubtful," or "Improved"

The terms "uncertain," "questionable," "doubtful," or "improved" were originally introduced to imply uncertainty of the outcome. They have also been used to define improved outcomes. When used strictly, these terms described cases that could not be assessed because of insufficient radiographic information and thus were not included in either the successful or unsuccessful outcome categories.^{1,2,6,22-24,28,57,62} Exclusion of these cases from the study sample usually lowered the success rate by approximately 5%, as demonstrated by recalculation of success rates in several of the relevant studies.^{2,6,22,57} By contrast, the same terms have been used to describe cases with a decrease in size of the radiolucencies and considered either as a successful or as an uncertain outcome for nonsurgical treatment^{7,17,19,40,41,50,51,55,61} and apical surgery.^{82,93,96,98,100,101,103,107,109,118,127,137-139,141,146,147,150,151,163,188} Use of this modified classification lowered the failure rate in comparison with the strict classification. In many other studies on apical surgery,^{84,89,99,112,116,117,120,122,130,133,136,138,140,145,183,189-191} "uncertain healing" has been used for a decrease in size of a radiolucency that appears different from "incomplete healing." In these studies, if "uncertain healing" persists for 4 years or longer, it is considered to be an unsuccessful outcome.

Consequences of Using the Terms "Success" and "Failure"

Clearly, the ambiguity of the term "success" confuses communication with patients. Of particular concern

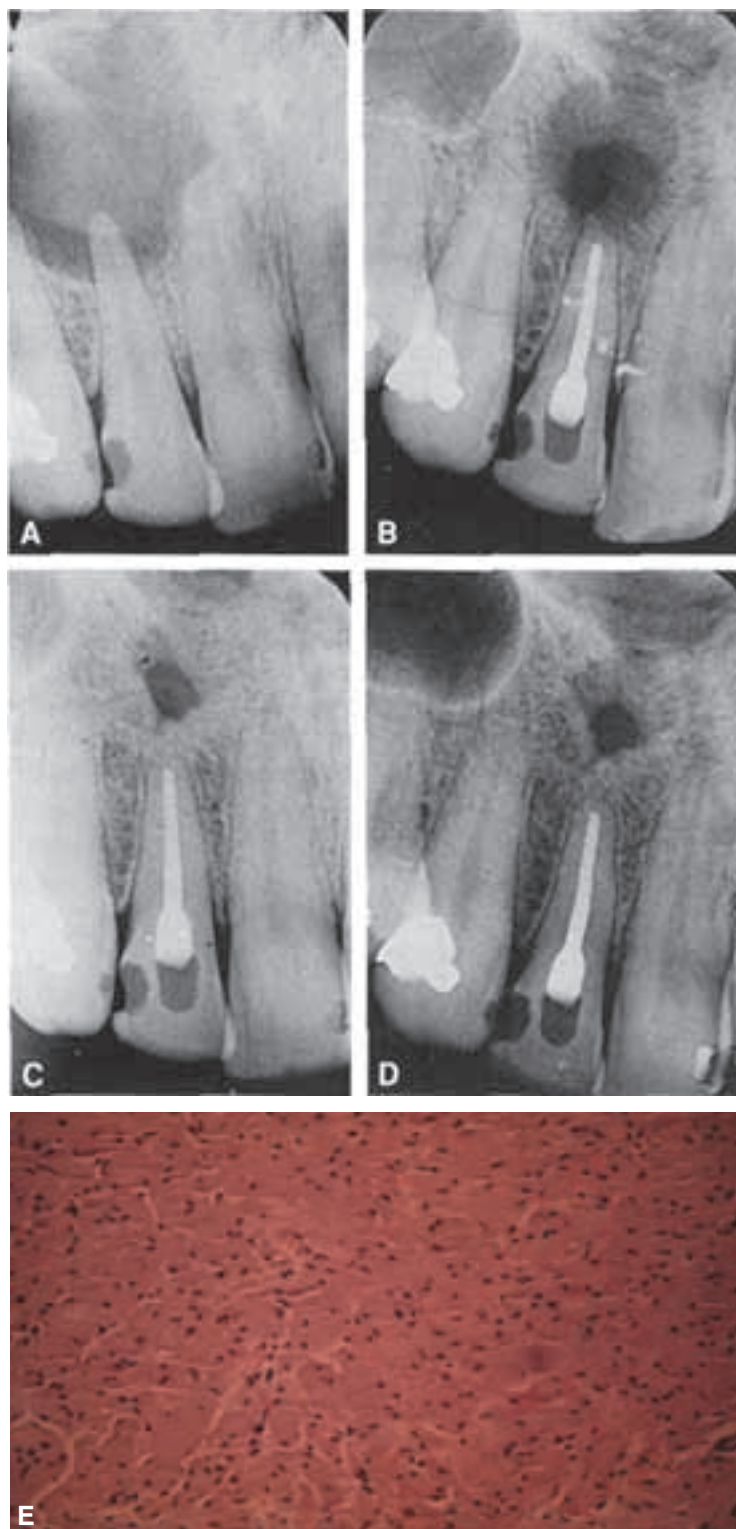

Figure 1 Progressive development of apical scar. This permanent artifact frequently follows through-and-through osseous destruction of both labial and palatal cortical plates. **A**, Before cyst enucleation. **B**, Six months following surgery. **C**, One year following surgery. **D**, Two years following surgery; scar is permanent. **E**, A similar nonpathologic radiolucent area was removed and examined; it is filled with fibrous connective tissue, no inflammatory cells. (**A–D**, Photos courtesy of Dr. M. Krasnoff; **E**, Photos courtesy of Dr. S.N. Bhaskar)

is the use of “success” for single-tooth implants, based on different criteria than those used in endodontics.^{192,193} The very high “success” rates reported for single-tooth implants^{193–197} may mislead patients who are weighing endodontic treatment against replacement of the tooth with an implant. Being unaware of the differences in the definition of “success,” the patient may opt for the better chance of “success,” and have a tooth removed that could remain functional for many years.

Classification of an unfavorable outcome as “failure,” used in many endodontic treatment outcome studies, is also a concern. This term does not imply the necessity to pursue any course of action, and in addition, it has a negative connotation.¹⁹⁸ It has been suggested⁵² that communication with patients can be improved by replacing the value-laden terms “success” and “failure” with neutral expressions, such as “chance of healing” and “risk of inflammation.” It is advisable, therefore, to avoid the terms “success” and “failure” in defining the *outcome* of endodontic treatment.

USE OF THE TERMS HEALING/DISEASE/FUNCTION FOR IMPROVED CLARITY

The general definition of success is “the accomplishment of an aim or purpose” (Oxford Dictionary), suggesting that the outcome is best defined in direct relation to the specific aim. In the context of endodontic treatment, the aim is to prevent or cure apical periodontitis.¹⁹⁹ Thus, the outcome of endodontic treatment should be related to “healing.”^{35,52,164,200,201} Although Rud et al.¹⁷⁴ introduced a classification for outcome assessment after apical surgery that referred to healing (complete, incomplete, uncertain, unsatisfactory), it was construed by others to represent “success” and “failure.”^{116,120, 138,143,150,151} Rather than depending on interpretations of “success” and “failure,” the terms “healed,” “healing,” and “disease” should be used to clearly describe the actual observation, as follows:

- **Healed:** Complete clinical and radiographic normalcy (no signs, symptoms, residual radiolucency) (Figure 2). This category also includes the typical appearance of a scar after apical surgery^{116,120,173,174, 181–183} (see Figure 1).
- **Healing (in progress):** Decrease in size of a radiolucency and clinical normalcy after a follow-up period shorter than 4 years (Figure 3).
- **Disease (refractory/recurrent/emerged apical periodontitis):** Presence of radiolucency (new, increased, unchanged, or reduced after observation exceeding 4 years) regardless of clinical presentation (Figure 4), or presence of symptoms regardless of radiographic appearance.

Use of these aim-related terms, to define the outcome of treatment, can greatly improve communication with patients. Patients pursuing treatment should be encouraged to identify specific aims and thus define their expected outcome that can be considered a success. The majority of patients may expect healing; however, individual patients may be satisfied with just elimination of clinical signs and symptoms. This may be particularly relevant when clinical conditions suggest a compromised prognosis, such as an extensive loss of supporting bone prior to apical surgery.¹¹⁰ In these circumstances, if a patient is still motivated to attempt treatment although healing is unlikely to occur, the aim of treatment is retention of the tooth in “asymptomatic function,” and the outcome is defined as follows:

- **Asymptomatic function:** Clinical normalcy with or without a persistent radiolucency, decreased or unchanged (Figure 5).

THE EVIDENCE-BASE FOR THE OUTCOME OF ENDODONTIC TREATMENT

Like all health care providers in the past, endodontists had been expected to make clinical decisions and prescribe treatment for individual patients

Figure 2 Outcome classification labeled as “healed” after initial treatment. **A**, Maxillary second molar with apical periodontitis extending along the mesial root surface, and associated sinus tract (traced with a gutta-percha cone). **B**, Completed treatment. **C**, At 1 year, the radiolucency is completely resolved and the tooth is symptom free, indicating the lesion has healed. (Reprinted with permission from Friedman 2002.¹⁶⁴)

Figure 3 Outcome classification labeled as “healing” after orthograde re-treatment. **A**, Three prefabricated posts in mandibular molar with post-treatment disease. **B**, Access was prepared through the crown and posts were removed; canals were dressed with calcium hydroxide. **C**, Completed root canal re-treatment. **D**, At 6 months, the lesion is reduced and the tooth is symptom free, indicating that healing is in progress. Regrettably, the access cavity was not properly restored. (Reprinted with permission from Friedman 2002.²²³)

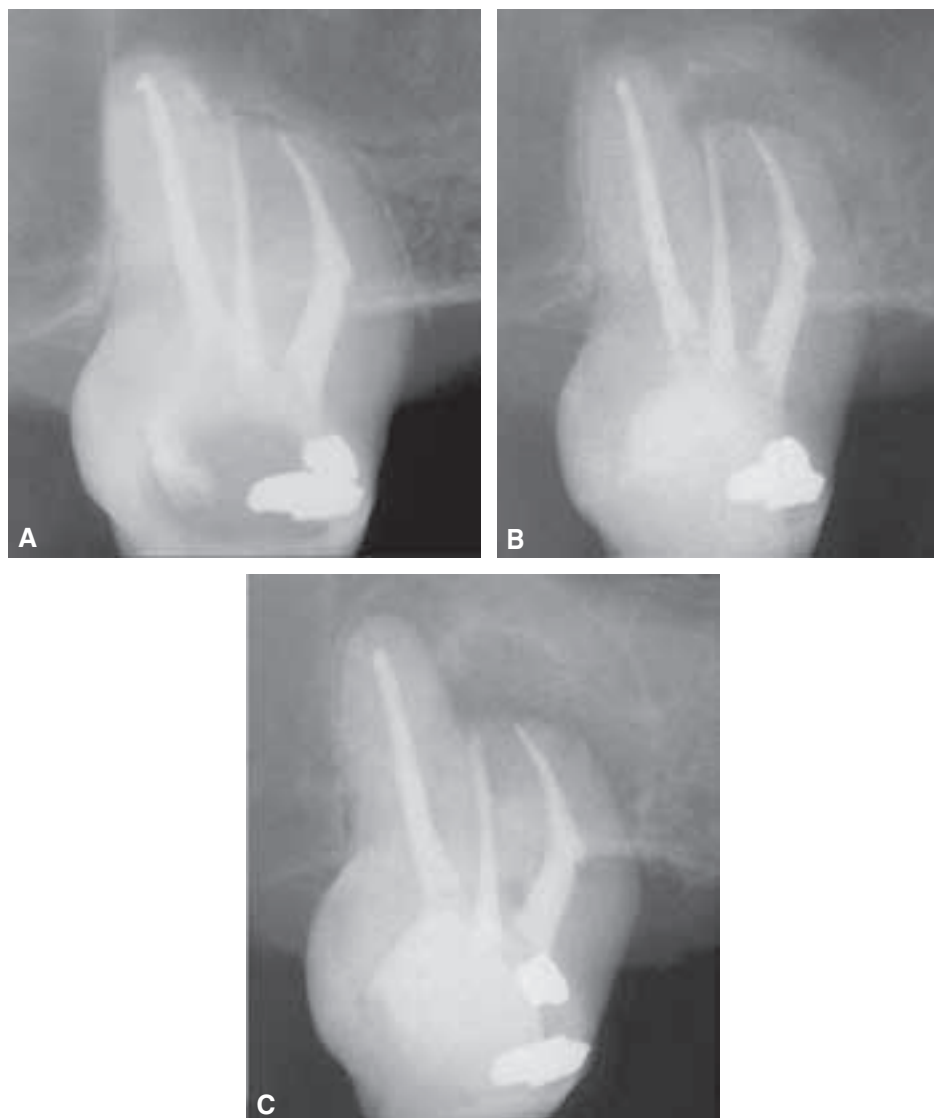

Figure 4 Outcome classification labeled as “emerged disease” after initial treatment. **A**, Immediate postoperative radiograph of maxillary second molar with no evidence of apical periodontitis. **B**, Emerged disease at 3 years. **C**, Further expansion of disease at 6 years. In spite of the presence of disease, the tooth is symptom free. (Reprinted with permission from Friedman 2002.²²³)

based on their knowledge and experience. Currently, health care providers are expected to base clinical decisions on evidence derived from clinical trials. Furthermore, they are required to share the evidence-base information with patients, and to encourage them to participate in the clinical decision-making process, in accordance with the concept of “patient autonomy.”^{202–206} Thus, endodontists should inform patients about the benefits and risks of available treatment alternatives and then allow patients to select specific treatments. To be able to do so, endodontists

must be well versed in the evidence, primarily the current knowledge about treatment outcomes, supporting the treatment procedures they suggest to patients.

As different forms of endodontic treatment have been used clinically for over 100 years, numerous studies have been published where information can be gleaned on the outcome of endodontic treatment encompassing data from over 20,000 treated teeth. As a whole, this extensive body of literature is characterized by great diversity of the reported outcomes. This

Figure 5 Outcome classification labeled as “functional” after initial treatment. **A–C**, Mandibular first molar with apical periodontitis, associated with gingival recession, probing depth beyond the apex, and extensive bone loss on the buccal aspect. The patient was advised of poor prognosis, but decided to proceed with treatment in an attempt to retain the tooth in function as long as possible. **D, E**, Completed root canal treatment and application of a resorbable guided tissue regeneration membrane. **F, G**, At 6 months, the radiolucency has been considerably decreased and the gingival tissue appears healthy. Although the prognosis remains poor, the patient’s goal has been achieved. Replacement of the defective crown has been deferred by the patient. (Reprinted with permission from Friedman 2002.¹⁶⁴)

has been demonstrated in several comprehensive reviews published at different junctures, on nonsurgical treatment reported in the first half of the twentieth century,¹ on apical surgery reported up to 1970,⁹⁹ and on both nonsurgical and surgical endodontic treatments reported from 1956 to 1997.¹⁶² These and subsequent narrative reviews^{164,200,201,207} have revealed inconsistencies and, at times, contradictions among the reported outcomes of nonsurgical and surgical endodontic treatments. Thus, despite the abundant information available, answers to many questions concerning the outcome of endodontic treatment procedures have been equivocal because of poorly standardized methodology of the many studies.¹⁶² The rapid evolution of clinical procedures has rendered results of specific studies less relevant today than when they were published.

To seek evidence for the outcome of state-of-the-art treatment, a review must focus on studies selected on well-defined criteria. Similarly, this chapter reviews *selected articles* reporting on the outcome of nonsurgical and surgical endodontic treatments for the prevention and therapy of apical periodontitis, to define the treatment outcomes, and to identify the predictors of outcome. The nonsurgical treatments, initial root canal treatment and orthograde re-treatment, are reviewed first, followed by surgical treatments.

GENERAL CONSIDERATIONS

Clinical studies fall into different design categories. Some confusion exists with regard to these categories, resulting in differences in reviews of the literature. For example, in a recent series of review articles on evidence-based endodontics,^{208–211} the authors defined the “cohort study” as a follow-up of an exposed cohort compared with an unexposed cohort, in contrast to the definition suggested below.

In this chapter, study categories are defined according to the Cochrane Collaboration (<http://www.informedhealthonline.org/item.aspx?tabid=15>):

- Prospective study: “In a prospective study, the study is designed ahead of time, and people are then recruited and studied according to the study’s criteria.”
- Retrospective study: “In a retrospective study, the outcomes of a group of people are examined in hindsight (‘after the event’). Retrospective studies are generally more limited in the data

available for analysis, as the data have rarely been collected with the needs of that particular study in mind. This kind of limitation means that a retrospective study is usually less reliable than a prospective study.”

- Clinical trial: “A clinical trial involves administering a treatment to test it. It is an experiment. Clinical trial is an umbrella term for a variety of health care trials . . . Types include uncontrolled trials, controlled clinical trials (CCT), community trials, and randomized controlled trials (RCT). A randomized controlled trial is always prospective.”
- Observational study: “A survey or nonexperimental study. The researchers are examining and reporting on what is happening, without deliberately intervening in the course of events.”
- Cohort study: “A ‘cohort’ is a group of people clearly identified; a cohort study follows that group over time, and reports on what happens to them. A cohort study is an observational study, and it can be prospective or retrospective.” [A prospective study is also named “concurrent cohort study,” while the retrospective study is named “historical cohort study.”²¹²]
- Case-control study: “Compares people with a disease or condition (‘cases’) to another group of people from the same population who do not have that disease or condition (‘controls’). A case-control study can identify risks and trends, and suggest some possible causes for disease, or for particular outcomes. A case-control study is retrospective.”
- Cross-sectional study: “Also called a prevalence study. It is an observational study. It is like taking a snapshot of a group of people at one point in time and seeing the prevalence of diseases or actions in that population.”
- Case series: “A case study is a report of a single experience. A case series is a description of a number of ‘cases.’”

One common strategy for appraisal of clinical studies has been developed for systematic reviews of the literature.²¹³ It ranks studies according to the following descending hierarchy of evidence, based on the research design and methodological rigor:

- Rigorous randomized controlled trial (RCT); systematic review (SR) or meta-analysis of the same.
- Rigorous cohort study; SR of the same; compromised RCT.
- Rigorous case-control study; SR of the same.

- Compromised cohort or case–control study; cross-sectional study; case series.
- Expert opinion; case report; narrative literature review.

The different designs of clinical studies may be best suited for different aims, focusing on effectiveness of different interventions, prognosis after a specific intervention, or risks associated with the intervention. Importantly, studies designed to assess prognosis should be differentiated from those designed to assess risk, because the prognostic factors identified by the former can be different from the risk factors identified by the latter.²¹² Accordingly, a review geared to answer specific questions should focus on reviewing studies with matched design.²¹² For example, the suggested design for questions regarding the prognosis is a cohort study, whereas the suggested design for questions regarding the benefits of different treatments is an RCT.^{212,214}

Evidence-based practice is defined as “... the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.”²¹⁵ Thus, reviews should focus on the best evidence available, even if it does not comply with the highest level. In this context, the methodological rigor of a clinical study is a crucial consideration,²¹⁶ as rigorous cohort studies can outweigh compromised RCTs. Also, it has been suggested that structured reviews of well-designed observational studies can yield consistent conclusions with those of systematic reviews and meta-analyses of RCTs.^{217,218} Therefore, to address the primary focus of this chapter—the prognosis of endodontic treatment—cohort studies that appear to be methodologically adequate are included in the appraisal process.

APPRAISAL OF ENDODONTIC OUTCOME STUDIES

A primary concern in the review of clinical studies is their validity and relevance.²¹³ Different forms of bias, frequently encountered in cohort studies, may distort their conclusions so that differences are demonstrated between groups that may not really exist, whereas existing differences may not be shown.²¹² Bias can potentially occur during assembly of the study cohort when groups of subjects differ in regard to other prognostic factors than the studied ones, and these extraneous factors may influence the outcome of the study.²¹² Thus, differences in outcome may be attributed to the assessed variables, although in reality they may result from inherent

differences at the beginning of the study. In endodontic cohort studies, assembly bias can occur if subjects differ in preoperative characteristics, such as presence or absence of apical periodontitis in studies on nonsurgical treatment, or prior treatment history before apical surgery, i.e., only initial treatment or also re-treatment. Bias can also occur if assembled subjects have a preferential capacity to heal. For example, the majority of subjects may be healthy, whereas the healing capacity of others may be impaired because of compromised systemic health. In studies on apical surgery, occasional teeth treated without apical periodontitis^{139,147} have a much better capacity to heal after surgery than the majority of the teeth affected by apical periodontitis. Another stage when bias can occur is during assessment of the outcome (measurement bias), when subjects differ in the chance of having a specific outcome detected.²¹² In the endodontic cohort studies, the clinical signs and symptoms may not be detected. A particular concern is examination of the outcome by the providers of treatment, whose interpretation of follow-up radiographs may be biased toward more favorable assessment.¹⁶⁵

To minimize bias in appraisal of studies on prognosis, the following checklist is suggested:^{212,215,219–221}

- Was the study cohort defined, assembled at the inception of the study, described in detail, entered at a similar point in the course of the disease?
- Was the referral pattern described?
- Were baseline features measured reproducibly?
- Was the follow-up achieved in at least 80% of the inception cohort, the follow-up period described, and long enough for the outcome to occur?
- Were the criteria used for outcome assessment described, objective, clinically important, and reproducibly measured?
- Was the outcome assessment blind?
- Was adjustment for extraneous prognostic factors carried out?

The criteria included in the checklist above can be grouped into four general categories, used as the basis for appraisal of the endodontic outcome studies. This extensive body of literature is characterized by great diversity of reported outcomes, caused by differences among the studies in the composition of study materials, treatment procedures, and methodology. Examples of these differences are highlighted below, from studies on nonsurgical and surgical treatments.

Cohort, at Inception and Endpoint of the Study

Prospective studies, where the cohort is defined before the onset of the study and observed over time, provide the best evidence. To avoid biased interpretations, the inception cohort should be clearly characterized, including data about the subjects' age, gender, and health status, types of teeth treated, proportion of teeth with apical periodontitis, and previous endodontic treatment history. All these variables can potentially influence the outcome. In fact, the considerable variation in cohort characteristics of the endodontic studies may have contributed to the great diversity of reported outcomes, as can be observed in the following examples:

- **Tooth location, number of roots:** The minority of studies on nonsurgical endodontic treatment include only anterior or single-rooted teeth,^{5,11,13–15,17,26,35,43,46,53,54,61,86,88,222} whereas the majority combine single- and multi-rooted teeth. By contrast, the majority of studies on apical surgery include primarily anterior or single-rooted teeth, fewer studies include a substantial proportion of multi-rooted teeth,^{84,100,121,122,129–131,133–137,139,145,148,190} and only a few studies include primarily multi-rooted teeth.^{102,107,108,117,118,140,141,147,191} Differences in complexity of treatment between single- and multi-rooted teeth may be reflected in the reported outcomes, particularly for apical surgery where access to the multi-rooted, posterior teeth is generally more restricted than to the anterior, single-rooted ones. Furthermore, in studies where each root is evaluated as an independent unit,^{2,19,22,37,39–41,43,52,56,57,61,74,81} the contribution of multi-rooted teeth to the total study sample is multiplied because they contribute two or three units each, as opposed to the single unit contributed by each single-rooted tooth. Also, when multi-rooted teeth are evaluated as whole units and assessed by the worst appearing root, the risk of observing refractory apical periodontitis after treatment is multiplied⁵⁰ (Figure 6). Thus, the outcome recorded is poorer than what would be recorded if each root of the multi-rooted tooth were evaluated independently.

- **Proportion of teeth with apical periodontitis:** The proportion of teeth with preoperative apical periodontitis ranges from less than 30^{2,7,8,15,21,37,40,57,65,69,72,80} to 100%,^{13,24,26,28,35,39,42,45,51,53–55,61,66,76,86,88,222} and it is not even specified in many other studies.^{4,20,25,29–32,49,52,56,62,79} It is well established that the presence of apical periodontitis has a negative influence on the outcome of nonsurgical endodontic treatment.²⁰⁰ Therefore, the proportion of the affected teeth included in the cohorts of different studies may have influenced the reported outcomes; the more such teeth included, the poorer may be the overall outcome reported.
- **Previous treatment history—initial treatment or re-treatment—before apical surgery:** The majority of teeth included in studies on apical surgery have had only initial root canal treatment performed previously; refractory apical periodontitis in these teeth is likely to be sustained by bacteria harbored within the root canal system. Because containing the intra-canal bacteria by means of a root-end filling may be ineffective, the outcome of the surgical procedure may be compromised.^{148,223} In one study, however, all the teeth had “at least one nonsurgical re-treatment to enhance canal debridement,”¹³⁸ and 91% of them healed. In another study¹⁴⁴ where 90% of the teeth healed, the authors state that “...if an existing root filling was deemed inadequate, it was replaced” indicating that an unknown proportion of teeth had re-treatment performed before surgery. Persistent disease after orthograde re-treatment is likely to be sustained by bacteria colonizing an inaccessible, possibly extra-radicular site (Figure 7). Because such sites can be eradicated by the surgical procedure, a healing rate in the range of 90% can be expected.^{148,223} Thus, the previous treatment history of the teeth included in studies on apical surgery is expected to influence the reported outcome.

Among the characteristics specified, the pattern of referral of the treated cohort should be described, including type of patients treated and case selection criteria used. These data help determine the external

Figure 6 Outcome assessment of a multi-rooted tooth after apical surgery. **A**, Root-filled mandibular first molar with persistent apical periodontitis; the mesial lesion is considerably larger than the distal one. **B**, Completed surgery, including root-end fillings with amalgam and varnish. **C**, At 2.5 years, the distal radiolucency is resolved, but the mesial remains. Presence of symptoms suggests persistence of apical periodontitis. The tooth was then evaluated as one unit in a clinical study,¹¹⁷ and being recorded as persistent disease. By contrast, if the roots were evaluated independently, the tooth would contribute two units, one healed and the other having persistent disease. (Reprinted with permission from Friedman 2006.²⁰¹)

validity (applicability to the population at large) of the reported results.²¹² Case selection is likely to determine the results of a clinical study,⁴⁹ as potential study subjects are included or excluded according to prognosis. Inspection of the endodontic outcome studies reveals drastic differences in case selection criteria, as follows:

- Case selection criteria: Among studies on nonsurgical treatment, cases judged to have an unfavorable prognosis or subjects with a compromised immune system were excluded in specific studies.^{11,29–31,54,66,71} By contrast, one study⁴⁰ included only teeth with obstructed canals in which the ability to fulfill

Figure 7 Persistent disease after previous re-treatment suggests probability of extra-radicular infection. **A**, Root-filled mandibular first molar with persistent apical periodontitis affecting the mesial root. **B**, Completed orthograde re-treatment of the mesial canals. **C**, At 1 year, the expanded lesion indicates persistence of apical periodontitis. As the previous re-treatment may have eliminated intra-canal bacteria, the infection may be sustained by extra-radicular bacteria. **D**, Completed surgery, including root-end filling with Super EBA. **E**, At 1 year after surgery, the lesion is healed. (Apical surgery and follow-up courtesy of Dr. Steven Cohen, Toronto, Canada; Reprinted with permission from Friedman 2006.²⁰¹)

the technical objectives of treatment was doubtful, whereas in other studies^{50,67,70,78,90} teeth were included even if they were compromised by advanced periodontal disease or procedural errors, without specific exclusion criteria. Among studies on apical surgery, teeth with deep periodontal defects, that could impair the prognosis, were frequently excluded.^{88,135,138,143,144,149,150} By contrast, one study¹¹⁰ included only teeth affected by loss of the buccal bone plate, whereas in the majority of studies, consecutive cases were included without specific exclusion criteria. Thus, the reported outcomes in specific studies may have been influenced by inclusion of teeth with poor prognosis in the study sample.

Availability of the entire study cohort for outcome assessment at the endpoint of the study is subject to population mobility, particularly in long-term studies. The outcome of treatment in the unavailable subjects is unknown. In the best-case scenario (if all missing subjects experienced a favorable outcome), the reported outcome would be better, whereas in the worst-case scenario (if all missing subjects experienced an unfavorable outcome), the reported outcome would be poorer. For example, in a study on apical surgery,¹⁴⁸ the recall rate was 85%, and 74% of the teeth have healed. The authors calculated that in the best-case scenario 80% of the teeth would be healed, whereas in the worst-case scenario 57% would be healed. Because the overall “healed” rate is further from the lower value than from the upper one, it appears to be overestimated.¹⁴⁸ Thus, when a large proportion of the inception cohort is unavailable, the results of the study may be considerably skewed and subject to speculation.^{1,212} The results may be considered invalid, unless the unavailable subjects are deceased or cannot be reached, suggesting that their absence is not related to the outcome.^{1,212} For this reason, at least 80% of the treated subjects should be examined at the endpoint of the study for a high level of evidence to be achieved.^{219–221} The rest of the inception cohort must be accounted for, so that “dropouts” (subjects who do not present for follow-up at their own volition; their absence may be related to the outcome of interest) and “discontinuers” (subjects who are excluded from the study by the investigator for accountable reasons, e.g., death or relocation; their absence is not related to the outcome of interest) are identified, allowing accurate calculation of the recall rate. The recall rates in the majority of the endodontic outcome studies fall below the requirements of a good level of evidence, as outlined below:

- **Recall rate:** The reported recall rates in the different studies on nonsurgical endodontic treatment have varied from under 20^{16,18,57} to over 90%.^{9,45,51,53,55,61,68,80,86,88} Similarly, in the studies on apical surgery, the recall rates varied from less than 20¹²⁹ to over 90%.^{84,88,89,100,101,103,107,109–111,113,114,118,122–124,128,131,132,137,138,141,147,150,151} Moreover, the recall rate is not even reported in many of the studies on nonsurgical treatment^{5,7,10,13,17,20,25,26,33,79,82} and on apical surgery.^{82,104,112,115,119,120,125,126,224} This may be one reason for the inconsistent outcomes reported among all the studies.

Finally, the size of the sample included in the clinical study may be required to exceed a predetermined threshold. The sample size is one of the determinants of the study’s internal and external validity.²¹⁴ It also determines the power of the statistical analysis, when assessing the effect of different variables on the outcome of treatment. The smaller the difference in outcome, the larger is the sample required in each group to achieve sufficient power for significance to be established,²¹⁴ as can be demonstrated in the following examples from endodontic outcome studies:

- **Sample size:** In a study of 86 teeth with apical periodontitis,⁵⁴ the difference in outcome of treatment in one session (64% healed, adjusted calculation) and two sessions (74% healed, adjusted calculation) was not significant. The authors’ power analysis suggested that 354 teeth would be required in each group to statistically substantiate the 10% difference in healing (with 80% power). Similarly, in an apical surgery study,¹⁴⁸ the difference in outcome of treatment in 58 teeth with persistent disease after initial root canal treatment (74% healed) and 32 teeth with persistent disease after root canal re-treatment (84% healed) was not significant. The authors’ power analysis suggested that 400 teeth would be required in the former group and 220 teeth in the latter group for the difference in their outcomes to be significant (with 80% power). Thus, in relatively small studies on nonsurgical treatment^{4,13,15,26,35,36,40,42,44,45,53–55,60,61,67,73–77,84–86,88,89} and apical surgery,^{84,88,89,102,104,107,110,111,113,114,118,123,126–129,135,137,141–143,148,150} specific variables may not have a significant association with the outcome, whereas in studies with large samples the same variables may emerge as significant outcome predictors.

Exposure (Treatment, Intervention)

The treatment procedures performed in the study should be explicitly described, so they can be related to the outcome without interpretation or guesswork.

Inspection of the endodontic outcome studies reveals a great variation in treatment procedures, as shown in the examples below:

- Asepsis (in nonsurgical treatment): In at least two of the studies,^{19,24} treatment was routinely performed without rubber dam. It can be assumed that in these and several other studies, asepsis was not strictly observed; compromised asepsis would impair the outcome in a given study.
- Root canal preparation and filling (in nonsurgical treatment): Specific preparation techniques, such as serial filing,²² and root filling materials, such as Kloroperka N-Ø and rosin-chloroform,^{37,41} offer a poorer outcome than alternative techniques and materials. Those reportedly ineffective procedures have been used in specific studies.^{1,19,20,22,28,35,40,41,43,47,53,86,88,225} By contrast, procedures alleged to be most effective, such as the “Schilder technique,” have been used in other studies, exclusively³⁴ or in part of the sample.^{67,70,78,79,90}
- Intra-canal medication (in nonsurgical treatment): Intra-canal medication may be critical for controlling root canal infection,^{35,226–231} but not all agents used are effective and beneficial. For example, arsenic and formaldehyde—both extremely toxic and no longer used as intra-canal medication—were used in at least one study.¹ Medications commonly used in the past, such as camphorated phenol and paramonochlorophenol, iodine potassium iodide (IKI), and formocresol, may be insufficient for disinfection of canals associated with apical periodontitis²²⁶ because their antimicrobial efficacy is short-lived.^{232–234} These medications have been used frequently, and may have compromised the results, in older studies,^{2,10–12,14,17,18,22–24,29–31} whereas the more effective calcium hydroxide dressing was used in more recent studies.^{35,37,39,43,50–52,54,55,57,61,62,66,67,70,71,75,78,80,86,88,90} By contrast, in specific studies^{21,32, 34,53,69} treatment was invariably completed in one session, without the use of any intra-canal medication.
- Bacterial culturing of canals (in nonsurgical treatment): In several studies, absence of bacterial growth in root canal samples (negative culture) was a prerequisite for root filling.^{6,28,35,43} Negative cultures are an indication of effective disinfection and have been associated with an improved prognosis relative to teeth with positive cultures.^{6,53,86}
- Root-end management (in apical surgery): Round burs, commonly used in the past for root-end cavity preparation, are inferior to the currently used ultrasonic tips.^{137,235–240} Likewise, previously highly prevalent root-end filling with amalgam has been shown to be inferior to the currently used materials, such as intermediate restorative material (IRM), ethoxybenzoic acid (EBA) cements, or mineral trioxide aggregate (MTA).^{241–245} The reportedly less effective strategies have been used in the majority of studies in the past and in several recent ones,^{84,88,89,132,134,136,145–147} whereas the current strategies, assumed to be more effective, have been used in other recent studies.^{131,134–139,141,142,144,148,150,151} Furthermore, in specific studies^{122,130,133,140,143,190,191,246} a root-end cavity was not prepared and the root-end was completely covered with bonded composite resin (Figure 8).
- Concurrent orthograde surgical treatment: There is a considerable difference in outcome between apical surgery performed alone on teeth where disease persisted after previous root canal treatment, and concurrent surgical and root canal treatments, consistent with the historic management of teeth with large lesions.²²⁴ The latter had been commonly applied in the past and therefore represented the majority of the samples in specific studies.^{94,98,99,102,108,109,112,114,116} In those studies, outcomes were often summarized for the entire study cohort, resulting in better outcomes reported than what should be expected if only apical surgery is performed.²²⁴ Thus, in many studies, the proportion of teeth that received not just apical surgery but also concurrent root canal treatment determined the reported outcomes.
- Pre- and postoperative restoration: The influence of the type and timing of a definitive restoration on the outcome of nonsurgical endodontic treatment is equivocal. However, it has been shown that absence of a sound restoration may impair the prognosis of nonsurgical treatment^{18,33,90} and apical surgery^{121,139,148} (Figure 9). In several studies,^{12,18,70,78,90} a proportion of the teeth had not

Figure 8 Root-end management with bonded composite resin. **A**, Vertical section through a root end with a bonded Retroplast “cap” (Retroplast Trading, Rörvig, Denmark). The cut root surface was prepared with a round bur to accommodate the resin. The bonded “cap” is sealing the main canal and an accessory one. **B**, Clinical view of a maxillary first molar with Retroplast bonded to the three root apices. **C**, Root-filled maxillary central incisor with extruded root filling and persistent apical periodontitis. **D**, At 9 years after surgery with bonded Retroplast at the root end, the lesion is healed. Originally, Retroplast was only slightly radiopaque; the current generation is fully radiopaque. (Photos courtesy of Dr. Vibe Rud, Copenhagen, Denmark; Reprinted with permission from Friedman 2006.²⁰¹)

been restored, possibly adversely influencing the outcome in these studies. The majority of studies have not provided detailed information about the restorative status of the treated teeth, but it is likely that in many studies the reported outcomes were influenced by inclusion of teeth with defective or missing restorations.

The treatment providers' expertise may determine the outcomes of studies, as skillful operators are less likely to perform procedural errors that might impair the outcome.⁴⁹ Therefore, the treatment providers (students, general dentists, residents, specialists) should be characterized to establish the external validity of the results.²¹² Examination of the endodontic studies reveals differences in the experience and qualifications of treatment providers that may be particularly important in studies on apical surgery:

- Treatment providers: Historically, apical surgery has been predominantly performed by oral surgeons,

but over the years, it has been performed with increasing frequency by endodontists. Endodontists have significantly modified the procedure, routinely using operating microscopes and microsurgical instruments, ultrasonic cavity preparation devices, novel materials for root-end filling, and improved strategies for hemostasis and suturing. It appears that until recently, the majority of oral surgeons have not kept up with these modified procedures¹⁴⁶ and their treatment outcomes may have fallen behind those of endodontists.¹³⁹ Providers of treatment in the different studies on apical surgery included oral surgeons, 84,89,93,95–103,105–109,112,116,117,119,120,122,124,126–128,130–132, 134,136,137,140,141,145–147,150,151,183,188,190,191 endodontists, 82,88,117,119,121,125,129,135,138,142,144,149 and resident students.^{82,121,139,143,148} In studies on nonsurgical endodontic treatment, providers of treatment varied from undergraduate students^{2,6–8,10,12,18,19,22,28,33,35,37,39,41,43, 48,49,52,56,63,66,74,81} to qualified endodontists.^{1,3–5,9,16,20, 21,25,29–32,34,36,49–51,54,55,61,62,69,71,75,79,80, 86,88,92}

Figure 9 Lack of definitive restoration and outcome classification labeled as “persistent disease” after initial treatment. **A**, Maxillary lateral incisor with extensive apical periodontitis. **B**, Completed treatment. Access cavity is temporarily restored with reinforced zinc-oxide eugenol (IRM). **C**, At 3 years, disease persists. This unfavorable outcome may have been caused by the failure to place a definitive restoration. (Reprinted with permission from Friedman 2002.¹⁶⁴)

Finally, studies may be excluded if the treatment procedures described are considered irrelevant to the review or unacceptable. This consideration can be demonstrated with the following two examples from endodontic studies:

- Acceptable, relevant procedures: In one study on nonsurgical treatment,^{29–31} roots associated with apical periodontitis were instrumented “to the approximate center of the lesion.” In one study on apical surgery,¹¹⁸ a specific “bony lid approach” has been described. Reviews concerned with typical forms of treatment may exclude both these studies.

Outcome Assessment

Strict rules should be followed when clinical outcomes are assessed, in order to minimize measurement bias.²¹² Outcome dimensions and measures should be clearly defined. Of the four dimensions of dental outcomes,²⁴⁷ the endodontic studies usually assess the physical/physiologic (pathosis, pain, and function) and the longevity/survival (tooth loss and time until

repeat treatment for same or new condition) outcomes, but seldom the psychological (perceived esthetics, level of oral health, and satisfaction with oral health status) and economic (direct and indirect cost) outcomes. Outcome measures used to assess these dimensions should be objective and applied consistently in a blinded manner. Therefore, examiners who assess the outcome should be different from the provider(s) of treatment, and they should be properly calibrated with their reliability established. Also, direct comparisons of preoperative and follow-up radiographs must be avoided. Of particular concern in endodontic studies is the interpretation of radiographs and the inconsistency of criteria used for outcome assessment, as explained below:

- Interpretation of radiographs: Radiographs have been used invariably as the principal outcome measure in follow-up studies after endodontic treatment; however, radiographs are poorly standardized, being subject to changes in angulation and contrast, and they do not capture subtle inflammatory changes in the periapical tissues.¹⁷⁷

Importantly, interpretation of radiographs is subject to bias.^{165–169} Those limitations of radiographs may undermine the reliability of the results; therefore, bias and inconsistency can be minimized by assessment made by blinded examiners who are calibrated for standardized interpretation.^{37,167,169–173}

This requirement has not been fulfilled in the majority of studies; thus, the reported outcomes are likely to reflect differences in radiographic interpretations.

- **Inconsistency of criteria:** The main cause for the diverse outcomes reported in clinical studies in endodontics is the inconsistency of the criteria used. There tends to be an overestimation of the healing potential in specific studies where healed and reduced lesions are grouped together.^{3,5,11,16,29–31,36,42,47,58,113,131}

To avoid ambiguity of reported outcomes, the follow-up period in clinical studies should be long enough to capture the outcome of interest. This requirement is particularly important in endodontic studies, where the conclusion of the dynamic healing processes must be captured in the majority of the study sample. Considerations specific to endodontic studies are outlined below:

- **Follow-up period:** One year has been suggested as an adequate follow-up period after nonsurgical and surgical endodontic treatments.^{52,116,120,189} Indeed, a short-term observation after nonsurgical treatment of teeth with apical periodontitis may demonstrate signs of healing^{1,45,50} and even reveal meaningful changes.^{52,66,248} Nevertheless, sufficient time is required to observe completion of the healing process.^{1,22,35,37,52,63,92,180} Thus, studies on nonsurgical treatment extending 1 year or less^{3,16,29–31,33,34,50,54,66,82} may considerably underestimate the healing potential.^{49,249} To record a stable treatment outcome, follow-up of 4 years or longer may be required.^{1,22,35,37,52,63,92} In studies on apical surgery, a particular concern is recurrence of disease (Figure 10), shown to occur in 5 to 42% of healed teeth after periods of 4 years or longer.^{88,96,103,125,128,142,147,189} For example, Kvist and Reit⁸⁸ report recurrence of disease at the 4-year follow-up, in 4 of 45 teeth (9%) recorded as healed at the 1-year follow-up. Therefore, short-term apical surgery studies^{82,84,89,101,107,115,118,122,124,130,134,135,137,141,143,146,150,151} may overestimate the healing potential, and the follow-up period should extend at least 4 years. For the purpose of this chapter, the minimum

follow-up of 1 year was required. Furthermore, because all root-filled teeth may in time become subject to adverse effects of periodontal and restorative deterioration, extensive follow-up periods are more likely to reveal the influence of those effects on the outcome. Indeed, long-term changes in outcome have been reported in several studies.^{1,63,92,180} The many studies vary considerably in the extent of follow-up periods; therefore, their reported outcomes are likely to reflect this variability.

Reporting of Data and Analysis

Clinical studies should be reported in sufficient detail for a reader to be able to identify potential bias and assess the validity of the study. Thus, all data pertaining to the study cohort, the exposure, outcome assessment, and analysis, should be clearly provided in the report. Examples are abundant in the endodontic studies where essential details are not reported. The results of such studies cannot be used as the basis for estimating the outcome in specific clinical conditions.

Statistical analyses are used in clinical studies mainly to examine associations between the outcome and different variables. This issue can be considerably confused by the nature of the analysis, or the lack thereof. Therefore, the statistical analysis should be designed so as to minimize potential bias. The analysis should take into account extraneous factors and the potential confounding effects of different prognostic factors. In observational studies where the prognostic factors cannot be controlled by the investigators, they should be observed and recorded to allow judicious analysis of the outcomes. Preferably, multivariate analyses should be used to account for all the variables. Confounding effects of different variables can be found in the endodontic studies, as demonstrated by the following examples:

- **Analysis and confounding effects:** In the vast majority of studies on both nonsurgical and surgical treatments, only bivariate analyses have been used that ignore potential confounding effects of multiple variables.¹ For example, one study on nonsurgical treatment²²⁵ offers two conclusions: (1) teeth in which overfilling occurred have a poorer outcome than teeth filled without overfilling, and (2) presence of apical periodontitis at the time of treatment has a strong negative influence on the outcome. The report reveals that overfilling occurred more frequently in teeth with apical periodontitis, suggesting that the poor outcome in

Figure 10 Recurrence of disease after confirmed healing following apical surgery. **A**, Root-filled maxillary lateral incisor with persistent apical periodontitis. **B**, Instrument film indicates extent of retrograde re-treatment carried out. **C**, Completed surgery, including a root filling with sealer and injectable gutta-percha. **D**, At 6 months, the lesion is healed. **E**, At 2.5 years, renewed radiolucency demonstrates recurrence of disease. (Reprinted with permission from Friedman 2006.²⁰¹)

overfilled teeth can be “blamed” on the presence of apical periodontitis. In studies on apical surgery, the presence or absence of a root-end filling has often been compared disregarding the fact that some teeth received root canal treatment in conjunction with surgery, whereas others did not. When performed, concurrent orthograde treatment had a strong positive impact on the outcome.^{116,120} Because root-end fillings were usually absent in these teeth, researchers concluded that teeth with-

out root-end fillings had a better outcome than teeth with root-end fillings.²²⁴ Thus, exclusive use of bivariate analysis may misrepresent the influence of specific variables on the outcome.

A specific concern in endodontic studies is the possibility to record the outcome for each root or for each tooth. Evaluating roots as individual units raises concerns in regard to multi-rooted teeth.¹⁶⁴ When the root is the evaluated unit, more weight is

assigned to studies with a large proportion of multi-rooted teeth than to studies that include primarily single-rooted teeth. Also, the outcome is better than if whole teeth are evaluated as units^{1,6,29–31,33,50,164} (see Figures 6). This can be demonstrated in the following examples:

- Unit of evaluation: In one follow-up study,⁶ healing was observed in 78% of teeth and in 83% of roots. Similarly, in a cross-sectional study of root-filled teeth in a specific population,¹⁷⁸ apical periodontitis was observed in 30% of the teeth but only 24% of the roots. Although the majority of the studies have considered the tooth as the evaluated unit, the individual roots have been evaluated as independent units in many of the studies on nonsurgical treatment^{1,2,19,22,37,40,41,43,52,63,72,81,92,248} and on apical surgery.^{102,108,117,119,130,133,140,149,190}

SELECTED STUDIES COMPRISING THE “BEST” EVIDENCE

Studies that have reported on the outcome of initial root canal treatment, orthograde re-treatment, apical surgery, and intentional replantation in the past 40 years are listed in Tables 1, 2, 3, and 4, respectively. Studies on surgical treatment are summarized in Tables 5–7. The outcomes in the tables are construed from the original reports, so that combined clinical and radiographic normalcy is classified as “healed,” reduced radiolucency combined with clinical normalcy is classified as “healing,” and absence of signs and symptoms is classified as “functional”—for several studies this is simply the sum of “healed” and “healing” (when both are available), whereas for others it includes also teeth where the radiolucency persisted.

True “survival” is not used as an outcome category, because in the majority of studies the outcome is calculated after extracted teeth are excluded from the sample. Data on the long-term survival of teeth after nonsurgical and surgical endodontic treatments are available from several specific studies.^{163,250–258} Typically, however, survival analyses of endodontically treated teeth are subject to bias. The “surviving” teeth do not necessarily represent all the teeth with a favorable endodontic treatment outcome;²⁵⁴ thus, the potential for healing may be overestimated. On the other hand, treatment-planning considerations occasionally lead to extraction of functional and periapically healthy teeth, particularly when such teeth require further restorative or periodontal treatment and the patients select to forego this

treatment and extract the tooth.²⁵⁴ Thus, the potential for healing may be underestimated. In recent years, researchers have modified the format of survival analyses, by using reviews of either patient charts or electronic databases of dental insurance providers to record untoward events, such as tooth extraction, orthograde re-treatment, or apical surgery in the long term after initial root canal treatment.^{253,255,256,259} This type of analysis also is subject to bias, and it appears to overestimate the healing potential after endodontic treatment.

Notation is made in the tables of the general compliance of the studies with the appraisal criteria outlined above. Studies that comply with any three of the four criteria—cohort, intervention, assessment, analysis/reporting—have been selected as methodologically adequate (insistence on strict compliance with all four criteria would result in a very narrow evidence base).

Table 1 includes 23 studies on initial root canal treatment.^{1,6,22,35,37,43,48,52–55,61,62,66,67,70–72,75,76,78,80,248} The samples of two of these studies^{37,54} have been repeated in later studies,^{39,72,76} and the samples from the Toronto Study series have been added up from the first study⁶⁷ throughout the successive ones.^{70,78} To avoid confounding of the analysis by repeated samples, only the most recent studies from these three clusters of studies are included in Table 5 reducing the number of selected studies to 18.

Additional six studies were selected on orthograde re-treatment^{1,6,43,86,88,90} and nine studies on apical surgery.^{88,138,139,143,144,148–151} None of the studies on intentional replantation meet the selection criteria; thus, the level of evidence to support the prognosis of this specific treatment modality is the lowest.

The methodology of the selected studies is rather uniform, but considerable differences still exist in case selection and composition of study materials. The selected studies represent the best available evidence for estimating the potential for healing after endodontic treatment. They also serve as reference for identifying significant outcome predictors (Tables 2–7).

Potential for Healing and Retained Function after NonSurgical Treatment (Tables 5, 6)

Initial root canal treatment and orthograde re-treatment share the same etiology and basic treatment procedures. It is appropriate, therefore, to lump them together into one category—nonsurgical treatment—when reviewing both their prognosis and outcome predictors.

Studies selected for review are in boldface.

^{*}Asymptomatic, without or with residual radiolucency (≥ not reported; rate is sum of healed and healing).

^aResults recorded at the final observation.

^bIncludes repeated material.

^cRoots considered as unit of evaluation, rather than teeth.

^dRecalculated after exclusion of cases classified as “uncertain.”

^eCases with procedural errors excluded.

^fResults recorded at 2-year observation.

^gAll canals obliterated to some extent.

^hTeeth treated in two sessions without intracanal medication excluded.

ⁱResults recorded at 4-year observation.

^ySatisfies criteria of acceptable quality.

ⁿDoes not satisfy criteria of acceptable quality.

Teeth Treated Without Associated Apical Periodontitis

Frequently, endodontic treatment is performed in teeth not associated with apical periodontitis. These teeth may undergo initial treatment, if the pulp is vital—intact (elective treatment) or irreversibly inflamed—or if it is necrotic but not infected. Root-

filled teeth may also undergo orthograde re-treatment even if they are not associated with apical periodontitis, if the root filling is suspected of becoming infected subsequent to placement of a new post/core and crown restoration. Distinct groups of teeth without apical periodontitis have been identified in the study samples of several of the selected studies on

nonsurgical treatment (Tables 5, 6). The reported outcomes in these teeth are rather consistent among these nine studies.

HEALED TEETH

The proportion of teeth that remained healed after initial treatment ranges from 88^{6,62} to 97%,⁴³ and after re-treatment, from 94⁶ to 98%.⁴³ The outcome in the two former studies (88%) appears to fall considerably below those of the other six studies (93–97%), and may be considered an outlier. As expected from the selected studies that are rather uniform methodologically, the range of their outcomes is considerably smaller than that observed across all studies (67–97%). Thus, the potential of

teeth to remain free of apical periodontitis after non-surgical treatment is 93 to 98%.

FUNCTIONAL TEETH

According to two studies^{78,90} that specifically address this outcome, the proportion of functional teeth after nonsurgical treatment is 93 to 95%. This figure represents both teeth *without and with* apical periodontitis at the time of treatment. Thus, the potential of teeth to remain asymptomatic and functional after nonsurgical treatment is at least 93%.

DYNAMICS OF DEVELOPING DISEASE

Development of apical periodontitis subsequent to initial treatment is usually quick; of all the affected

teeth, approximately 75% show signs of the disease within the first year after treatment.^{52,80} In the following years, the risk of developing disease is not increased⁵² and late emergence of the disease is infrequent, suggesting that follow-up beyond 1 year may not be necessary.⁵² Occasionally, however, a lesion

that was observed to develop within 4 years after treatment may later disappear,¹ or a lesion may develop many years after treatment.^{63,92} Even though these late developments are uncommon, their occurrence suggests that long-term follow-up of the treated teeth may be beneficial.

Teeth Treated with Associated Apical Periodontitis

Teeth associated with apical periodontitis may undergo initial treatment for a primary infection of a necrotic pulp. Root-filled teeth may undergo orthograde re-treatment for a persistent or newly developed infection after a previous treatment. Distinct groups of teeth with apical periodontitis have been identified in 17 of the selected studies on initial treatment^{1,6,22,35,43,48,52–55,61,62,66,71,72,75,78} and the 6 studies on re-treatment.^{1,6,43,86,88,90} The outcomes reported in these studies still vary considerably, although the studies are methodologically compatible (Tables 5, 6).

HEALED TEETH

The proportion of teeth that healed completely after initial treatment ranges from 73⁶ to 90%,²² and after re-treatment, from 56⁸⁸ to 86% (in teeth without perforation).⁹⁰ These ranges are smaller than those observed across all studies on initial treatment (46–97%) and re-treatment (28–98%), as expected from the methodologically uniform selected studies. Furthermore, the outcomes of two studies on re-treatment^{43,88}—56% (approximate; the exact rate was not provided) and 62%—fall considerably below those reported in the other studies, whereas the 90% outcome of initial treatment²² falls above the reported range. These atypically low and high outcomes may

be considered as outliers. *Thus, the potential of teeth with apical periodontitis to heal after nonsurgical treatment is 73 to 86%.*

Considering the uniformity of outcome criteria among the selected studies, the reported outcomes may have varied because of the following factors:

- Differences in tooth types or in definition of the evaluated unit—tooth or root:¹⁶⁴ The better outcomes are reported in studies that either included only single-rooted teeth^{35,53} or calculated the outcome for each root.^{43,260} Use of the root as the evaluated unit in studies with multi-rooted teeth usually improves the outcome compared with the use of the whole tooth as the evaluated unit.¹⁶⁴ It should be noted, however, that lower outcomes have been reported in several other selected studies where roots were assessed as the evaluated units.^{39,52,54}
- Differences in case selection:⁴⁹ Cases treated by undergraduate students in several studies^{6,22,35,39,43} may have been uncomplicated. By contrast, cases complicated by anatomy, advanced periodontal disease, or procedural errors (that occurred before referral for treatment) were occasionally included in one series of studies.^{78,90}
- Prerequisite of a no-growth (negative) bacterial culture before root filling:^{22,35,43} A significantly higher outcome of initial treatment has been reported when canals were filled after a negative culture (94% healed) than after a positive culture (68%).⁵³ An even greater difference in

outcome has been demonstrated in re-treated teeth filled after negative (80%) and positive (33%) cultures.⁸⁶

- Differences in restoration: In the studies reported by the Umeå, Sweden group,^{35,43,53,86} all teeth were restored immediately after endodontic treatment (personal communication), using a layer of zinc-oxide eugenol to seal the canal orifices.⁵³ Also in the study by Peters and Wesselink,⁶¹ all the teeth were reportedly well restored. By contrast, 5 to 10% of the teeth in the Toronto Study series^{78,90} were not definitively restored 4 to 6 years after treatment. Absence of a definitive restoration may allow microbial ingress into the filled canals²⁶¹ and consequent persistence of apical periodontitis.

HEALING IN PROGRESS

The proportion of teeth that demonstrate progressive or incomplete healing has not been frequently reported in the selected studies. When reported, progressive healing ranges from 9³⁵ to 21%.⁶¹ Typically, the proportion of incomplete healing is inversely proportional to the follow-up period, because the completion of the healing process cannot be captured after a short follow-up;¹⁶⁴ however, this typical pattern is not evident in the selected studies. *Thus, the potential of teeth with apical periodontitis to demonstrate incomplete healing after nonsurgical treatment is approximately 10 to 20%.*

FUNCTIONAL TEETH

From six studies on initial treatment^{35,39,52,55,61,78} and one study on re-treatment,⁹⁰ it appears that the proportion of functional teeth after nonsurgical treatment ranges from 88⁵² to 96%.⁶² Additional information can be gathered from the nonselected studies (see Tables 1 and 2). In these tables, asymptomatic function was noted only for healed and healing teeth, where symptoms were absent by definition. It can be assumed that additional asymptomatic teeth were present but not reported in the studies, because they did not show radiographic improvement. It appears, therefore, that the proportion of the functional teeth approaches or even exceeds 95%. It is also noteworthy that the reported survival rates—80% survival after initial treatment of teeth with apical periodontitis,¹⁶³ 86% general 5-year survival,²⁵⁴ and at least 93% survival in chart/database reviews^{253,255,256,259}—have been rather high. *Thus, the potential of teeth with apical periodontitis to*

remain functional after nonsurgical treatment may approximate 95%.

This excellent potential for retained asymptomatic function *definitely justifies conservative endodontic treatment in teeth with primary or refractory apical periodontitis and reasonable restorative and periodontal prognosis.* If initial treatment or re-treatment is considered feasible and acceptable to the patient, tooth extraction and replacement should not be contemplated.

DYNAMICS OF HEALING

Healing of apical periodontitis ensues within the first year after nonsurgical treatment,^{88,249} so that signs of healing are evident in nearly 90% of the teeth that heal eventually.⁵² Completion of the healing process, however, often requires a longer time. Therefore, of all the teeth that heal eventually, only about 50% appear completely healed by 1 year,¹⁷ the majority appear healed after 2 years,^{35,37} and a small percentage appear healed only after 4 to 5 years,^{17,35,37,43,52,88} or even longer.^{1,63,92} In the interim follow-up periods, additional teeth demonstrate further reduction of the radiolucency.^{28,35,37,43,52} For example, at 4 years about 13% of the teeth showed radiographic improvement,⁵² whereas closer to 6 years nearly 7% of the teeth showed improvement.^{70,78,90} Two studies with uniquely long follow-up periods offer an insight into the long-term healing dynamics after initial treatment⁶³ and re-treatment.^{63,92} Over 6% of the initially treated teeth, and as many as 50% of the re-treated teeth were observed to still have disease 10 to 17 years after treatment but were completely healed a decade later, resulting in an improved outcome in the long term. The late healing was mainly characteristic of teeth with surplus root filling material.⁹² Taking the healing dynamics into consideration, a demonstrated continuous reduction of the radiolucency (comparing at least two follow-up examinations) may be considered as a forecast of complete healing at a later time.³⁵

Reversal of the healing process after nonsurgical treatment (Figure 11) is uncommon,^{1,52,88} prompting the suggestion that extended follow-up of teeth that demonstrate signs of healing after 1 year may be unnecessary.⁵² Notwithstanding the progressive nature of the healing process, all root-filled teeth remain constantly challenged by intra-oral microorganisms, placing them at risk of recurrent apical periodontitis in the long term, even if they are completely healed in a short term after therapy. For example, over 1% of teeth were observed to be healed 10 to 17 years after treatment but were reverted to disease a decade later.⁶³ To address the possibility of long-term changes, periodic follow-up of root-filled teeth is advocated as a viable routine.

Figure 11 Reversal or regression in healing of apical periodontitis after re-treatment. **A**, Failing root canal treatment in mandibular premolar. **B**, Immediate postoperative radiograph of mandibular first premolar with apical periodontitis. **C**, At 7 months, the clearly reduced radiolucency is indicative of healing in progress. **D**, At 2 years, the radiolucency has grown larger again beyond its original size, indicative of reversal of the healing process. (Reprinted with permission from Friedman 2002.¹⁶⁴)

Teeth treated by apexification appear to demonstrate a different pattern of healing dynamics. Of those that had not shown signs of healing during apexification, approximately 66% healed after conclusion of treatment with a definitive root filling, whereas of those that appeared healed during the apexification process, approximately 8% reverted to disease 2 to 3 years after definitive root filling.⁴⁶

In the long term, apical periodontitis lesions are expected to heal completely;^{1,41,249} however, infrequently very extensive lesions can heal without total resolution of the radiolucency. In such cases, the residual radiolucency represents a fibrous periapical tissue (apical scar), rather than a pathologic lesion^{35,262–265} (see Figure 1).

Potential for Healing and Retained Function after Apical Surgery

Patients deliberating different options for management of refractory apical periodontitis should consider the benefit—primarily the potential for healing—and risks associated with each treatment alternative. Apical surgery is a viable alternative to orthograde re-treatment; the potential for healing it offers should be weighed against that offered by re-treatment.

In contrast to the uniform characteristics of the selected studies on nonsurgical treatment, the nine selected studies on apical surgery^{88,138,139,143,144,148–151} differ considerably in their cohort (population) and exposure (intervention) characteristics (Table 7). An important difference can be observed in regard to the treatment history before surgery, including only initial treatment, orthograde re-treatment, or apical surgery. For example, teeth that received previous orthograde re-treatment comprised 100% of the sample in one study,¹³⁸ an unknown proportion of the sample in another study¹⁴⁴ (personal communication), and close to 40% of the samples in two other studies,^{139,148} whereas the remaining studies^{88,143,149–151} did not mention the previous treatment history of their cohorts. The outcome of apical surgery is expected to be better when it is preceded by orthograde re-treatment, as highlighted below. Also, the proportions of teeth that received previous apical surgery varied, comprising 44,¹³⁹ 33,¹⁴⁹ and close to 10%^{148,151} of the study cohorts. By contrast, only first-time surgery was included in one study,¹⁴³ whereas the remaining three studies^{88,144,150} do not characterize their cohorts in regard to previous surgery. The outcome of repeat surgery is expected to be poorer than that of first-time surgery. These and other differences among the selected studies result in a considerable inconsistency in the reported outcomes.

HEALED TEETH

The proportion of teeth that healed completely after apical surgery ranges from 37%¹³⁹ to 91%.¹³⁸ Contrary to the expectation from the selected studies that are rather uniform methodologically, the range of their outcomes is almost as large as that observed across all studies (31%–98%) (Table 3). The highest two outcomes of 90%¹⁴⁴ and 91%¹³⁸ may have been affected by previous orthograde re-treatment, whereas the lowest outcome of 37%¹³⁹ appears to fall considerably below the range reported in the remaining four studies (60%–89%); these atypically high and low outcomes may be considered as outliers. *Thus, the potential for teeth to heal completely after apical surgery is 60% to 89%.* Considering the uniformity of outcome criteria among the selected studies, the reported outcomes may have varied because of the following factors:

- Assembly bias, particularly from inclusion of previously re-treated teeth in the study sample: The site where persistent bacteria colonize may differ in the case of persistent disease after initial treatment and when disease persists after orthograde re-treatment.^{148,223} In the latter, “intra-canal irritants and contamination” were reduced¹³⁸ suggesting that infection is sustained by bacteria located in inaccessible sites: canal ramifications close to the apex,^{265–267} the outer surface of the root tip,^{268,269} or the periapical tissue.^{270–287} Bacteria harbored in all these sites would be eradicated by the resection of the root tip and periapical curettage; therefore, the potential for healing is excellent, as demonstrated in two studies where 84¹⁴⁸ and 91%¹³⁸ of previously re-treated teeth healed after subsequent surgery. By contrast, when disease persists after initial treatment, bacteria are more likely to be located within the root canal.^{86,184, 186,187,266,288–303} The surgical procedure does not eliminate these bacteria, but rather an attempt is made to enclose them with a root-end filling. The proportion of previously re-treated teeth in the study sample has been specified in only three of the studies.^{138,139,148}
- Differences in treatment procedures: In one of the selected studies,⁸⁸ less current techniques and materials were used than those used in the more recent studies.^{138,139,143,144,148–151} First, the root-end cavities in the former study were prepared with round burs, as opposed to the ultrasonic cavity preparation (Figure 10B) in the recent studies, that results in deeper, cleaner, and better-aligned root-end cavities with less risk of lingual perforation.^{235,237, 238,240,304,305} Second, amalgam was used for root-end filling in the former study,⁸⁸ whereas IRM, Super EBA cement, MTA, or a dentin-bonded

composite resin was used in the recent studies, with the expectation of improved clinical performance based on favorable outcomes in animal studies.^{241–246} In addition, in five of the recent studies also magnification and micro-instruments were used^{144,148–151} that facilitate visualization and treatment of accessory canals and isthmuses, as well as detection of root cracks.^{238,304–307} Use of these modern tools allows the clinician to keep the bony crypt small and to reduce the apical bevel, so that fewer dentinal tubules become exposed.^{235,237,238,240,305,308} Collectively, these current procedures may have improved the outcome in most of the recent studies,^{138,143,144,148–151} compared with the study where these techniques were not used.⁸⁸

HEALING IN PROGRESS

Progressive healing appears to range from 6%¹⁴⁴ to 33%.¹³⁹ Similarly to nonsurgical treatment, a high proportion of progressive healing captured in a study is typical of a short follow-up period;¹⁶⁴ therefore, the reporting of the highest proportion of progressive healing in a study with a follow-up of 4 years or longer¹³⁹ is surprising. This atypical pattern could possibly be explained if the study cohort included many large lesions that healed by formation of a fibrous scar and were classified as “uncertain healing” (consistent with this chapter’s definition of “healing in progress”); by contrast, in the other selected studies scars were classified as “incomplete healing” (consistent with this chapter’s definition of “healed”). *Thus, the potential of teeth to demonstrate incomplete healing after apical surgery is approximately 5% to 30%, depending on the case selection and outcome classification used.*

FUNCTIONAL TEETH

From eight studies,^{138,143,144,148–151} it appears that the proportion of functional teeth after apical surgery exceeds 89%. This outcome does not take into account all lost teeth; therefore, it overestimates the chances of teeth to be retained after apical surgery. Also, it is not synonymous with the lower “survival” rate reported in another study;²⁵⁷ however, it is noteworthy that typically, a survival analysis may underestimate the potential for tooth survival, when functional teeth without disease are extracted for reasons unrelated to the endodontic outcome. *Thus, the*

potential of teeth to remain functional after apical surgery may approximate or exceed 90%.

This good potential for retained asymptomatic function justifies conservative surgical treatment in teeth with primary or refractory apical periodontitis and reasonable restorative and periodontal prognosis. If apical surgery is considered feasible and acceptable to the patient, tooth extraction and replacement should not be contemplated.

DYNAMICS OF HEALING

Healing progresses within the first year after apical surgery,^{88,189} so that of all the teeth that heal eventually, 35% to 60% appear healed by 1 year.^{105,106,116,145,147,183,189}

About half of the teeth that show signs of healing at 1 year continue to heal, whereas about one quarter revert to disease; therefore, of the teeth that heal eventually, approximately 85% appear healed by 3 years.^{96,116,189} Definitive outcomes (healed or diseased) observed at 1 year have been suggested to remain stable up to 3 to 5 years,^{96,103,105,142,189} supporting the suggestion that the 1 year follow-up may be considered conclusive, except for teeth that show healing in progress.^{183,189}

Notwithstanding the suggested stability of the outcome observed at 1 year, 5 to over 40% of healed teeth have been shown to revert to disease in the long term^{88,96,103,125,128,142,147,189} (see Figure 4). Thus, recurrence of apical periodontitis is more prevalent after apical surgery than after nonsurgical treatment. To address the risk of recurrent disease in the long term, it is advisable to extend the follow-up and periodically examine the treated teeth.

Whereas apical scar formation after nonsurgical treatment is infrequent, healing by a fibrous scar rather than deposition of bone is quite common after apical surgery^{173,174,181–183} (see Figure 1). Apical scars form particularly when both the buccal and lingual bone plates are perforated at the conclusion of the surgical procedure.^{116,120} Post-surgery apical scars appear to remain stable over time;¹⁸³ therefore, they are considered a surrogate for a healed site.^{173,174,183}

Etiology of Refractory Apical Periodontitis after Treatment

As highlighted in the previous sections of this chapter, persistence of apical periodontitis after endodontic treatment is not highly prevalent, but it is not uncommon either. Thorough comprehension of the etiologic factors of disease persistence is required for clinicians to devise strategies for preventing and for managing

this unfavorable and frustrating occurrence. For the major part, persistent apical periodontitis is sustained by persistent or recurrent infection; however, the sites colonized by bacteria and the pathways of bacteria–host interactions may differ in nonsurgically and surgically treated teeth.

REFRACTORY INFECTION AFTER NONSURGICAL TREATMENT

Refractory apical periodontitis after initial treatment has been shown to occur in selected cases in response to nonmicrobial factors, including foreign materials and true cysts.^{309–312} It appears this is not a common occurrence; it has been demonstrated in three out of nine specimens (33%) where disease persisted despite verified reduction of intra-canal bacteria before root filling, to a level below detection.⁴³ However, routine endodontic cases do not employ strict bacteriologic monitoring to verify bacterial elimination before root filling; therefore, if disease persists after routine treatment, a higher proportion of infective etiology and a lower proportion of nonmicrobial etiology are expected.

Indeed, evidence of microbial etiology of refractory apical periodontitis after nonsurgical treatment is consistent and undisputed.^{223,296} Bacteria sustaining the disease process can colonize the following sites:

- The root canal system: This is the most frequently documented site of bacteria in teeth with refractory apical periodontitis.^{86,184,186,187,265–267,288–303,313} The bacteria have either survived the root canal treatment procedures⁵³ or invaded the filled canal space after treatment, possibly through a coronal pathway.²⁶¹
- The periapical tissues: Ample evidence has been accumulated demonstrating specific bacteria, particularly *Actinomyces israelii* and *Propionibacterium propionicum*, established in the periapical tissues of root-filled teeth with persistent disease, even after elimination of root canal bacteria.^{271–282,302} These bacteria have either penetrated the host tissues during a long-term infection of the root canal system or were inoculated periapically during treatment. Refractory apical periodontitis caused by bacteria established outside the root canal system is referred to as “extra-radicular” infection.
- Other extra-radicular sites and bacteria: Different bacterial species, other than *Actinomyces*, have been identified outside the root canal space and implied in extra-radicular infection.^{270,283–287} Bacteria were shown colonizing the root surface in cementum lacunae,^{314,315} forming plaque-like biofilms sur-

rounding the apical foramina,^{268–270,316–319} and lodged in dentin debris inadvertently extruded periapically during treatment.³²⁰ Notwithstanding the current evidence, the role of these demonstrated extra-radicular bacteria in the etiology of refractory apical periodontitis has not been sufficiently elucidated. Whether these bacteria sustain infection without dependence on presence of root canal bacteria still requires clarification; an unequivocal answer will have an important impact on strategies for management of refractory apical periodontitis. Until such answer is available, current knowledge suggests that refractory apical periodontitis is predominantly caused by root canal infection, with extra-radicular infection per se affecting a small percentage of cases.²²³

Even though repeated root canal disinfection during orthograde re-treatment specifically targets intra-canal bacteria, bacteria can still survive and sustain persistent apical periodontitis after re-treatment.^{86,294,301} Nevertheless, the persistence of disease despite re-treatment increases the probability of the other etiologic factors highlighted above, including foreign body reaction and true cysts,^{309,310} or extra-radicular infection.^{268–316,270–287,314–320} This increased probability provides the rationale for apical surgery, as the treatment of choice for refractory apical periodontitis after orthograde re-treatment. The surgical procedure is well suited to address the likely etiologic factors.

REFRACTORY INFECTION AFTER APICAL SURGERY

Typical apical surgery comprises an attempt to seal an infected canal with a root-end filling. Persistence of apical periodontitis after surgery usually suggests that the bacteria are not effectively contained within the canal space.²²⁴ Placement of a root-end filling is a technique-sensitive procedure, because of restricted accessibility and the challenge in preparing a well-centered root-end cavity of sufficient depth that is aligned with the long axis of the canal and seals all possible foramina and isthmuses. Considering the intricacy of the procedure, several pathways may allow continued interaction of root canal bacteria with the host tissues, resulting in persistence or recurrence of apical periodontitis:

- Communication through the margins of the root-end filling: Failure of the root-end filling to effectively seal the canal may result from poor

placement, poor adaptation to the canal walls, or poor sealing ability of the filling material.²²⁴

- Communication through accessory canals or isthmuses: Root canals in the apical third often diverge into multiple foramina, and in specific teeth, isthmuses are consistently present between canals. A root-end filling may fail to seal accessory foramina or isthmuses, particularly when it is placed without magnification and illumination aids.^{238,321}
- Communication through exposed dentinal tubules: Apical resection is typically performed with a bevel, leaving open dentinal tubules at the cut surface. The number of opened tubules corresponds to the angle of the bevel;³²² at times, the angle is so acute that a shallow root-end filling does not internally seal all the tubules that open on the surface. The remaining open tubules communicate between the root canal space and periapical tissues.^{322–324}

The typical apical surgery procedure targets the secondary etiologic factors, nonmicrobial and extraradicular infection, in addition to the attempted seal of the primary etiologic factor, intra-canal infection. Considering the bacterial pathways outlined above, persistence of disease after apical surgery is likely to be sustained by persistent root canal infection.²²⁴ This probability provides the rationale for orthograde re-treatment, as the treatment of choice for refractory apical periodontitis after apical surgery. The re-treatment procedure may eliminate the likely etiologic factor. In selected cases, however, re-treatment may not be feasible. In such cases, the apical surgery procedure should be repeated, with an emphasis on effective sealing of the infected root canal.

Factors Influencing Healing after Endodontic Treatment (Tables 3, 5, 6, 7)

In the current structure of the clinical decision-making process, clinicians are expected to advise patients of the prognosis of available treatment alternatives. Furthermore, it is incumbent upon every clinician, once a treatment option is selected, to maximize the prognosis by using treatment methods based on solid evidence. In view of these requirements, this section focuses primarily on the selected studies that comprise the best evidence for initial treatment,^{1,6,22,35,43,48,52–55,61,62,66,71,72,75,78,80} orthograde re-treatment,^{1,6,43,86,88,90} and apical surgery.^{88,138,139,143,144,148–151} Additional studies whose samples are included in specific selected studies^{37,67,70,76,248} are also cited when appropriate. The nonselected studies are cited only where selected studies are not available as reference. The factors listed are divided into pre-, per-, and post-treatment categories.

The pretreatment variables should be recognized and duly considered at the stage when different treatment alternatives are weighed, for example, when selection has to be made between orthograde re-treatment, apical surgery or extraction and replacement. They form the basis for projecting the potential for healing, representing the expected benefit of treatment. The per-treatment variables should be recognized and duly considered at the stage when treatment is planned and executed, particularly when treatment strategies and techniques are selected. They can be instrumental in improving the outcome of endodontic treatment and thus maximizing the patient's benefit. The only post-treatment variable related to nonsurgical treatment is the definitive restoration, considering the common division of labor in nonsurgical treatment, whereby the restoration procedure is performed after completion of the root canal treatment procedures. However, it cannot be overemphasized that the restoration procedure is an inseparable component of the endodontic treatment continuum,³²⁵ and may as well be considered a per-treatment variable. The only post-treatment variable related to apical surgery procedure is the results of a periapical tissue biopsy obtained during treatment. It may be considered when the follow-up schedule is devised.

Factors Influencing Healing after Nonsurgical Treatment

The similarities between initial treatment and orthograde re-treatment justify the consideration of the same pre-, per-, and post-treatment variables as outcome predictors. It is noteworthy that the evidence base for re-treatment is limited to only a few selected studies that do not allow conclusive assessment of the influence of many factors on the outcome. Also, specifically for re-treatment, characteristics of the previous root canal treatment history also have to be considered in the pretreatment category. These include the previous root filling, a perforation that may be present in a minority of re-treated teeth, and the time elapsed since initial treatment. As a conclusion to this review of outcome predictors in nonsurgical treatment, a specific section is dedicated to elimination of root canal bacteria, in recognition of their critical role in the etiology of refractory apical periodontitis.

PRETREATMENT VARIABLES

Age and Gender of the Patient

Except for one selected study⁷² reporting a better outcome of initial treatment in older patients, age and gender have not been significantly associated with

the outcome in the majority of the selected studies on initial treatment^{22,43,48,61,62,78} and in the only re-treatment study that examined these factors.⁹⁰ Thus, the patient's age and gender do not appear to influence the potential for healing after nonsurgical endodontic treatment.

Systemic Health

The first selected study that examined the patient's health as a variable reported no significant association with the outcome.¹ Until recently, no other studies have addressed systemic health as a potential outcome predictor. A recent selected study⁷⁵ suggests that a compromised nonspecific immune system impairs the outcome of nonsurgical treatment in teeth with apical periodontitis. Similarly, a poorer outcome is reported in diabetic patients in a nonselected study.⁶⁵ Even though further evidence is required to confirm the association between the patient's systemic health and healing after nonsurgical treatment of teeth with apical periodontitis, the potential for healing appears to be poorer in immune-compromised patients in general, and diabetics in particular. The poorer prognosis, however, does not preclude treatment, as healing is still possible in these patients

Tooth Location

A better outcome is reported in mandibular teeth than in the maxilla in one selected study,⁷² whereas in another selected study²² a better outcome is reported in specific teeth (maxillary canines and second premolars, mandibular canines) without significant differences observed for anterior, posterior, maxillary, and mandibular teeth. Other selected studies have shown no association between tooth location and the outcome of initial treatment^{48,55,61,62,78} and re-treatment.⁹⁰ Multi-rooted teeth have been shown to have a better outcome than single-rooted teeth in two selected studies,^{1,6} but the opposite has been shown in two recent selected studies,^{78,90} possibly reflecting the use of teeth (as opposed to roots) as the evaluated units, multiplying the chances of persistent disease by the number of roots.^{78,90} Thus, the location and type of the tooth do not appear to influence the potential for healing after nonsurgical endodontic treatment.

Clinical Signs and Symptoms

Several selected studies have reported comparable treatment outcomes in asymptomatic teeth and in teeth presenting with pretreatment symptoms, after initial treatment^{35,43,48,55,72,78} and re-treatment.⁹⁰

Thus, presence or absence of symptoms does not appear to influence the potential of healing after non-surgical endodontic treatment.

Pulp Vitality or Necrosis (in Initial Treatment)

From two selected studies,^{62,78} it appears that the outcome is better in teeth with vital than with necrotic pulps. This finding, however, is confounded by the presence or absence of apical periodontitis; therefore, the assessment should be limited to teeth without apical periodontitis. In the absence of apical periodontitis, the pulp status is not significantly associated with the outcome of treatment.^{22,43,72,78} Thus, the pulp status does not appear to influence the potential of healing after initial endodontic treatment in teeth without apical periodontitis.

Presence or Absence of Radiolucency

The majority of the selected studies on initial treatment^{1,6,52,62,71,72,75,78} have demonstrated a significantly poorer outcome (10%–15% difference) in teeth affected by apical periodontitis than in unaffected teeth. A similar difference (10%–20%) has been reported in selected studies on re-treatment.^{1,6,43,90} In teeth with apical periodontitis, there may be difficulties in the repair process of the periapical tissues, and the ability to disinfect the root canal system is limited¹ (see Antibacterial Efficacy of Intra-Canal Procedures). Pretreatment apical periodontitis has a strong negative influence on the potential for healing after nonsurgical endodontic treatment.

Size of Radiolucency

Several selected studies have reported better outcomes in teeth with small lesions (≤ 5 mm in diameter) than in larger lesions, after initial treatment^{1,6,55,62,72} and re-treatment.⁸⁶ A smaller number of root canal bacteria found in teeth with smaller lesions appeared to explain the clinical findings;³⁵ however, comparable outcomes have been reported for small and large lesions in other selected studies on initial treatment^{35,43,48,53,61,78} and re-treatment.⁹⁰ Thus, the size of the radiolucency does not appear to influence the potential for healing after nonsurgical endodontic treatment.

Periodontal Support

Only few studies have examined the periodontal condition as a variable in nonsurgical treatment. A better outcome in teeth with better marginal support is reported in one selected study,⁷² but in other selected

studies^{43,78,90} the periodontal status has not been significantly associated with the outcome. Periodontal defects present at the time of treatment are a sign of advanced periodontal disease that in time may necessitate extraction of the affected teeth. Indeed, in one selected study⁶⁷ over 50% of teeth extracted 4 to 6 years after initial treatment were lost because of periodontal disease, and in a survival analysis of root-filled teeth with periodontal disease,²⁵¹ the proportion of periodontal-driven extractions was 66% of all lost teeth over a 9-year period. Thus, periodontal defects do not appear to influence the potential for healing after nonsurgical endodontic treatment; however, advancing periodontal disease may cause loss of affected teeth over time.

Apparent Quality of Previous Root Filling (in Re-treatment)

One selected study on re-treatment⁹⁰ reports a significantly better outcome (15% difference) in teeth with apical periodontitis that have inadequate length or density of the previous root filling, compared with teeth with apparently adequate root fillings. In addition, one nonselected study⁹¹ reports a poorer outcome in teeth where the previous root filling deviates from the pathway of the canal, than in teeth with unaltered morphology. The inadequately filled canals “constituted the infected sites, which, when re-treated, could be effectively disinfected and sealed, leading to healing.”⁹⁰ By contrast, adequately filled canals may host root canal bacteria not susceptible to re-treatment procedures, or they may be free of bacteria when the disease is sustained by extra-radicular infection, cysts, or a foreign body.⁹⁰ Such extra-radicular etiologic factors do not respond to re-treatment. Thus, an apparent poor quality of the root filling in previously treated teeth with apical periodontitis has a positive influence on the potential for healing after re-treatment.

Previous Perforation (in Re-treatment)

Very little information is available on the outcome of teeth in which a root or chamber perforation

occurred. In the first nonselected study that examined this variable,³²⁶ healing is reported around 58% of perforations repaired with amalgam or gutta-percha. In a more recent selected study,⁹⁰ complete healing is reported in only 36% of teeth with apical periodontitis and perforations repaired with resin-modified glass ionomer cement, prompting the authors to speculate that “possibly, the use of MTA could have been beneficial.” MTA was used for perforation repair in a case series study,³²⁷ and all 16 treated teeth appeared to be healed 1 year or longer after treatment (Figure 12). Thus, a previous perforation may have a negative influence on the potential for healing after re-treatment, depending on the material used to seal the perforation.

Elapsed Time after Previous Treatment (in Re-treatment)

This variable has been examined in only one selected study,⁹⁰ where a comparable outcome is reported in teeth re-treated within 1 year or longer after initial treatment. Thus, the time elapsed since previous treatment does not appear to influence the potential for healing after re-treatment.

PER-TREATMENT VARIABLES

Based on the information gleaned from the selected studies, the per-treatment variables are clearly more critical in teeth with apical periodontitis than in teeth with intact periapical tissues.

Length of Canal Preparation and Filling

Several selected studies^{1,6,72} qualify that the length of canal preparation should be distinguished from the length of the root filling; however, most frequently only the length of the root filling is addressed. In five of the selected studies,^{1,6,43,48,72} the length of the root filling has been significantly associated with the outcome of initial treatment, whereas no such association has been reported in eight selected studies.^{35,55,61,62,66,71,75,78} Similar inconsistency exists in studies on re-treatment, where one selected study⁹⁰ reports a poorer outcome in teeth with

Figure 12 Re-treatment in conjunction with an internal perforation repair. **A**, Mandibular molar with a distal root perforation into the furcation and associated bone loss. **B**, Completed re-treatment and perforation seal with mineral trioxide aggregate (MTA) (ProRoot MTA; Tulsa Dental, Tulsa, OK). **C**, At 1.5 year, the bone in the furcation area is healed. Regrettably, the tooth has not been properly restored.

inadequate (too long or too short) root fillings, whereas two selected studies^{43,86} do not corroborate this finding.

Impaired healing in teeth with extruded root fillings, particularly in the presence of apical periodontitis, has been shown in several selected studies.^{1,6,43,48} The damage may have resulted from over-instrumentation and inoculation of the periapical tissues with

infected debris, rather than from the extruded root filling^{43,320} (Figure 13). Possibly, extruded root filling materials slow down healing of apical periodontitis and delay it as long as to the third decade after treatment,⁹² even though they can be totally or partially removed during the healing process.^{1,44,225}

One selected study⁴³ reports impaired healing in teeth with apical periodontitis, where canals

Figure 13 Periapically extruded root filling. Maxillary first molar with 2 gutta-percha cones extruded at least 10 mm beyond the terminus of both the buccal apices. Although the same conditions apparently exist in both roots, the mesiobuccal root is associated with apical periodontitis whereas the distobuccal root is not, suggesting that the cause of apical periodontitis is not the extruded gutta-percha. (Reprinted with permission from Friedman 2002.¹⁶⁴)

were prepared and filled excessively short (2 mm or shorter); however, an earlier selected study reported by the same group³⁵ does not support this finding. Thus, the root filling length does not appear to influence the healing potential after nonsurgical endodontic treatment in teeth without apical periodontitis. With apical periodontitis present, the healing potential may be better if the canal is filled 0 to 2 mm short of the root end.

Apical Enlargement

Intra-canal bacteria can penetrate the dentin of teeth with apical periodontitis^{315,328} to a depth of 150 to 250 μm ³²⁹⁻³³¹ and remain protected from the antibacterial action of irrigants and medications.³³² It appears that the infected dentin can only be removed by enlargement of the canal by 300 to 500 μm , e.g., to ISO size 50 to 70 if the first file that binds is size 20. Because such extensive apical enlargement may enhance disinfection in the apical portion of the canal,³³³⁻³³⁵ it should also improve the outcome of treatment. However, apical enlargement has not been significantly associated with

the outcome of initial treatment in four selected studies,^{22,61,62,72} whereas in a fifth selected study,¹ it appeared to impair the outcome. There is, therefore, no clinical evidence to support extensive apical enlargement in teeth with apical periodontitis. Possibly, this is due to problems associated with both extensive and minimal apical enlargement. Extensive enlargement can result in canal transportation if not carried out skillfully, whereas minimal enlargement may not remove infected dentin. Both effects would compromise healing.¹⁶⁴

Most importantly, however, it should be noted that the true extent of apical enlargement cannot be assessed because the pretreatment canal dimensions in all the studies are unknown. Thus, there is insufficient data available to assess the influence of apical enlargement on the healing potential after initial endodontic treatment, and no data at all on apical enlargement in re-treatment.

Bacterial Culture Before Root Filling

Bacteriologic root canal sample without bacterial growth (negative culture) obtained before root filling was first associated with a better outcome by Engström et al.,⁶ however, the microbiologic techniques utilized in this selected study did not adequately address the anaerobic endodontic pathogens.⁵³ Three decades later Sjögren et al.,⁵³ in one of the selected studies using an advanced anaerobic bacteriologic technique during initial treatment, reported healing in 94% of teeth that had a negative culture before root filling, in contrast to only 68% in teeth with positive cultures. In a parallel selected study on re-treatment,⁸⁶ 80% of teeth with negative cultures before root filling healed, compared with 33% of teeth with positive cultures. In a recent selected study,⁷⁶ a better outcome is reported in teeth treated in two sessions, where negative cultures were obtained at the beginning of the second session after dressing with calcium hydroxide, compared with teeth with positive cultures. Furthermore, the bacterial species recovered from the canal also may influence the prognosis.⁵³ All these findings, clearly demonstrating a significant association between negative cultures obtained with reliable culturing methods and the potential of healing after nonsurgical endodontic treatment, are apparently disputed by another selected study.⁶¹ Significant or not, state-of-the-art techniques for obtaining bacteriologic samples from root canals are not readily available for use in the day-to-day endodontic practice.⁵³ Therefore, their usage should be directed mainly toward research to assess the efficacy of root canal treatment regimens. Thus, results

of bacterial cultures obtained from root canals before root filling do not appear to influence the healing potential after nonsurgical endodontic treatment.

Number of Treatment Sessions

In recent years, considerable research efforts have been made to study the potential for healing after treatment in one session or two. In teeth without apical periodontitis, there is no difference in healing related to one or two treatment sessions⁸⁰ as the canals are not infected. In infected canals, however, root canal bacteria cannot be effectively eliminated in a single treatment session.⁵³ This and other studies^{226–229,231,333,334,336} emphasize the need for intra-canal medication in order to maximize disinfection, suggesting a better outcome when treatment is performed in two sessions with an effective intra-canal medication used. However, this premise is not supported by the selected studies on initial treatment^{54,55,61,78} and re-treatment,⁹⁰ that report nonsignificant inconsistent differences in healing in the range of 10%, after treatment in one or two sessions. As all these studies are underpowered—their samples are too small to show significance of the observed differences—this may have been the main reason for the lack of significance reported.

The number of sessions in multi-session treatment does not appear to influence the outcome in one of the selected studies.²² However, it appears that efforts should be made to avoid prolongation of treatment, as teeth treated in one or two sessions have been shown to survive longer than teeth treated in three sessions or more.¹⁶³ Sirén et al.³³⁷ suggest that teeth treated in multiple visits are at a greater risk of becoming infected with *E. faecalis* and developing refractory apical periodontitis.

As shown by one of the selected studies,⁵³ the potential for healing after treatment in one session is good. In fact, a systematic review of the pertinent literature concludes that “the biological benefit of multi-session treatment has not been supported by clinical evidence.”³³⁸ Thus, there is insufficient data available to assess the influence of the number of treatment sessions (one or two) on the healing potential after nonsurgical endodontic treatment in teeth with apical periodontitis. However, prolongation of treatment for more than two sessions should be avoided.

Flare-Up During Treatment

In several of the selected studies, there has been no significant association between flare-ups and the out-

come of initial treatment^{1,22,35,43,61,78} and re-treatment.⁹⁰ Thus, occurrence of flare-up or pain in the course of treatment does not appear to influence the healing potential after nonsurgical endodontic treatment.

Materials and Techniques

In contrast to the frequent occupation of the profession with endodontic techniques and materials, and the multitude of in vitro studies focused on comparing them, there is only limited information available in the selected studies on the influence of specific treatment regimens on the potential for healing. Only few aspects of materials and techniques have been examined, as follows:

- Instrumentation technique: A better outcome is reported using the “standardized” technique than the “serial” technique in one selected study;²² however, both techniques are seldom used today. In recent selected studies examining current canal preparation techniques in initial treatment, there has been no significant association between the outcome and the use of hand or engine-driven instruments,⁷⁵ different engine-driven instrument systems,⁷¹ and the degree of taper.⁶² Thus, the instrumentation technique does not appear to influence the healing potential after initial treatment, and by extension, also after re-treatment.
- Intra-canal medication: A survival analysis study¹⁶³ suggests a better potential for survival of teeth where canals were dressed with calcium hydroxide than teeth dressed with other medications or with canals left empty between treatment sessions. In the absence of data from follow-up studies, there is insufficient data available to assess the influence of the type of intra-canal medication on the healing potential after nonsurgical endodontic treatment in teeth with apical periodontitis.
- Sealer: One sealer, Kloroperka N-Ø, is identified as adversely influencing the outcome in a selected study with a mixed sample of teeth without and with apical periodontitis.⁷² The researchers suggest that the choice of sealer may influence the prognosis, but only in teeth without apical periodontitis. Indeed, in a subsample of teeth with apical periodontitis³⁹ and in three subsequent selected studies of larger populations reported by the same group,^{48,56,66} the outcomes have been comparable for different sealer types. Thus, with the exception of Kloroperka N-Ø, the type of sealer does not appear to influence the healing potential after nonsurgical endodontic treatment.

- **Root filling technique:** In two selected studies that have examined different root filling techniques in initial treatment, comparable outcomes have been reported for hybrid and vertical compaction,⁶² and for lateral and vertical compaction.⁷¹ Thus, the technique used for root filling does not appear to influence the healing potential after initial treatment and, by extension, also after re-treatment.
- **Comprehensive technique:** In the recent selected Toronto Study series,⁷⁸ the proportion of healed teeth with apical periodontitis treated with the classic Schilder technique—flared canal preparation with ample irrigation and root filling with vertically-compacted warm gutta-percha—is significantly higher (10% difference) than in teeth treated with step-back or modified step-back instrumentation and lateral compaction of gutta-percha. Notwithstanding the demonstrated significance, the difference between the techniques requires validation from a RCT, because the Toronto Study was not randomized and controlled to assess the influence of a single variable on the outcome. Notably, in the re-treatment study of the Toronto Study series,⁹⁰ the difference healing between the same two techniques was smaller and not significant. Thus, in spite of the indication of the superiority of the Schilder technique, there is insufficient data available to assess the influence of this comprehensive treatment technique or others on the healing potential after nonsurgical endodontic treatment in teeth with apical periodontitis.

Complications

In one selected study,⁷² there is no significant association between mid-treatment complications and healing. However, in several other selected studies,^{1,22,43,78} healing has been impaired by complications, including perforation of the pulp chamber or root, file breakage at a stage that prevents cleaning of the canal, and massive extrusion of filling materials. It is noteworthy that endodontists currently may successfully manage these complications; for example, a recent review³³⁹ concludes that “in the hands of skilled endodontists prognosis was not significantly affected by the presence of a retained fractured instrument,” in contrast to early selected studies^{1,22} that reported poorer outcomes in teeth with broken instruments. Likewise, a recent case series study³²⁷ reports complete heal-

ing of all 16 teeth in which perforations were repaired with MTA. In regard to re-treatment, a recent selected study⁹⁰ reports a comparable outcome in teeth with and without mid-treatment complications. Thus, the negative influence of mid-treatment complications on the healing potential after nonsurgical treatment may be offset by current management strategies. Nevertheless, complications should be avoided, as depending on their severity they may impair healing of the affected teeth.

POST-TREATMENT VARIABLES

Restoration

When bacteria become established in the pulp chamber, they can penetrate the filled root canal, as shown *in vitro*,^{340–351} and apical periodontitis can develop subsequently, as shown in an animal model.^{261,352} Indeed, in one selected study,⁹⁰ impaired healing is reported in teeth that had not been definitively restored after re-treatment. The type of the restoration (temporary, definitive, filling, cast) has not been significantly associated with healing after initial treatment^{53,78} and re-treatment.⁹⁰ However, one selected study⁴³ reports less healing in teeth restored with crowns and those serving as bridge abutments, than in teeth restored with fillings.

The restoration has also been examined in several cross-sectional studies, with conflicting results. In one study,³⁵³ presence or absence of posts is not associated with healing, if at least 3 mm of the root filling remains under the post. In two other studies,^{178,354} posts have been associated with an increased prevalence of apical periodontitis, whereas the opposite was reported in a third study.³⁵⁵ It is noteworthy that cross-sectional studies provide a low level of evidence. In the selected studies,^{43,78,90} there has been no significant association between the presence or absence of posts and the outcome of initial treatment and re-treatment. Thus, the type of the intra-radicular, intra-coronal, and extra-coronal restoration does not appear to influence the healing potential after nonsurgical endodontic treatment, as long as the tooth is definitively restored in a timely manner.

Nevertheless, the survival or loss of root-filled teeth clearly depends on the restoration, and

Figure 14 Risks associated with post-retained restorations of endodontically treated teeth (from left to right)—perforation, root fracture, and post fracture. (Reprinted with permission from Friedman 2002.¹⁶⁴)

particularly restorative failure.³⁵⁶ For example, in the selected Toronto Study series,^{67,70,78,90} over 35% of the 87 teeth extracted 4 to 6 years after treatment were lost because of restorative considerations. In a survival analysis after endodontic treatment,¹⁶³ 53% of extracted teeth were lost because of fracture (root or crown is not specified), with additional teeth extracted because of a “prosthetic need.” In addition, posts have been implicated in vertical root fracture and tooth loss in approximately 9% of cases,³⁵⁶ as well as in root perforations that impair healing.³⁵⁷ Clearly, posts present a risk to root-filled teeth (Figure 14); they should be used sparingly and with caution.

ANTIBACTERIAL EFFICACY OF INTRA-CANAL PROCEDURES

Pretreatment presence of apical periodontitis is the dominant variable influencing the potential for healing after nonsurgical treatment. Apical periodontitis is

sustained by root canal infection; therefore, “the bacteriological status of the root canal at the time of root filling is a critical factor in determining the outcome of endodontic treatment,”⁵³ suggesting that improved bacterial elimination may be considered as a surrogate measure for improved outcomes. The antibacterial efficacy of intra-canal procedures, measured by the proportion of bacteriological samples below the level of bacterial detection (negative culture) and by the number (density) of bacteria in the samples, is briefly reviewed below.

Irrigation

Root canal preparation coupled with inactive irrigants does not predictably eliminate bacteria, resulting in less than 50% negative cultures, regardless of the use of stainless-steel hand instruments or nickel–titanium engine-driven ones.^{227,230,333} By contrast, irrigation with $\geq 0.5\%$ sodium hypochlorite considerably improves bacterial elimination, resulting in 50 to 80% negative cultures, and over 99% reduction in bacterial counts, from an order of 10^5 to 10^2 .^{53,76,228,229,231,336,358–365} Subsequent irrigation with IKI may not improve bacterial elimination, resulting in over 70% negative cultures.³⁶⁰ A similar result over 70% negative cultures may be expected after use of a new immersion-irrigating agent, MTAD, without significant improvement in bacterial elimination.³⁶⁵

Bacterial elimination during re-treatment has been evaluated considerably less than in initial treatment. Instrumentation and irrigation with sodium hypochlorite have resulted in 70% to 77% negative cultures,^{294,301} a comparable efficacy to that reported for initial treatment. Further irrigation with IKI may improve bacterial elimination, resulting in 95% negative cultures.²⁹⁴

Dressing with Medication

The efficacy of antibacterial dressing between subsequent treatment sessions has met with much controversy. Initially, a superior efficacy of intra-canal dressing with calcium hydroxide has been clearly demonstrated,^{35,226} and corroborated in more recent studies,^{231,358,361} resulting in over 85% negative cultures and reduction of bacterial counts to the order of 10^1 . In other studies,^{333,334,363,366} bacterial elimination was not as dramatic, resulting in only 60 to 80% negative cultures. In stark contrast, a decline in negative cultures to 70% or less and an increase in bacterial counts have been reported in three recent studies.^{76,359,360} Considerable differences in root canal culturing methodology

make it difficult to reconcile these contrary findings, as the methodology itself has been questioned.³⁶⁷ Nevertheless, the available data suggest that “calcium hydroxide has limited effectiveness in eliminating bacteria from human root canal when assessed by culture techniques.”³⁶⁸

In regard to alternative intra-canal medications, dressing with clindamycin results in 76% negative cultures, similar to that achieved with calcium hydroxide.³³⁶ Dressing with 2% chlorhexidine-gluconate liquid results in a decline in negative cultures—from 68 to 45%—and in increase in bacterial counts from the order of 10^2 to 10^3 .³⁶² A 2% chlorhexidine gel appears to be more effective than the liquid; the proportion of negative cultures may remain stable with slightly reduced bacterial counts.^{363,365}

The efficacy of intra-canal dressing with calcium hydroxide during re-treatment appears to be limited.³⁰¹ The authors report a decrease in negative cultures, from 77% after canal preparation to 57% after dressing with calcium hydroxide alone or mixed with chlorhexidine. After further canal preparation in the second treatment session negative cultures increased to 87%, but fell again to 70% after subsequent dressing.³⁰¹

Clearly, more research is required to unequivocally establish the critical role of intra-canal dressing, with calcium hydroxide or another effective medication, in the elimination of root canal bacteria in nonsurgical endodontic treatment. However, notwithstanding the recent data challenging the efficacy of intra-canal medication, it is noteworthy that the proportion of negative cultures appears to increase, and the bacterial counts appear to decrease at the end of the second treatment session, compared with the end of the first session.^{76,333,359,362,365,301} *Thus, the two-session treatment with interim dressing appears to improve bacterial elimination beyond what can be achieved in one treatment session.*

Apical Enlargement

Progressive enlargement of the root canal in early studies^{333,334} has not significantly improved bacterial elimination. In a more recent study,²³⁰ bacterial counts are somewhat reduced when the apical portion of the canal is enlarged from ISO size 45 (size 25 in curved canals) to size 50 and 60 (size 30 and 35 in curved canals). The bacterial reduction is even more pronounced when sodium hypochlorite is used,²³¹ and a further reduction is reported when the canal is enlarged with nickel-titanium instruments to very large sizes.³³⁵

The antibacterial efficacy of apical enlargement in re-treatment has not been assessed. When re-treatment is

performed with any technique, a considerable amount of root filling residue remains attached to the canal walls.^{369–386} Such residue may interfere with bacterial elimination, as it may shelter subjacent bacterial colonies. A recent *in vitro* study³⁸⁶ indicates that the amount of residue can be reduced by further enlargement of the canal beyond its dimensions before re-treatment. Thus, bacterial elimination may also be improved by progressive apical enlargement during re-treatment.

In summary, copious irrigation with sodium hypochlorite delivered deep apically by means of a small gauge needle and substantial apical enlargement to sizes approximating those listed in a series of morphometric studies^{260,387,388} are the critical basic steps in the elimination of root canal bacteria. The additional efficacy of root canal dressing with calcium hydroxide, chlorhexidine, or other medications has been cast into doubt and requires clarification. Because bacteria are the primary cause of refractory apical periodontitis, their maximal elimination by meticulously applying the aforementioned combination of therapeutic means improves the potential for healing after nonsurgical endodontic treatment.

Factors Influencing Healing after Apical Surgery

The majority of the selected studies on apical surgery have attempted to associate observed outcomes with different variables. For the major part, these variables are different from those that have been examined in relation to nonsurgical treatment.

PRETREATMENT VARIABLES

Age, Gender, and Systemic Health of the Patient

Age and gender have not been significantly associated with the outcome in the selected studies.^{138,139,148,151}

Systemic health has not been examined as a variable in any of the studies. Thus, the patient's age, gender, and systemic health do not appear to influence the potential for healing after nonsurgical endodontic treatment.

Tooth Location

Comparable outcomes have been reported for different tooth types in both the maxilla and the mandible in several selected studies.^{138,139,148,149,151} The only exception is the frequent healing by scar tissue—consistent with complete healing—observed in maxillary

lateral incisors.^{116,120} Apparently, convenience of access and the specific root anatomy influence the potential for healing after apical surgery to a greater extent than the location of the tooth.

Clinical Signs and Symptoms

Teeth with signs and symptoms appear to demonstrate less healing, as suggested by one selected study¹⁵¹ and one nonselected study.¹¹² However, in two selected studies,^{139,148} there have been no significant association between the outcome and absence or presence of pretreatment symptoms. Thus, presence or absence of symptoms does not appear to influence the potential for healing after apical surgery.

Size of Radiolucency

One selected study¹³⁹ suggests that the lesion size has no significant influence on healing. However, another selected study¹⁴⁸ reports a significantly better outcome in teeth with small lesions (≤ 5 mm in diameter) than in teeth with larger lesions. A similar pattern is reported in a recent study, but without statistical significance.¹⁵¹ Wang et al.¹⁴⁸ suggest that small lesions are completely eradicated when the crypt is surgically enlarged to gain adequate access, resulting in creation of an excisional wound in the surrounding bone.³⁸⁹ Curettage of large lesions may be incomplete and an excisional wound is not created, as the access is adequate and the crypt is not enlarged to avoid injury to adjacent anatomic structures. When the lesion is very large (≤ 10 mm in diameter), healing by scar tissue frequently occurs, as shown in nonselected studies.^{116,120} Thus, teeth with lesions not exceeding 5 mm appear to have a better potential for healing after apical surgery.

Supporting Bone Loss

Several nonselected studies^{99,103,105,110,112,147} have suggested a poor prognosis for teeth with considerable vertical or marginal bone loss. Such bone loss can compromise periodontal reattachment by apical migration of gingival epithelium, possibly enabling bacteria present in the periodontal pocket to invade the periapical site and prevent healing. Thus, considerable attachment loss of the treated tooth may have a negative influence on the potential for healing after apical surgery.

Restoration

Frequently in apical surgery, the restoration type is a pretreatment variable, because the teeth are already

restored at the time of treatment. A poorer outcome in teeth with a defective restoration or with a post is reported in one selected study,¹³⁹ but this finding is not supported by two other selected studies.^{148,151} Nevertheless, defective restorations can impair the survival of root-filled teeth³⁵⁶ (see Figure 9); indeed, in one selected study,¹⁴⁸ 7 of the 10 teeth extracted 4 to 8 years after treatment were lost because of restorative considerations, whereas 2 teeth were extracted because of fracture, and 1 tooth because of refractory apical periodontitis. Thus, there is insufficient data available to assess the influence of the type of the restoration on the potential for healing after apical surgery, as long as the tooth is adequately restored.

Apparent Quality of Previous Root Filling

The previous root fillings can be characterized by their material, density, and length. According to two selected studies,^{139,148} the type of the filling material and the filling density—absence (see Figure 4) or presence (see Figure 7) of voids—are not associated with the outcome. In one selected study,¹⁴⁸ a significantly better outcome is reported when the filling is too short (≥ 2 mm from the root end) or too long (extruded beyond the root end) than when its length is adequate; however, this finding is not supported by two other selected studies.^{139,151} Thus, there is insufficient data available to assess the influence of the length of the filling, whereas the type and density of the existing root filling do not appear to influence the potential for healing after apical surgery.

Second-Time Surgery

One selected study focusing on second-time surgery,¹⁴⁹ a nonselected study,¹⁸⁸ and a systematic review of several nonselected studies³⁹⁰ have concluded that the outcome of second-time surgery is poorer than that of first-time surgery. This conclusion is not supported by three selected studies.^{139,148,151} In one of these studies,¹⁴⁸ the difference in the proportion of healed teeth between first-time (79%) surgery and second-time (62%) surgery is not significant; however, with only eight teeth included in the second-time surgery group, this analysis is underpowered. Nevertheless, the authors suggest that modified case selection criteria and techniques may have improved the outcome of second-time surgery in their study compared with previous studies; typically, second-time surgery uses the same case selection criteria and techniques as the first-time surgery, whereas they routinely preferred root canal re-treatment over second-time surgery (Figure 15), and when surgery was selected, the technique differed from

Figure 15 Persistent disease after apical surgery—treated by orthograde re-treatment. **A**, Root-filled and previously surgically-treated maxillary lateral incisor, with a broken file, poorly placed root-end filling, and persistent apical periodontitis. **B**, The film shows fit of the master cone during orthograde re-treatment. All restorative material was removed from the coronal portion of the tooth, revealing an extensive cavity. **C**, Completed root canal re-treatment. The root-end amalgam was displaced outside the canal. **D**, At 2 years, the lesion is healed. (Reprinted with permission from Friedman 2006.²⁰¹)

Figure 16 Repeat (second-time) surgery. **A**, Root-filled and previously surgically-treated maxillary lateral incisor with persistent apical periodontitis, and a gutta-percha cone tracing the sinus tract. **B**, Completed repeat surgery, comprising retrograde re-treatment and filled with mineral trioxide aggregate (MTA). **C**, At 3 years, the lesion is healed. (Reprinted with permission from Friedman 2002.²²³)

that of the first-time surgery¹⁴⁸ (Figure 16). Thus, the second-time surgery may offer a poorer potential for healing than first-time surgery, unless an improved strategy is used.

PER-TREATMENT VARIABLES

Level of Apical Resection and Degree of Beveling

A better outcome is reported after resection at the mid-root level than at a more apical level in one nonselected study.¹⁰² A more conservative resection may expose canal ramifications that can allow intra-canal bacteria to sustain disease after surgery.²³⁸ Therefore, the root should be resected approximately 3 mm from the apex, where ramifications are fewer.^{305,391} Furthermore, a more coronal resection

level facilitates preparation of the root-end cavity and filling. Thus, a more coronal level of resection may have a positive influence on the potential for healing after apical surgery.

The degree of bevel should be minimal to avoid the risk of missing canals emerging at the lingual aspect of the root.^{238,305} Furthermore, a minimal bevel also reduces the number of exposed dentinal tubules on the cut root surface, minimizing the pathway available for root canal bacteria to sustain disease after surgery^{141,305,322,324} (Figure 17).

Presence or Absence of a Root-End Filling

A root-end filling is placed to establish an effective barrier against interaction of intra-canal bacteria with the periapical tissues.²²⁴ This rationale applies in all teeth where apical periodontitis is presumably sustained by persistent intra-canal infection.²²⁴ When

Figure 17 Patent dentinal tubules at the cut apical root surface. A specimen, taken 6 months after apical surgery on a dog, then subjected to dye leakage and sectioned vertically. The root-end filling was dislodged to allow assessment of dye penetration. Note the beveled cut surface and dye penetration through the dentinal tubules, demonstrating the communication between the root canal and apical environment. The dentinal tubules can provide a pathway for intra-canal bacteria to bypass the root-end filling and sustain the disease process. (Reprinted with permission from Friedman 2006.²⁰¹)

extra-radicular infection is suspected, a root-end filling may be superfluous^{148,224} (Figure 18); indeed, in one selected study,¹⁴⁸ seven of eight teeth (88%) suspected for extra-radicular infection healed without receiving a root-end filling.

Many nonselected studies published over the years^{93,96,98,102,106,108,112,116,120} have suggested that presence of a root-end filling impairs the prognosis. As stated in one of these studies,¹¹⁶ “retrofills have a strong negative effect on the end results.” It is note-

worthy that in these studies, root-end fillings were placed only in the teeth treated exclusively by apical surgery, but not in teeth where orthograde treatment was performed in conjunction with surgery. Therefore, comparison of teeth without and with root-end fillings was confounded by orthograde treatment, performed concurrently with the former but not with the latter.²²⁴ However, when only surgically treated teeth are analyzed in the same studies and others, better outcomes can be observed with root-end fillings than without.^{93,102,105,117,121} Thus, placement of a root-end filling may have a positive influence on the potential for healing after apical surgery, particularly when persistent root canal infection is presumably the cause of persistent disease.

Root-End Cavity Design

The classical root-end cavity drilled with a small round bur has been replaced in the past two decades with two main modifications. Rud et al.^{122,246,392} bonded a “cap” of composite resin—Retroplast—over the cut root surface to seal all possible bacterial pathways, including the main canal, accessory canals, isthmuses, and exposed dentinal tubules (see Figure 8). To avoid adverse effects of shrinkage, Retroplast is placed as a thin layer into a concavity created in the resected surface with a large round bur. In two selected studies,^{143,151} the proportions of “healed” and “healing” teeth 1 year after apical surgery with Retroplast are 73% and 85%, respectively. The outcomes in these studies and several nonselected ones where Retroplast was used^{122,130,133,140,190,246} appear to surpass the outcomes reported in studies where root-end cavities have been prepared and filled with a variety of materials (Tables 3, 7). Other composite resins, such as Geristore^{393,394} and OptiBond,²³⁸ can possibly be used as alternatives to Retroplast; however, their clinical effectiveness in this application has not been reported.

Thus, there is no strong evidence to suggest that both modifications of the classical root-end cavity—bonded apical “cap” and ultrasonic preparation—offer a better potential for healing after apical surgery; however, there is a sound clinical rationale for using both approaches. Both approaches also offer greater ease and consistency of application than the outdated drilling of the root-end cavity with small round burs.

Carr^{238,304} developed special angled tips for ultrasonic use that significantly modified the form of the root-end cavity. These tips can be used with less beveling of the cut root surface and in smaller crypts than burs.^{141,237,238,240,305} Most importantly, the

Figure 18 Suspected extra-radicular infection—placement of root-end fillings may be superfluous. **A**, Mandibular central incisors with extensive apical periodontitis. **B**, Completed root canal therapy. **C**, At 2 years, the lesion is enlarged suggesting persistence of the disease, possibly because of extra-radicular infection. **D**, Completed surgery consisting of only periapical curettage. **E**, At 1 year after surgery, the lesion is healed. (Reprinted with permission from Friedman 2006.²⁰¹)

created cavities are deeper, allowing the root-end filling to seal exposed dentinal tubules from within the canal.^{235,237,240} Furthermore, the cavities are cleaner and better aligned with the long axis of the canal, reducing the risk of root perforation on the lingual aspect.^{236,239,240} A better outcome after ultrasonic root-end cavity preparation than after use of burs has been reported in two nonselected studies;^{134,136} however, the analyses in both studies were confounded by extraneous factors, undermining their conclusions. It is noteworthy that the “healed” rates reported in the selected studies in which root-end cavities were prepared with ultrasonic tips range from 37 to 91%;^{138,139,144,148–151} this wide range is not

different from that of studies where root-end cavities were drilled with burs.

Quality and Depth of Root-End Filling

Only one selected study¹³⁹ highlights the significance of the quality of the root-end filling, particularly its correct placement, whereas another selected study¹⁴⁸ reports comparable outcomes for root-end fillings extending ≥ 2 mm into the canal space. However, the frequent beveling of the apical surface of the root precludes reliable radiographic assessment of the depth of the root-end filling.¹³⁹ Thus, there is insufficient data available to assess the influence of the root-end filling depth, ranging from 1 to 4 mm, on the

potential for healing after apical surgery. Nevertheless, the potential for healing is certainly improved after accurate placement of the root-end filling.

Root-End Filling Material

A plethora of restorative and endodontic materials have been suggested over the years for root-end filling, including amalgam (with or without varnish), zinc-oxide eugenol cement (plain or reinforced), EBA and Super EBA cement, polycarboxylate cement, glass ionomer cement, gutta-percha (burnished or injectable), composite resin, cyanoacrylate glue, Teflon, gold foil, titanium screws, and Cavit. In the past decade, MTA has gained popularity as a root-end filling material.^{244,395} This plethora of materials has primarily been assessed using *in vitro* models with highly inconsistent results.^{224,396} To better simulate clinical conditions, Friedman et al.³⁹⁷ developed an *in vivo* model (Figure 19) that has been used with some variations in several studies.^{241–245,398} In these animal studies, IRM,^{241,242}

Super EBA,^{243,245} MTA,²⁴⁴ and Diaket³⁹⁸ have performed better than other materials. However, animal studies do not provide the evidence-base required for supporting the clinical effectiveness of these root-end filling materials.

Several nonselected studies, primarily nonrandomized clinical trials, have assessed different root-end filling materials, including Biobond,⁹⁷ Cavit,^{101,103} glass ionomer cement,^{124,128,399} Retroplast,²⁴⁶ IRM,^{115,121,146} EBA,^{115,121,127} gold leaf,¹²³ and titanium inlay.⁴⁰⁰ Amalgam has been frequently used as the “gold standard” control in these studies. The conclusions of all these studies are undermined by their methodological inadequacies. For example, amalgam and EBA cement can be compared in three studies: EBA cement is significantly superior in one study (95% vs. 51% success, respectively),¹¹⁵ marginally superior in the second study (57% vs. 52%, respectively),¹²⁷ and marginally inferior in a third study (65% vs. 71%, respectively).¹²¹ Better evidence is available in recent selected RCTs^{143,144,150} and

Figure 19 An animal model for assessing the efficacy of root-end filling materials. **A**, Mandibular premolars in a dog, with apical periodontitis induced by inoculation of the canals with plaque. **B**, Clinical view of the crypts and root-end fillings with amalgam and varnish in all the canals of the four premolars. **C**, Radiographic view of completed surgery. **D**, At 6 months, some of the lesions are healed and others are not. Healing is the measure of the sealing efficacy of the root-end fillings. (Reprinted with permission from Friedman 2006.²⁰¹)

a selected nonrandomized trial.¹⁵¹ Retroplast is significantly better for apical “cap” bonding than glass ionomer cement (observed to detach in several teeth).¹⁴³ Apical bonding with Retroplast is apparently comparable with root-end filling with MTA.¹⁵¹ When root-end fillings are used, MTA appears to be equally effective to IRM.^{144,150} Healing may be poorer when using Super EBA than MTA.¹⁵¹ Thus, for the apical bonded “cap” approach, Retroplast offers a better potential for healing, whereas for the intra-canal root-end cavity approach, the potential for healing does not appear to be influenced by use of IRM or MTA, but may be somewhat compromised by use of EBA cements.

Hemostasis

Different hemostatic agents, including epinephrine-saturated pellets, ferric sulfate, bone wax, thrombin, calcium sulfate, Gelfoam, Surgicel, and collagen wound dressing, have been routinely used for crypt control by many clinicians.^{238,305,401,402} Good hemostasis is critically important for the quality of the root-end filling²³⁸ and bonding of an apical “cap.”¹⁴³ However, in a recent selected study,¹⁴⁸ there was no significant association between the outcome and the use of hemostatic agents. Thus, use of hemostatic agents does not appear to influence the potential for healing after apical surgery.

Concurrent Surgical and Orthograde Treatment

Concurrent apical surgery and initial treatment or re-treatment addresses all possible bacterial sites, including root canal ramifications, the apical root surface, and the periapical tissue. Furthermore, when these procedures are performed concurrently “infection is eliminated and re-infection is prevented.”¹²⁰ Therefore, the outcome is usually better in studies combining both procedures in the majority of the sample than in studies where only apical surgery was performed.^{207,224} The difference between the two approaches is also evident in specific nonselected studies.^{93,96,98,99,102,106,116} It confirms that root canal bacteria are the predominant cause of refractory apical periodontitis,^{302,303} and that they may still sustain the disease process in spite of the root-end filling. Currently, however, apical surgery is not considered imminent when the root canal is accessible from the coronal pathway; rather, it is performed alone as an alternative to orthograde re-treatment. Thus, the better potential for healing offered by performing concurrent apical surgery and orthograde treatment is merely of academic interest.

Retrograde Root Canal Re-treatment

An alternative to the typical root-end filling is an attempt to instrument, irrigate, and fill the root canal as far coronally as can be reached from the apical end.^{111,113,403–407} Studies on retrograde re-treatment have reported complete healing in 71% to 100% of the teeth, with persistent disease not exceeding 16%.^{111,113,148,408} The deeper barrier placed using this approach, between intra-canal bacteria and the periapical tissue, offers an advantage over the standard root-end filling. Nevertheless, continued bacterial ingress into the canal, under the restoration and along the post, may result in recurrence of disease (see Figure 10). Thus, even though retrograde re-treatment may not prevent recurrence of disease, it can enhance the outcome of apical surgery.

Magnification and Illumination

The use of aids to enhance visualization during apical surgery has become more common among clinicians than in the past. Magnification aids include loupes,¹⁵⁰ operating microscopes,^{304,409,410} and endoscopes.^{411,412} The latter two also greatly enhance illumination. These aids improve operator convenience, while also facilitating identification of root and canal anatomy and improving control of all aspects of the surgical procedure by improving the view of the surgical field.^{238,304–308,411–413} One nonselected study¹³⁵ reports 97% “success” and implies that the outcome of apical surgery can be improved by use of the operating microscope and Super EBA cement as the root-end filling. In several selected studies, loupes were used to enhance visualization,^{148–150} whereas the operating microscope or endoscope were used in other selected studies.^{144,151} As the value of magnification and illumination has not been assessed at an adequate level of evidence, there is no data available to assess their influence on healing after apical surgery. Nevertheless, there is a sound rationale for use of these aids to improve the quality of the surgical procedure.

Laser Irradiation

The rationale for laser irradiation of the resected root surface and crypt in apical surgery is the potential for sterilization, hemostasis,^{414–416} and the prevention of dentin permeability on the cut root surface.^{417–421} Notwithstanding the theoretical benefits of laser irradiation, healing after apical surgery does not appear to be influenced, as shown in animal studies^{397,422} and in a clinical trial.¹³⁴ Thus, healing after apical surgery is unlikely to be affected by use

of laser irradiation in different steps of the procedure.

Barriers and Bone Grafting Substances

Incorporation of guided regeneration barriers^{423,424} and various bone grafting substances^{425–429} has been advocated in apical surgery. The handful of case series reports^{424,430–433} do not provide evidence to support the routine use of these procedures. Thus, healing after apical surgery is unlikely to be enhanced by use of barriers and bone grafting substances. When such are applied, care must be taken to avoid infection.

Operator's Skill

The individual operator's skill has been suggested to influence the potential for healing in two nonselected studies.^{102,119} Among the selected studies, resident students were the treatment providers in three studies,^{139,143,148} whereas specialists, either oral surgeons or endodontists, performed the treatment in the remaining six studies.^{138,144,149–151,434} Therefore, reference to operator skill in the selected studies is scarce. Thus, even though it is likely that the operator's skill may influence the potential for healing after apical surgery, there is insufficient data available to assess the extent of this influence.

Complications

Complications that may occur during apical surgery include a perforation in the opposing (lingual or palatal) aspect of the root or cortical bone plate, maxillary sinus exposure, or paresthesia of the inferior alveolar nerve. Information on the relation of these complications to healing is scarce. Perforation of the opposing bone plate may not influence healing beyond an increased rate scar tissue.^{116,120,148} Healing also appears to be unaffected by perforation into the sinus.^{100,107,191} Paresthesia has been reported in as many as 20% of patients after apical surgery in mandibular molars.¹⁴⁷ The majority of these patients regained normal sensation within 3 months after surgery, in 1% the sensory deficit lingered for 2 years, and in 1% it lingered beyond 2 years.¹⁴⁷ There was no association of the sensory deficit with periapical healing. Thus, healing after apical surgery does not appear to be affected by procedural complications. Sensory deficit, although not related to healing, must be considered as a risk when mandibular molars are treated.

Antibiotics

The rationale for prescribing antibiotics after apical surgery is to prevent infection of a postoperative hematoma. According to three selected studies,^{139,148,151} a course of systemic antibiotics starting before and continuing after treatment does not influence healing. Thus, the use of systemic antibiotics is unlikely to influence healing after apical surgery.

POST-TREATMENT VARIABLE

Results of Biopsy

The periapical pathologic tissue is frequently removed during apical surgery and submitted to histopathologic examination. Theoretically, the biopsy results defining the pathologic lesion—apical periodontitis or cyst—might be used as indicators of the potential for healing. A significant association between the biopsy results and healing has been reported in one selected study¹⁴³ but not in two other selected studies.^{138,148} These conflicting reports may be the result of differences in processing of biopsy specimens. Routine biopsies are seldom subjected to serial sections and therefore may not accurately reflect the nature of the pathologic lesion. Thus, a biopsy report on the nature of the lesion removed during apical surgery should not be used to project the potential for healing.

Potential for Healing and Retained Function after Intentional Replantation

Intentional replantation as an endodontic treatment modality has been used over the years as an alternative to difficult endodontic treatment,¹⁵⁶ apical surgery, and root canal re-treatment,⁴³⁵ and even to prevent “predictable failures.”⁴³⁶ In accordance with current concepts, intentional replantation may be used as an alternative to extraction, when both re-treatment and apical surgery are not feasible in situ.^{152,154,437,438} (Figure 20). The expected goal is survival of the replanted tooth, considered as success¹⁵⁵ even if pathologic processes persist. Therefore, direct comparison of success and failure between intentional replantation and root canal re-treatment or apical surgery is not appropriate.

A replanted tooth requires healing of the attachment apparatus without root resorption. Periapical healing appears to be determined by survival of the periodontal ligament and cementum along the root surface,^{439,440} and by infection of the root canal⁴⁴¹ and the socket.⁴⁴² Reattachment without resorption is affected by the trauma associated with exarticulation,

Figure 20 Intentional replantation when conventional treatment (orthograde re-treatment and apical surgery) is not feasible. **A**, Root-filled, previously surgically-treated, maxillary first premolar with persistent apical periodontitis and deep probing to the apex on the distal aspect. **B**, Completed intentional replantation that included two root-end fillings with MTA. **C**, At 3 months, the lesion is considerably decreased. **D**, At 2 years, the treated tooth is completely healed. The probing depth at the distal aspect is reduced to 4 mm.

extraoral manipulation and replantation, the extraoral time and environment, and the type and duration of splinting.^{443,444} The optimal conditions for healing after intentional replantation include: (1) gentle extraction and reinsertion; (2) careful extraoral manipulation of the root, keeping it moist; (3) retrograde cleaning and filling of the root canal as far coronally as possible; (4) replantation within 15 minutes; (5) flexible splinting for 7 to 14 days and elimination of occlusal contacts; (6) pre- and post-operative antibiotic regimen; and (7) pre- and post-operative antiseptic mouth rinsing.

The majority of the studies on healing after intentional replantation (Table 4) have been reported over 20 years ago, and no current studies are available. According to the available studies, the “success” rate of intentional replantation ranges from 34%¹⁵² to 93%,¹⁵⁶ whereas the survival rate appears to exceed 80%, but the evaluation criteria are often vague. Although the treatment procedures in the studies listed in Table 4 differ considerably, their clinical protocols seldom meet the currently recognized requirements for successful replantation of teeth. For example, Grossman and Chacker¹⁵³ did not place root-end fillings in 28 replanted root-filled teeth with refractory apical periodontitis; this was likely the cause of refractory infection observed in 27% of their material. Emmertsen and Andreasen¹⁵² replanted the teeth after 30 to 60 minutes and tapered some roots by grinding to facilitate replantation; both factors compromise the tissues on the root surface, increasing the risk of resorption. When root fillings were performed, the inefficient method of gutta-percha and Kloroperka N-Ø was frequently used. Many roots were only sealed apically by root-end filling without a root filling; these roots were frequently associated with inflammatory root resorption, probably caused by persisting intra-canal bacteria that propagated through the dentinal tubules and infected the root surface.⁴⁴⁵ A similar technique was used in all or part of the sample in two more recent studies.^{158,160} Deeb¹⁵⁴ performed the root canal treatment and occasionally also the coronal restoration outside the mouth, probably extending the extraoral period over 15 minutes.

The realistic treatment outcome of proper intentional replantation cannot be assessed on the basis of the published studies, because of their procedural inadequacy. Projection from reported outcomes after replantation of traumatically avulsed teeth is inappropriate, because intentional replantation affords superior control over most of the factors influencing healing. In the absence of suitable clinical studies,

clues about the potential for healing may be obtained from animal studies on replantation and root resorption, where intentional replantation was the actual experimental procedure. These studies suggest that development of progressive root resorption may be minimized to 4% or below, when the optimal conditions for replantation are present.⁴⁴³ Indeed, three of the clinical studies on intentional replantation have reported root resorption in only 2% to 5% of the replanted teeth (see Table 4). Replacement resorption should not occur at all¹⁵⁸ because of the optimal extraoral time and environment. Indeed, in spite of the compromised protocol in one study,¹⁵² replacement resorption occurred in only 4% of the teeth. Beyond the prevention of resorption, healing of apical periodontitis may be achieved rather predictably, because the infected root canal can be effectively sealed when the root-end filling is carried out extraorally. The low incidence of resorption and persistent infection after intentional replantation is corroborated by many case reports.^{435–437,446–456} These reports have demonstrated the predictable healing potential after intentional replantation performed in well-controlled conditions, albeit at the lowest level of evidence.

Dynamics of Resorption

When resorption develops after intentional replantation, in the majority of the teeth it is discernible within 1 year.¹⁵² This is definitely true regarding inflammatory resorption. Replacement resorption may be first observed radiographically several years after replantation.⁴⁴⁰ However, it may be indicated clinically much earlier than radiographically, by a specific sound pitch upon percussion.

Realistic Outcome of Endodontic Treatment in the Population

The prevalence of apical periodontitis in the general population in different countries has been reported in many cross-sectional studies.^{178–180,354,355,457–492} These studies have highlighted an alarmingly high prevalence of apical periodontitis among root-filled teeth (Table 8), ranging from 20% to over 60%, and they reflect the realistic outcome of endodontic treatment in the general population. The reported prevalence is lower in some of the studies because those populations have less remaining teeth than populations of other studies. Less remaining teeth suggests that teeth affected by refractory apical periodontitis after endodontic treatment may have been extracted, and thus not accounted in the respective studies.⁴⁷⁷

Because the cross-sectional study methodology does not allow collection of all the data regarding the treatment histories of the observed root-filled teeth, the reported “snapshot” data of the percentage of teeth presenting with periapical radiolucency is subject to interpretation.⁴⁹³ Some of the radiolucencies captured

may have been reduced from their original size and healing, if the teeth have been captured shortly after treatment. Thus, the proportion of root-filled teeth with refractory apical periodontitis may be overestimated. However, when specific populations were re-examined 6 to 11 years after their first account in a cross-sectional

study, those lesions that were observed to heal were offset by a comparable number of new lesions that had developed.^{180,482,494,495}

Attempts to use the cross-sectional data to explore relationships between healing and specific clinical variables, notably the apparent quality of the restoration and root filling, have been contradictory. One study⁴⁷² suggests that the quality of the restoration influences healing more than the quality of the root filling, whereas other studies suggest the opposite⁴⁴¹ or report no difference.^{179,355,478,480,483} These contradictions arise from the limitations of the cross-sectional methodology, that is unsuitable for investigating such relationships.²¹² Thus, the influence on healing of the quality of the restoration or the root filling cited in these studies is not valid.

Expansion of the data collected in cross-sectional studies has been attempted in recent years by interviewing the subjects included in the studies and ascertaining that recently treated teeth are excluded.^{179,476,478,483} Nevertheless, even with the improved methodology, vital information on the pretreatment diagnosis and treatment methods is still unavailable. One observation, however, is con-

sistent throughout the cross-sectional studies—the apparent quality of the root fillings is poor in the majority of the treated teeth (see Table 8) and possibly correlated with the poor outcome observed in the studies.^{355,480}

Comments on Case Selection

Selection of cases for endodontic treatment takes into consideration the potential for healing and retained function, but also health and socioeconomic factors. Contraindications to treatment include nonrestorable and periodontally hopeless teeth, patients with extensive dental problems and restricted resources (that should be selectively utilized to benefit as many teeth as possible), and medically compromised patients at high-risk of infection or, for surgical procedures, those with bleeding disorders.

From the endodontic perspective, none of the preoperative clinical variables truly contraindicates therapy. The potential for healing after endodontic therapy of apical periodontitis is good, and the chance to retain a well-restored tooth in symptom-free function over time is excellent. Therefore, whenever it is feasible, either nonsurgical or surgical

SURGICAL PROCEDURES IN ENDODONTICS

CHAPTER 33

ENDODONTIC SURGERY

GERALD N. GLICKMAN, GARY R. HARTWELL

Historical Perspectives

Endodontic surgery, once thought to be a therapy of last resort, has advanced in recent years to increase the clinician's ability to achieve more predictably successful clinical outcomes. Advances in technology including specially designed instruments, improved root-end filling materials, and better visualization with microscopes, along with a more thorough understanding of the biology of wound healing, have all contributed to the contemporary concept of "microsurgical endodontics." In fact, patient misconceptions about endodontic surgery were negated in a recent study by Iqbal et al.¹ in 2007 who demonstrated that patients, following "microsurgical endodontics," claimed the procedure was better than expected and reported less or equal postoperative discomfort compared to nonsurgical endodontic treatment.

Despite these recent advances, endodontic surgery is not new to contemporary dentistry. The first recorded endodontic surgical procedure was the incision and drainage of an acute endodontic abscess performed over 1500 years ago.² Since that time, endodontic surgical procedures have continuously evolved as a result of the valuable contributions of many pioneers in dentistry including Abulcasis, Farrar, Fauchard, Hullihan, Martin, Partsch, and Black.³

In 1910, William Hunter's classic presentation, "*An Address on the Role of Sepsis and Antisepsis in Medicine*," was delivered to the Faculty of Medicine of McGill University in Montreal; it had a major impact on dentistry and initiated the concept of "focal infection," the ramifications of which still remain today. Consequently, the development of endodontic surgery was best characterized as both progressive and regressive—progressive because of the advancements in flap design and root-end management techniques and regressive because

advocates of focal infection considered pulpless teeth to be foci of infection and ultimately responsible for arthritis, nephritis, and other systemic diseases. While tremendous strides were made in the development and application of endodontic surgical techniques, the concepts involved in endodontic surgery were unjustly being attacked by the medical profession.³

While Hunter's presentation initiated a major conflict, it turned out to be the stimulus for the development of endodontics and endodontic surgery.

The results of scientific investigation and the clinical application of the techniques and concepts developed during the second half of the twentieth century represent the foundation of what is known and will be practiced into the twenty-first century. However, endodontic surgery is dynamic and it is imperative that scientific investigation continues; concepts, techniques, and materials used in "microsurgical endodontics" must be continually evaluated and modified and more emphasis must be placed on the assessment of long-term clinical outcomes with a better understanding of the molecular basis for surgical wound healing.

Indications, Contraindications, and Classification

During the last 20 years, endodontics has seen a dramatic shift in the application of periradicular surgery. Previously, periradicular surgery was commonly considered the treatment of choice when nonsurgical treatment had failed or if existing restorative or prosthetic treatment would be endangered by orthograde treatment.⁴ Grossman et al.⁵ provided a list of indications for endodontic surgery including the presence of large and intruding periapical lesions, overfilled canals, incomplete apical

root formation, and destruction of the apical constriction by over-instrumentation amongst others. In addition, the dental literature contains an abundance of clinical articles, scientific reports, and textbook chapters that provide extensive lists of indications for periradicular surgery. However, many of the previously accepted indications are no longer valid in light of current concepts of the biological basis for endodontic treatment. Therefore, it must be recognized that periradicular surgery has become very selective in contemporary endodontic practice.

The emphasis on nonsurgical retreatment of endodontic failures has probably had the single greatest impact on the indications for surgical intervention in the treatment of endodontic pathosis. Studies reporting the success rate for nonsurgical retreatment indicate success rates as low as 62% to as high as 98% depending on the clinical status of the case.⁶⁻¹⁰ With the advent of the microscope and microsurgical tools, nonsurgical retreatment has become more predictable. Given these success rates and improved technology, there are specific indications for periradicular surgery today. These are (1) failure of nonsurgical retreatment (treatment has been rendered at least two times), (2) failure of nonsurgical (initial) treatment and retreatment is not possible or practical or would not achieve a better result, or (3) when a biopsy is necessary. It is paramount that these indications must be in the best interests of the patient, within the skills of the clinician, and reflective of biological principles of endodontic therapy.

Few absolute contraindications to endodontic surgery exist. Most contraindications are relative and they are usually limited to three areas: (1) the patient's medical status, (2) anatomical considerations, and (3) the practitioner's skills and experience. When considering performing any surgical procedure on a patient who reports a major system disorder (cardiovascular, respiratory, digestive, hepatic, renal, immune, or skeleton-muscular), a thorough medical history is mandatory. Following the identification of all potential medical complications and a review of the patient's current drug regimen, a consultation with the primary care physician or specialist may be in order. The dentist should explain to the physician the needed endodontic surgical treatment, including a brief description of the procedure, anesthetic agents and other drugs to be used, the approximate length of time required for the procedure, and the expected length of recovery. In this way, the physician can more adequately assess the medical risks involved and can assist the endodontist in determining the appropriate treatment modifications. These modifications may be preoperative (alteration of drug therapy, sedative or hypnotic, and systemic antibiotics), intra-operative (N₂O₂ and intravenous

sedation), or postoperative (re-establishment of drug therapy, sedatives, and analgesics).

Although anatomical considerations will be addressed later in this chapter, it should be emphasized that the majority of these present contraindications that must be addressed as they relate to each individual patient. The major anatomical considerations of importance to endodontic surgery involve (1) the nasal floor, (2) the maxillary sinus, (3) the mandibular canal and its neurovascular bundle, (4) the mental foramen and its neurovascular bundle, and (5) anatomical limitations to adequate visual and mechanical access to the surgical site. A skilled surgeon with the needed microsurgical armamentarium is usually able to circumvent these anatomical limitations and accomplish successful endodontic surgery.¹¹

It is imperative that dental professionals keep in mind that all treatment rendered by them to their patients must be in the patients' best interests and at the highest quality of care. As a professional, one has an obligation to know one's limitations of clinical skills and to perform treatment procedures consistent with those limitations. The majority of endodontic surgical procedures should be performed by trained endodontic specialists. When receiving care of a specialized nature, patients need and deserve treatment that meets the standard of care delivered by competent practitioners trained as specialists.¹²

A contemporary classification of endodontic surgery is as follows:³

1. Fistulative surgery
 - a. Incision and drainage (I&D)
 - b. Cortical trephination
 - c. Decompression procedures
2. Periradicular surgery (primary focus of this chapter)
 - a. Curettage
 - b. Root-end resection
 - c. Root-end preparation
 - d. Root-end filling
3. Corrective surgery
 - a. Perforation repair
 - i. Mechanical (iatrogenic)
 - ii. Resorptive
 - b. Periodontal management
 - i. Root resection
 - ii. Tooth resection
 - c. Intentional replantation

Treatment Planning for Periradicular Surgery

As was previously discussed, the indications for and the application of periradicular endodontic surgery have

undergone dramatic changes in the last two decades. These changes have been evident especially when dealing with the treatment of failed nonsurgical endodontic treatments. The most important principle of endodontic diagnosis and treatment planning is that the primary modality for endodontic treatment failure should be nonsurgical endodontic retreatment whenever possible.^{3,4,9,13-17} The importance of thorough and meticulous presurgical planning cannot be over-emphasized. Not only must the practitioner and staff be thoroughly trained, but also all necessary instruments, equipment, and supplies must be readily available in the treatment room. This requires that every step of the procedure be carefully planned and analyzed. The potential for possible complications must be anticipated and incorporated into the presurgical planning.

Good patient communication is essential for thorough surgical preparation. It is important that the patient understands the reason surgery is needed as well as other treatment options available. The patient must be informed of the prognosis for a successful outcome and the risks involved in the surgical procedure in addition to the benefits. It is also important that the patient is informed of the possible short-term effects of the surgery such as pain, swelling, discoloration, and infection. Signed consent forms are essential.

A presurgical mouth rinse will improve the surgical environment by decreasing the tissue surface bacterial contamination and thereby reducing the inoculation of microorganisms into the surgical wound. Chlorhexidine gluconate (Peridex) has been shown to decrease salivary bacterial counts by 80% to 90% with a return to normal within 48 hours.¹⁸ Gutmann and Harrison recommend that chlorhexidine gluconate oral rinses should be started the day prior to surgery, immediately before surgery and continued for 4 to 5 days following surgery. The reduction in numbers of oral bacteria prior to and during the early postsurgical period and the inhibition of plaque formation produce a markedly improved environment for the wound healing.³

Most periradicular surgical procedures, regardless of their indication, share a number of concepts and principles in common: (1) need for profound local anesthesia and hemostasis; (2) management of soft tissues; (3) management of hard tissues; (4) surgical access, both visual and operative; (5) access to root structure; (6) periradicular curettage; (7) root-end resection; (8) root-end preparation; (9) root-end filling; (10) soft tissue repositioning and suturing; and (11) postsurgical care. All of these concepts and principles may not be employed in any given surgery. However, an in-depth knowledge and understanding of these principles, and

the manner in which they relate to the biology and physiology of the tissues involved, is of major importance. The strict adherence to and application of these principles will greatly influence the success of the surgical treatment and minimize patient morbidity.

Anatomical Considerations

Anatomical structures that may be of importance during endodontic surgery include the neurovascular bundle associated with the greater palatine foramen, the mandibular canal, and the mental foramen; the floor of the nose; the maxillary sinus; and any other anatomical structures that limit or compromise visualization and access to the surgical site. One must also be cognizant of individual root anatomy where more than one root canal system is present within a single root and an isthmus exists between the canals. An endodontist or other surgeon with the appropriate training, experience, skill level, and armamentarium can usually circumvent these anatomical limitations and accomplish endodontic surgery in a predictable and successful manner.

During surgical procedures on maxillary incisors, the floor of the nose will infrequently be encountered unless the roots of the incisors are extremely long or the periradicular lesion extends superiorly and has eroded through the bony floor of the nose. The greater palatine foramen (Figure 1) is most frequently located between the maxillary second and third molars in a position approximately 1 cm from the margin of the palatal gingiva toward the midline of the palate.¹⁹ The greater palatine foramen and its

Figure 1 Opening of greater palatine foramen (arrow). Note location of groove where neurovascular bundle courses in posterior portion of the palate.

contents generally do not pose a problem because very few apical surgical procedures are performed on the palatal root of maxillary second and third molars.

Exposure of the maxillary sinus may occur when apical surgical procedures are performed on the roots of any of the teeth located in the maxillary posterior quadrants. It has been reported by Eberhardt et al.²⁰ that the apex of the mesiobuccal root of the maxillary second molar is closest to the floor of the maxillary sinus (mean = 0.83 mm) and that the apex of the buccal root of the maxillary first premolar is furthest away (mean = 7.05 mm). The root apices of the maxillary second premolar, mesiobuccal, and distobuccal roots of the maxillary first molar were all approximately 2.8 mm from the floor of the sinus. Twelve autopsy specimens and 38 human patients were subjected to computed tomography to arrive at these means.

Ericson et al.²¹ noted in 314 apical surgical procedures performed on maxillary canines, premolars, and molars in 276 patients that oroantral communication was noted in 41 cases (13%). They found in this clinical study that the sinus communication did not impair healing, as there was no difference in the success rate between those cases with or without sinus exposure. In another clinical study reported by Rud and Rud,²² a sinus perforation occurred in 50% of 200 maxillary first molars treated with an apical surgical procedure. Of the cases with a sinus exposure, only two developed a postoperative sinusitis.

When performing surgical procedures on teeth in situations where the apical lesion has not penetrated the cortical plate, the surgeon should be aware of the mean thickness of bone that must be penetrated to reach the root apices. Jin et al.²³ calculated the mean distance from the root apices to the buccal or palatal cortical plate for the root or roots of every tooth group except third molars. One thousand eight hundred and six teeth were evaluated using computed tomography in a population of 66 Asian patients. In a similar computed tomography study conducted by Eberhardt et al.,²⁰ only maxillary premolars and the maxillary first and second molars were studied. The greatest mean distance between a root apex and the buccal cortical plate reported in the two studies was for the distal root of the mandibular second molar with a mean distance of 8.51 mm.²³ The tooth with the root apex closest to the buccal cortical plate was the maxillary canine (mean = 1.64 mm) in one study²³ and the buccal root of the maxillary first premolar (mean = 1.63mm) in the second study.²⁰

When performing apical surgery on mandibular premolars and molars, it is not only important to

know the location of the root apices in relationship to the buccal cortical plate but also to the relationship of the root apices to the mandibular canal. The distal root of the mandibular second molar is located furthest from the buccal cortical plate, and as one progresses forward in the arch, the root apices of each succeeding tooth become progressively closer to the buccal cortical plate.^{23,24} The mandibular canal follows an "S-shaped" pathway as it moves from a position inferior and buccal to the distal root apex of the mandibular second molar to a more lingual position inferior to the mesial root apex of the mandibular second molar and the apices of both roots of the mandibular first molar. The canal then crosses back to a more buccal position beneath the apex of the mandibular second premolar.^{25,26} Denio et al.²⁶ found that the root apices of the mandibular second molar (mean = 3.7 mm) and the mandibular second premolar (mean = 4.7 mm) were closest to the mandibular canal. The mesial root apex of the mandibular first molar was found to be furthest from the canal (mean = 6.9 mm). Similar results were noted in the study by Littner et al.²⁵

The anatomy and location of the mental foramen has been studied by multiple investigators.²⁷⁻³⁴ According to the studies,^{27-30,34} the mental foramen may be located anywhere between the apex of the mandibular first premolar and the mesial root of the mandibular first molar. In two reports^{27,28} where 100 adult mandibles were studied, the most frequent location was apical to the mandibular second premolar (Figure 2). This was also the most frequent location in another study³⁰ which looked at 75 dry mandibles. In a study³⁴ of 105

Figure 2 Most frequent location of mental foramen is inferior to the apex of the root of the mandibular second premolar.

cadaver specimens, the most frequent location was found to be between the apices of the mandibular first and second premolars. In another study²⁹ that reviewed 1,000 full mouth series of radiographs, 70% were found to be located between the apices of the two premolars. It is obvious that this foramen can be quite variable in location for different individuals.

Phillips et al.³⁰⁻³² compared the size of the mental foramen as measured on dry mandibles with the size measured on periapical and panoramic radiographs. The mean horizontal measurement on the 75 dry mandibles was 4.6 mm and the mean vertical measurement was 3.4 mm. The periapical radiographic measurement was smaller with a mean of 2.6 mm for the horizontal and 2.3 mm for the vertical. The measurements from the panoramic film were slightly larger than those obtained from the periapical radiographs (horizontal mean = 2.9 mm and vertical mean = 2.5 mm). In two-thirds of the 75 dry specimens, the foramen was found to exit in a posterior and superior direction.³⁰

When performing apical surgery on a root containing more than one root canal system, the surgeon must be aware that an isthmus may exist between the canals. Weller et al.³⁵ were one of the first to point out the significance of the isthmus in surgical endodontics. In mesiobuccal roots of the maxillary first molar with two root canal systems, they reported the highest incidence of an isthmus occurred in the apical 3 to 5 mm and that an isthmus was present 100% of the time at the 4 mm level. In a more recent clinical study,³⁶ an isthmus was found in 76% of mesiobuccal roots of maxillary first molars with a 3 to 4 mm apical root resection. In a micro-computed tomographic study,³⁷ an isthmus was found to be present in 85% of the time in the mesial root of the mandibular first molars evaluated. This incidence of isthmuses in the mesial root of mandibular first molars is very close to the 83% reported in a clinical surgical study.³⁶ In von Arx's³⁶ clinical study, an isthmus was found 36% of the time when the distal root of mandibular first molars presented with two canals.

Anesthesia and Hemostasis

The injection of a local anesthetic agent that contains a vasoconstrictor has two equally important objectives: (1) to obtain profound and prolonged anesthesia and (2) to provide good hemostasis both during and after the surgical procedure. Failure to obtain profound surgical anesthesia will result in needless pain and anxiety for the patient. Inadequate hemostasis will result in poor visibility of the surgical site

thus prolonging the procedure, resulting in increased patient morbidity. With the proper handling of any medical condition, with which the patient may present, and the selection of an appropriate anesthetic agent and vasoconstrictor, it is possible to accomplish both objectives.

The selection of an appropriate anesthetic agent should always be based on the medical status of the patient and the desired duration of anesthesia needed. The two major groups of local anesthetic agents are the esters and amides. The important difference between these groups is not in their ability to produce profound anesthesia but in the manner in which they are metabolized and the potential for allergic reactions. Esters have a much higher allergic potential than amides.³⁸ The only ester local anesthetic available in dental cartridges in the United States is a combination of propoxycaine and procaine (Ravocaine).

The amide group of local anesthetics, which include lidocaine (Xylocaine), mepivacaine (Carbocaine), prilocaine (Citanest), bupivacaine (Marcaine), etidocaine (Duranest), and articaine (Ultracaine), undergo a complex metabolic breakdown in the liver. Patients with a known liver dysfunction should be administered amide local anesthetic agents with caution due to the potential for a high systemic blood concentration of the drug. Patients with severe renal impairment may be unable to remove the anesthetic agent from the blood, which may result in an increased potential for toxicity due to elevated blood levels of the drug. Therefore, significant renal dysfunction presents a relative contraindication, and dosage limits should be lowered.^{39,40}

The high clinical success rate in producing profound and prolonged local anesthesia along with its low potential for allergic reactions makes lidocaine (Xylocaine) the anesthetic agent of choice for periradicular surgery. Selection of another anesthetic agent is indicated only in the presence of a true documented contraindication. If the use of an amide anesthetic agent (lidocaine) is absolutely contraindicated, the ester agents, procaine-propoxycaine with levonordefrin (Ravocaine with Neo-Cobefrin) is presently the only choice.³⁹

The choice of vasoconstrictor in the local anesthetic will have an effect on both the duration of anesthesia and the quality of hemorrhage control at the surgical site.³⁹⁻⁴² Vasopressor agents used in dentistry are direct acting, sympathomimetic (adrenergic) amines that exert their action by stimulating special receptors (alpha- and beta-adrenergic receptors) on the smooth muscle cells in the microcirculation of various tissues. These agents include epinephrine (Adrenalin), levonordefrin (Neo-Cobefrin), and levarterenol

(Levophed, Noradrenaline, and norepinephrine).³⁸ For the purpose of hemostasis, there is little or no justification for the use of levarterenol. The degree of hemostasis required for most periradicular surgical procedures cannot be produced safely by levarterenol.³⁸

There are two types of adrenergic receptors in tissues, alpha and beta, that respond differently when stimulated. However, depending on the specific tissue, one will usually predominate. Gage⁴³ demonstrated that the action of a vasopressor drug on the microvasculature is dependent upon (1) the predominant receptor type and (2) the receptor selectivity of the vasopressor drug. Alpha receptors predominate in the oral mucosa and gingival tissues while beta receptors predominate in skeletal muscle.^{40,44} Epinephrine receptor selectivity is approximately equal for alpha and beta receptors. Levonordefrin receptor selectivity, however, is primarily for alpha-adrenergic receptors. Stimulation of the alpha-adrenergic receptors will result in contraction of the smooth muscle cells in the microvasculature with a subsequent reduction of blood flow through the vascular bed. Stimulation of the beta-adrenergic receptors will result in a relaxation of the smooth muscle cells in the microvasculature with a subsequent increased blood flow through the vascular bed. As epinephrine selectivity is equal for alpha and beta receptors, and beta receptors predominate in skeletal muscle, it is important not to inject epinephrine into skeletal muscles in the area of endodontic surgery or a vasodilation with increased blood flow will result.^{40,43}

Epinephrine is the most effective and most widely used vasoconstrictor agent in dental anesthetics.^{38,45-47} The other vasopressors available are less effective. Even though they are used in higher concentrations in an effort to compensate for their lower effectiveness, the difference in the degree of clinical effect is readily observable. Many studies have been reported measuring the plasma catecholamine levels and the clinical effects of the injection of epinephrine containing local anesthetics for dental treatment.⁴⁸⁻⁵² The results of these studies indicate that even though the plasma level of catecholamines increases following the injection, this increase does not generally appear to be associated with any significant cardiovascular effects in healthy patients or those with mild to moderate heart disease. Pallasch⁵³ has stated that the hemodynamic alterations seen with elevated plasma epinephrine are usually quite short in duration, probably because of the very short plasma half-life of epinephrine, usually less than 1 minute. He also stated that the good achieved by the inclusion of vasoconstrictors in dental local anesthetics greatly outweighs any potential deleterious effects of these agents.

Figure 3 Osteotomy on mandibular molar. Note excellent hemorrhage control following reflection of a full mucoperiosteal flap. Collagen was used as a hemostatic agent during root-end filling.

For periradicular surgery, it is imperative that profound prolonged anesthesia and maximum hemostasis be achieved (Figure 3). In addition to the choice of anesthetic and vasopressor agents, the sites and technique of injection are important factors as well. It is significant to note that nerve block anesthesia involves injection in close proximity to a main nerve trunk that is usually located some distance from the surgical site. Thus, the vasopressor agent in the anesthetic preparation used in nerve block anesthesia will not significantly affect the blood flow at the surgical site. Profound nerve block anesthesia can be achieved with a local anesthetic containing dilute (1:100,000 or 1:200,000) epinephrine.⁴⁰

Hemostasis, unlike anesthesia, however, cannot be achieved by injecting into distant sites.⁴⁵ Larger vascular channels are not affected by the injected vasopressor, only the small vessels of the microvasculature. An inferior alveolar nerve block injection effectively blocks pain transmission from the surgical site; however, the vasopressor injected has no effect on the inferior alveolar artery and normal blood flow continues to the peripheral surgical site. Therefore, additional injections must be administered in the soft tissue in the immediate area of the surgery. This is accomplished by local infiltration using a higher concentration of epinephrine (1:50,000) in the anesthetic solution. In the maxilla, infiltration anesthesia can simultaneously achieve anesthesia and hemostasis. It is important to note that whatever technique is used to obtain anesthesia, infiltration in the surgical site is always required to obtain hemostasis.⁵⁴

The infiltration sites of injection for periradicular surgery are always multiple and involve deposition of anesthetics throughout the entire surgical field in the alveolar mucosa just superficial to the periosteum at

the level of the root apices. Following block anesthesia, using a 30-gauge needle with the bevel toward bone, a small amount of solution (0.25 to 0.50 mL) should be slowly deposited. The needle tip is then moved peripherally (mesially and distally) and similar small amounts are slowly injected in adjacent areas.⁴⁵ The rate of injection in the target sites directly affects the degree of hemostasis. The recommended injection rate is 1 mL/min, with a maximum safe rate of 2 mL/min. Rapid injection produces localized pooling of solution in the injected tissues, resulting in delayed and limited diffusion into adjacent tissues. This results in minimal surface contact with the microvascular bed and less than optimal hemostasis.

The amount of anesthetic solution needed varies and is dependent upon the size of the surgical site. In a small surgical site involving only a few teeth, one cartridge (1.8 cc) of solution containing 1:50,000 epinephrine is usually sufficient to obtain adequate hemostasis. For more extensive surgery involving multiple teeth, it is rarely necessary to inject more than two cartridges (3.6 cc) of anesthetic (1:50,000 epinephrine) to achieve both anesthesia and hemostasis.

It is important that the endodontic surgeon be aware of the delayed beta-adrenergic effect that follows the hemostasis produced by the injection of vasopressor amines. A rebound occurs from an alpha (vasoconstriction) to a beta (vasodilation) response and is termed reactive hyperemia or the rebound phenomenon.⁵⁵ Following the injection of a vasopressor amine, tissue concentration of the vasopressor gradually decreases to a level that no longer produces an alpha-adrenergic vasoconstriction. The restricted blood flow slowly returns to normal but then rapidly increases far beyond normal, as a beta-adrenergic dilation occurs.^{40,55} This rebound phenomenon is not the result of beta-receptor activity but results from localized tissue hypoxia and acidosis caused by the prolonged vasoconstriction.⁴⁴ Once this reactive hyperemia occurs, it is usually impossible to reestablish hemostasis by additional injections. Therefore, if a long surgical procedure is planned (multiple roots or procedures), the more complicated and hemostasis-dependent procedures (root-end resection, root-end preparation and filling) should be done first. The procedures that are least dependent on hemostasis, such as periradicular curettage, biopsy, or root amputation, should be reserved for last. The rebound phenomenon has another important clinical implication, postsurgical hemorrhage and hematoma. These possible postsurgical sequelae are best minimized by proper soft tissue repositioning and postsurgical care, to be covered in more detail later in this chapter.

Soft Tissue Management and Flap Design

Optimal surgical access, both visual and operative, is a requirement for all surgical procedures. Visual access enables the endodontic surgeon to see the entire surgical field while operative access allows the clinician to perform the requisite surgical procedures with the highest quality and in the shortest period of time. This will result in the least amount of surgical trauma and a reduction in postsurgical morbidity. Surgical procedures require the intentional wounding of specific tissues, and the subsequent wound healing depends on the type of tissues wounded and the type of wound inflicted. The clinician's goal must always be to minimize trauma to both the soft and hard tissues involved in the surgical procedure. Periradicular surgical procedures will require reflecting a mucoperiosteal flap.

Good surgical access is fundamentally dependent on the selection of an appropriate flap design. Numerous flap designs have been proposed for periradicular surgery. Although no single flap design is suitable for all surgical situations, the full mucoperiosteal triangular flap is the design most frequently indicated. However, it is still incumbent upon the clinician to know the advantages and disadvantages of each flap design.

Regardless of the design of the surgical flap, there are a number of principles and guidelines that apply to the location and extent of incisions. The adherence to these principles and guidelines will ensure that the reflected soft tissues will fit snugly in their original position, will properly cover the osseous wound site, and provide an adequate vascular bed for healing.

1. Avoid horizontal and severely angled vertical incisions. The gingival blood supply is primarily from the same vessels supplying the alveolar mucosa. As these vessels enter into the gingiva, they assume a vertical course parallel to the long axis of the teeth and are positioned in the reticular layer superficial to the periosteum. They are known as the suprapariosteal vessels.^{56,57}

They are arterioles with a diameter of about 100 μm and are the terminal branches of the buccal, lingual, greater palatine, inferior alveolar, and superior alveolar arteries.⁵⁸ Collagen fibers of the gingiva and alveolar mucosa provide structural strength to these tissues. Collectively, these fibers are termed the gingival ligament. This ligament consists of a number of fiber groups that form attachments from crestal bone and supracrestal cementum to the gingiva and the periosteum on the buccal and lingual radicular bone. The collagen fibers that attach to the

periosteum course over the crestal radicular bone in a direction parallel to the long axis of the teeth.⁵⁹

Horizontal and severely angled incisions, such as used in semilunar flaps and in broad-based rectangular flaps, shrink excessively during surgery as a result of contraction of the cut collagen fibers that run perpendicular to the line of incision. As a result of this shrinkage, it is often difficult to return the flap edges to their original position without placing excessive tension on the soft tissues. This often results in tearing-out of the sutures and subsequent scar formation from healing by secondary intention. Horizontal or severely angled incisions may also result in interference of the blood supply to the non-reflected gingival tissues due to severance of the gingival blood vessels that run perpendicular to the line of incision. The initial portion of the vertical incision should be placed perpendicular to the gingival margin toward the midsection of the papilla and gradually turning the incision parallel to the tooth axis.

2. Avoid incisions over radicular eminences. Radicular eminences, such as the canine, maxillary first premolar and first molar mesiobuccal root prominences, often fenestrate through the cortical bone or are covered by very thin bone with a poor blood supply. These bony defects may lead to soft tissue fenestrations if incisions are made over them. Vertical (releasing) incisions should be made parallel to the long axis of the teeth and placed between the adjacent teeth over solid interdental bone, never over radicular bone.
3. Incisions should be placed and flaps repositioned over solid bone. Incisions should never be placed over areas of periodontal bone loss or periradicular lesions. Without good solid bone to support the repositioned edges of the mucoperiosteal flap, inadequate blood supply results in necrosis and sloughing of the soft tissue. The endodontic surgeon must take into consideration the extent of osseous bone removal necessary to accomplish the intended periradicular surgery when designing the flap so the repositioned flap margins will be supported by solid bone. Hooley and Whitacre⁶⁰ suggest that a minimum of 5 mm of bone should exist between the edge of a bony defect and the incision line.
4. Avoid incisions across major muscle attachments. Incisions across major muscle attachments (frena) make repositioning of the flap and subsequent healing much more difficult. Healing and scar tissue formation by secondary intention healing often results. This can be circumvented by laterally extending the horizontal incision so the vertical

incision bypasses the muscle attachment and it is included within the flap.

5. Tissue retractor should rest on solid bone. The extension of the vertical incision should be sufficient to allow the tissue retractor to seat on solid bone, thereby leaving the root apex well exposed. If the vertical incisions are not adequately extended, there will be a tendency for the retractor to traumatize the mucosal tissue in the fold at the base of the flap. This may affect the blood supply to these tissues and will result in increased postsurgical morbidity.
6. Extent of the horizontal incision should be adequate to provide visual and operative access with minimal soft tissue trauma. In general, the horizontal incision for mucoperiosteal flaps in periradicular surgery should extend at least one to two teeth lateral to the tooth to be treated. This will allow for adequate surgical access and minimize tension and stretching of the soft tissue. A time-tested axiom regarding the length of an incision is that more trauma results from too short an incision rather than too long, and incisions heal from side-to-side, not end-to-end.
7. The junction of the horizontal sulcular and vertical incisions should either include or exclude the involved interdental papilla. Vertical releasing incisions should be made parallel to the long axis of the teeth and placed between the adjacent teeth over solid interdental bone, never over radicular bone. The vertical incision should intersect the horizontal incision and terminate in the intrasulcular area at the mesial or distal line angle of the tooth. The involved interdental papilla should never be split by the vertical incision or intersect the horizontal incision in the mid-root area.
8. The flap should include the entire mucoperiosteum (full thickness): marginal, interdental and attached gingiva, alveolar mucosa, and periosteum. Full-thickness flaps result in less surgical trauma to the soft tissues and better surgical hemostasis than split-thickness flaps. The major advantages of full-thickness flaps are derived from the maintenance of the suprapariosteal blood vessels that supply these tissues.

According to Gutmann and Harrison,⁵⁷ the two major categories of periradicular surgical flaps are the full mucoperiosteal flaps and the limited mucoperiosteal flaps. The location of the horizontal component of the incision is the distinguishing characteristic between the two categories of surgical flaps. All full mucoperiosteal flaps involve an intrasulcular horizontal incision with reflection of the marginal and interdental (papillary)

Table 1 Classification of Surgical Flaps

1. Full mucoperiosteal flaps
 - A. Triangular (one vertical releasing incision)
 - B. Rectangular (two vertical releasing incisions)
 - C. Trapezoidal (broad-based rectangular)
 - D. Horizontal (no vertical releasing incision)
 - E. Papilla-base flap
2. Limited mucoperiosteal flaps
 - A. Submarginal curved (semilunar)
 - B. Submarginal scalloped rectangular (Luebke-Ochsenbein)

gingival tissues as part of the flap. Limited mucoperiosteal flaps have a submarginal (subsulcular) horizontal, or horizontally orientated, incision, and the flap does not include the marginal or interdental tissues. The addition of plane geometric terms to describe flap designs, as suggested by Luebke and Ingle,⁶¹ provides for an easily identifiable classification of periradicular surgical flap designs. The classification of periradicular surgical flaps is summarized in Table 1, and a description of these flaps and their application in endodontic surgery follows.

The triangular flap is formed by a horizontal, intrasulcular incision, and one vertical releasing incision (Figure 4). The primary advantages of this flap design are that it affords good wound healing, which is a result of a minimal disruption of the vascular supply to the flapped tissue, and ease of flap re-approximation with a minimal number of sutures required. The major disadvantage of this flap design is the somewhat limited surgical access it provides due to the single vertical releasing incision. This limited surgical access often makes it difficult to expose the root apices of long teeth (e.g., maxillary cuspids) and mandibular anterior

Figure 4 Full mucoperiosteal triangular flap with one vertical incision and a horizontal intrasulcular incision. A distal vertical relaxing incision (dotted line) is often used to relieve tension on soft tissues during flap reflection and increases visibility for a maxillary first molar.

teeth. In posterior surgery, both maxillary (Figure 5) and mandibular (Figure 6), the vertical releasing incision is placed at the mesial extent of the horizontal incision. This affords the surgeon the maximum visual and operative access with minimum soft tissue trauma. For anterior surgery, the vertical releasing incision should be placed at the extent of the horizontal incision closest to the surgeon and is therefore dependent on the surgeon's position to the right or left of the patient. After reflecting a triangular flap, sometimes the surgeon may find it necessary to obtain additional access. This can be easily obtained by placement of a distal relaxing incision. A relaxing incision is a short vertical incision placed in the marginal and attached gingiva and located at the extent of the horizontal incision opposite the vertical releasing incision. This

Figure 5 Triangular flap to perform periapical surgery on the distobuccal root of a maxillary molar.

Figure 6 Triangular flap to perform periapical surgery on a mandibular second premolar.

incision is also good for relieving flap retraction tension while achieving adequate surgical access. Due to the excellent wound healing potential of this flap design and the generally favorable surgical access it provides, use of the triangular mucoperiosteal flap is recommended whenever possible. It is recommended for maxillary incisors and posterior teeth. It is the only recommended flap design for mandibular posterior teeth because of anatomic structures contraindicating other flap designs.⁵⁷

The rectangular flap is formed by an intrasulcular, horizontal incision and two vertical releasing incisions (Figure 7). The major advantage of this flap design is increased surgical access to the root apex (Figure 8). This flap design is especially useful for mandibular anterior teeth, when multiple teeth are involved in the surgery, and for teeth with long roots such as maxillary canines. The major disadvantages of the rectangular flap design are the difficulty in re-approximation of the flap margins and wound closure. Postsurgical stabilization is also more difficult with this design than the triangular flap. This is primarily due to the fact that the reflected tissues are held in position solely by the sutures. This results in a greater potential for postsurgical flap dislodgment.

The trapezoidal flap is similar to the rectangular flap with the exception that the two vertical releasing incisions intersect the horizontal, intrasulcular incision at an obtuse angle. The angled vertical releasing incisions are designed to create a broad-based flap with the vestibular portion being wider than the sulcular portion. The desirability of this flap design is predicated on the assumption that this will provide a better blood supply to the flapped tissues. While this concept is valid in other tissues, such as the skin, its application

Figure 7 Full mucoperiosteal rectangular flap with two vertical releasing incisions and a horizontal intrasulcular incision. Rectangular flaps are frequently used in the mandibular anterior region or when multiple teeth require endodontic surgery.

Figure 8 Rectangular flap to perform periapical surgery on maxillary central and lateral incisors.

is unfounded to periradicular surgery.⁶² The blood vessels and collagen fibers in the mucoperiosteal tissues are oriented in a vertical direction so the angled vertical releasing incisions will sever more of these vital structures. This will result in more bleeding, a disruption of the vascular supply to the non-flapped tissues, and shrinkage of the flapped tissues. The trapezoidal flap is contraindicated in periradicular surgery.⁶²

The papilla-base flap is designed to prevent recession of the papilla following endodontic surgery as it essentially excludes the papillae (Figure 9). The technique involves two different incisions at the papillary base: a shallow first incision at the base followed by a second incision directed toward the crestal bone. Once the papillae are incised, a full thickness mucoperiosteal flap is elevated. Although this flap design is

Figure 9 Papilla-based flap consists of at least one vertical incision connected by the papilla-based incision and intrasulcular incision in the cervical area of the teeth. This flap is designed to preserve the papilla and prevent recession.

more challenging to master, if properly executed, it can produce excellent results.⁶³

The horizontal or envelope flap is created by a horizontal, intrasulcular incision with no vertical releasing incisions. This flap design has very limited application in periradicular surgery due to the limited surgical access it provides. Its major applications in endodontic surgery are limited to repair of cervical defects (root perforations, resorption, caries, etc) and hemisections and root amputations.

The submarginal curved or semilunar flap is formed by a curved incision in the alveolar mucosa and the attached gingiva. The incision begins in the alveolar mucosa extending into the attached gingiva and then curves back into the alveolar mucosa. There are no advantages to this flap design, and its disadvantages are many including poor surgical access and poor wound healing which results in scarring (Figure 10). This flap design is not recommended for periradicular surgery.

The submarginal scalloped rectangular flap is a modification of the rectangular flap discussed previously in that the horizontal incision is not placed in the gingival sulcus but in the buccal or labial attached gingiva (Figure 11). The horizontal incision is scalloped and follows the contour of the marginal gingiva above the free gingival groove. The major advantages of this flap design are that it does not involve the marginal or interdental gingiva and the crestal bone is not exposed. The primary disadvantages are that the vertically oriented blood vessels and collagen fibers are severed. The result is more bleeding and a greater potential for flap shrinkage, delayed

Figure 10 Scar (arrow) in the gingival tissues resulting from the use of a semilunar flap for periapical surgery.

Figure 11 Limited mucoperiosteal Luebke-Ochsenbein flap with two vertical incisions connected by a scalloped submarginal horizontal incision in the attached gingiva. This design is essentially limited to the maxilla with a sufficient amount of attached gingiva.

healing, and scar formation (Figure 12A&B). When considering the use of this flap design, the endodontic surgeon must keep in mind that the horizontal, scalloped incision must be placed and the flap repositioned over solid bone. Careful evaluation of any buccal or labial periodontal pockets must also be made in order to minimize the possibility of leaving non-flapped gingival tissue without bony support. The importance of properly angled diagnostic radiographs cannot be overemphasized when considering the use of this flap design. The size and position of any periradicular inflammatory bone loss must also be considered when placing the horizontal incision to ensure that the margins of the flap, when re-approximated, will be adequately supported by solid bone. Proponents of this flap design stress the importance of not involving the marginal gingiva and the gingival sulcus in the horizontal incision that may result in an alteration of the soft tissue attachment and crestal bone levels. It has been reported, however, that with proper re-approximation of the reflected tissues and good soft tissue management, the gingival attachment level is minimally altered or unchanged when full mucoperiosteal flaps are employed.

The key element in preventing loss of soft tissue attachment level is ensuring that the root-attached tissues are not damaged or removed during surgery.^{62,64,65} It has also been reported that crestal bone loss is minimal (about 0.5 mm) when full mucoperiosteal flaps are used in periodontal surgery. These procedures may involve apical positioning of flaps, excision of marginal gingiva, and root planning that must rely on new attachment of soft tissue to cementum. Unlike periodontal surgery, endodontic surgery

Figure 12 **A**, Submarginal flap at the time of suture placement; **B**, Submarginal flap 3 months postsurgery. Note scarring along submarginal incision line.

can accomplish reattachment that results in little or no crestal bone loss. Harrison and Jurosky⁶⁵ reported that crestal bone showed complete osseous repair of resorptive defects and no alteration of crestal height following periradicular surgery using a triangular (full mucoperiosteal) flap. In the absence of periodontal disease, a complete return to anatomic and functional normalcy can be expected following periradicular surgery using triangular or rectangular flap designs.⁵⁷

Periradicular surgery from a palatal approach is more difficult due to the clinician's limited visual and operative access to this area. The only flap designs indicated for palatal approach surgery are the horizontal (envelope) and the triangular, with the latter being preferred. The palatal surgical approach should be limited to the posterior teeth (Figure 13A&B). Anterior teeth should be approached from the labial except

when radicular pathosis dictates a palatal approach, for example, curettage of a cyst located toward the palate. The horizontal intrasulcular incision for the triangular flap should extend anteriorly to the mesial of the first premolar or, for the horizontal (envelope) flap, to the midline. It should extend distally as far as needed to afford access to the involved palatal root. A distal relaxing incision extending a few millimeters from the marginal gingiva toward the midline or over the tuberosity area can be added to achieve better access and to relieve tension on the distal extent of the flap. The vertical releasing incision for the triangular flap should extend from a point near the midline and join the anterior extent of the horizontal incision mesial to the first premolar. There is no validity to concerns regarding a potential hemorrhage problem with vertical incisions in the palatal mucosa in the

Figure 13 **A**, Palatal flap reflected and sutured to opposite side of arch to afford better access and visualization; **B**, Bony defect and palatal root apex of maxillary first molar exposed.

premolar area. The greater palatine artery branches rapidly as it courses anteriorly, and an incision in the premolar area results in a minimal disruption to the vascular supply.

The palatal mucosa is tough and fibrous, and flap reflection and retraction can be difficult in this area. Placement of a sling suture in the flapped tissue attached to a tooth or a bite block on the opposite side of the maxillary arch (see Figure 13A) may aid the surgeon in improving visual and operative access by eliminating the need to manually retract the flap while performing this potentially difficult surgical procedure.

Following the selection of the flap design, it is important to select the proper scalpel blade to accomplish the delicate task of making smooth, clean atraumatic incisions. Incisions for the majority of mucoperiosteal flaps for periradicular surgery can be accomplished by using one or more of four scalpel blades, No. 11, No. 12, No. 15, and No. 15-C. The horizontal incision should be made first, followed by the vertical releasing incisions to complete the perimeters of the flap design. The horizontal incision for a full mucoperiosteal flap (Figure 14) begins in the gingival sulcus and should extend through the fibers of the gingival attachment to the crestal bone. Care should be exercised to ensure that the interdental papilla be incised through the mid-col area, separating the buccal and lingual papilla and incising the fibers of the epithelial attachment to crestal bone. Because these tissues are extremely delicate and space is very limited, this important incision is best made with a small scalpel blade, such as No. 11 or No. 15C. By holding the scalpel handle in a pen grasp and using finger rests on the teeth, the surgeon can

achieve maximum control and stability when performing these delicate incision strokes. An attempt should be made to accomplish the horizontal incision using as few incision strokes as necessary in order to minimize trauma to the marginal gingiva.

The horizontal incision for a limited mucoperiosteal flap should begin in the attached gingiva and be placed about 2 mm coronal to the mucogingival junction. The incision should be scalloped following the contour of the marginal gingiva. It is important that the horizontal incision never be placed coronal to the depth of the gingival sulcus. The depth of the gingival sulcus must be measured prior to placement of this flap design. The No. 15 or No. 15-C scalpel blade is recommended for this incision. An attempt should be made to incise through the gingiva and periosteum to the cortical bone using firm pressure and a single, smooth stroke. Multiple incision strokes will result in increased trauma to the gingival tissue, which may contribute to retarded healing and scar formation.

Vertical releasing incisions, whether for full or limited mucoperiosteal flaps, should always be vertical and placed between adjacent teeth over interdental bone (Figure 15). They should never be placed over radicular bone. The incision should penetrate through the periosteum so that it can be included in the flap. The incision stroke should begin in the alveolar mucosa and proceed in a coronal direction until it intersects the horizontal incision. Contrary to an often, well-ingrained surgical axiom, however, it is not necessary to accomplish this incision in a single stroke.⁵⁷ It is often difficult to accomplish penetration completely through the gingiva, mucosa, submucosa, and periosteum in a single stroke of the scalpel. An initial

Figure 14 Horizontal sulcular incision with a No. 11 Bard Parker scalpel blade.

Figure 15 Vertical incision with a No. 15 Bard Parker scalpel blade.

incision stroke that penetrates the mucosa and gingiva can be followed by a second that penetrates through the periosteum to the surface of the cortical bone. More accurate placement of the vertical releasing incision will often result from this two-stroke incision technique because less pressure is required on the initial stroke, affording the surgeon more control over the direction of the scalpel blade. It may be necessary to replace the scalpel blade with a fresh, sharp one in order to produce clean, sharp incision lines.

Reflection of soft tissues for full or limited mucoperiosteal flaps is a very critical process in the effort to reduce surgical trauma and postsurgical morbidity. Marginal gingiva is very delicate and easily injured. It is, therefore, not appropriate to begin the reflective process in the horizontal incision for full mucoperiosteal flaps (Figure 16). The supracrestal root attachment fibers are of even greater clinical significance than the marginal gingiva. These root attachment fibers are easily damaged or destroyed by direct reflective forces. Damage to these tissues may result in the loss of their viability, allowing for apical epithelial down growth along the root surface. This epithelial down growth will result in increased sulcular depth and loss of soft tissue attachment level.^{57,66} Maintenance of the viability of these root attachment fibers, however, will likely result in the soft tissue attachment levels being unaltered following surgery.^{64,67}

Initiating the flap reflective process in the horizontal incision for submarginal flaps is not as injurious to the soft tissues as in the full flap design as the horizontal incision for the former is placed in attached gingiva. This will, however, result in damaging forces

Figure 16 Initial undermining elevation of the flap should begin in the vertical incision in attached gingiva.

being applied to a critical wound edge and should be avoided whenever possible. The horizontal incision is more subject to delayed wound healing than the vertical incisions in this flap design. Additional trauma to the attached gingival tissues during flap reflection may result in tissue shrinkage and healing by secondary intention, which results in increased scar tissue formation. The reflective procedure for the limited mucoperiosteal flap should begin in the attached gingiva of the vertical incision whenever possible.

Flap reflection is the process of separating the soft tissues (gingiva, mucosa, and periosteum) from the surface of the alveolar bone. This process should begin in the vertical incision a few millimeters apical to the junction of the horizontal and vertical incisions. The periosteal elevator of choice should be used to gently elevate the periosteum and its superficial tissues from the cortical plate (Figure 17A). Once these tissues have been lifted from the cortical plate and the periosteal elevator can be inserted between them and the bone, the elevator is then directed coronally. This allows the marginal and interdental gingiva to be separated from the underlying bone and the opposing incisional wound edge without direct application of dissectional forces. This technique allows for all of the direct reflective forces to be applied to the periosteum and the bone. This approach to flap reflection is referred to as “undermining elevation.”⁵⁷ This “undermining elevation” should continue until the attached gingival tissues (marginal and interdental) have been lifted from the underlying bone to the full extent of the horizontal incision (see Figure 17B). After reflection of these tissues, soft tissue elevation is continued in an apical direction, lifting the alveolar mucosa, along with the underlying periosteum, from the cortical bone until adequate surgical access to the intended surgical area has been achieved. Small bleeding tissue tags will often be noted on the exposed surface of the cortical bone once the flap is fully reflected (see Figure 17C), especially in the interradiolar depressed areas. Bleeding from these tissue tags will stop in a few minutes and they should not be damaged or removed. Research evidence strongly suggests that these bleeding tissue tags are cortical retained periosteal tissues and may play an important role in healing and reattachment of the flap to the cortical bone.⁶⁵

In posterior mandibular surgery, it is important to be aware of the presence of the mental foramen and its associated neurovascular bundle. The most common location of the mental foramen is directly inferior to the crown of the second premolar and mesial to and inferior to its root apex (see Figure 2); however,

Figure 17 **A**, Initial elevation of flap; **B**, Flap partially reflected; **C**, Flap completely reflected.

anatomical variances can occur (Figure 18). The mental foramen is visible approximately 75% of the time on periapical radiographs. When it is not visible on the radiograph, it is usually below the border of the film.^{30,31} During flap reflection in the mandibular premolar area, the surgeon must be alert to subtle changes in the resistance of the periosteum to separation from the cortical bone. The resistance of Sharpey's fibers, which attach the periosteum to the bone, to separation results in a thin, white band at the junction of the flapped soft tissues and the cortical bone. Because there are no Sharpey's fibers attaching the periosteum to the border of the mental foramen, this thin, white band will disappear when the border of the mental foramen has been reached. Further reflection of the soft tissues in this area will result in the identification of the neurovascular bundle as it exits from the foramen. Maximum protection to the neurovascular bundle will

Figure 18 Neurovascular bundle exiting from mental foramen. The endodontic surgeon must be cognizant of anatomic variances so as to avoid injury during surgery.

be best achieved by its early identification during the flap reflective process. This will allow the surgeon to avoid injury to these important anatomic structures during the remainder of the surgical procedure.

Flap retraction is the process of holding in position the reflected soft tissues. Proper retraction depends on adequate extension of the flap incisions and proper reflection of the mucoperiosteum. It is necessary to provide both visual and operative access to the periradicular and radicular tissues. The tissue retractor must always rest on solid cortical bone with light but firm pressure. In this way, it acts as a passive mechanical barrier to the reflected soft tissues. If the retractor inadvertently rests on the soft tissue at the base of the flap, mechanical trauma to the alveolar mucosa may result in delayed healing and increased postsurgical morbidity. Selection of the proper size and shape of the retractor (Figure 19) is important in minimizing soft tissue trauma. If the retractor is too large, it may traumatize the surrounding tissue. If the retractor is too small, flapped tissue falls over the retractor and impairs the surgeon's access. This results not only in increased soft tissue trauma but also in extending the length of the surgical procedure. An axiomatic principle of endodontic surgery is that the longer the flap is retracted, the greater the postsurgical morbidity. This is a logical conclusion based on the probability that blood flow to the flapped tissues is impeded during flap retraction. In time, this will result in hypoxia and acidosis with a resulting delay in wound healing.⁵⁷

Regardless of whether the retraction time is short or long, the periosteal surface of the flap should be irrigated frequently with physiologic saline (0.9%

Figure 19 Examples of endodontic tissue retractors (Top—Arens Tissue Retractor; Middle—Selden retractor; Bottom—University of Minnesota retractor).

sodium chloride) solution. Saline should be used, rather than water, because the latter is hypotonic to tissue fluids. It is not necessary to irrigate the superficial surface of the flap because the stratified squamous epithelium prevents dehydration from this surface. Limited mucoperiosteal flaps are more susceptible to dehydration and may require more frequent irrigation than full mucoperiosteal flaps.⁵⁷

Hard Tissue Management and Curettage

Following reflection and retraction of the mucoperiosteal flap, surgical access must be made through the cortical bone to the roots of the teeth. Where cortical bone is thin, as in the maxilla, a large periradicular lesion may result in the loss of buccal or labial cortical plate, or if a natural root fenestration is present, the tooth root may be visible through the cortical plate. In other cases, the cortical bone may be very thin, and probing with a small sharp curette will allow the penetration of the cortical plate.

The most difficult and challenging situation for the endodontic surgeon is when several millimeters of cortical and cancellous bone must be removed to gain access to the root, especially when no periradicular radiolucent lesion is present. A number of factors should be considered to determine the location of the bony window in this clinical situation. The angle of the crown of the tooth to the root should be assessed. Often the long axis of the crown and its root are not the same, especially when a prosthetic crown has been placed. When a root prominence or eminence in the cortical plate is present, the root angulation and position is more easily determined. Measurement of the entire tooth length can be obtained from a well-angled radiograph and transferred to the surgical site by the use of a measured sterile file or ruler. After a small defect has been created on the surface of the cortical plate, a radiopaque marker, such as a small piece of lead foil from a radiographic film packet or a small piece of gutta-percha, can be placed in the bony defect and a direct (not angled) image exposed. The radiopaque object will provide guidance for the position of the root apex. When the cortical plate is intact, another method to locate the root apex is to first locate the body of the root coronal to the apex where the bone covering the root is thinner. Once the root has been located and identified, the bone covering the root is slowly and carefully removed with light brush strokes, working in an apical direction until the root apex is identified (Figure 20). The root surface can be distinguished from the surrounding osseous tissue in four

Figure 20 Root end located following careful osseous removal.

ways: (1) root structure generally has a yellowish color, (2) roots do not bleed when probed, (3) root texture is smooth and hard as opposed to the granular and porous nature of bone, and (4) it is surrounded by the periodontal ligament. Under some clinical conditions, the root may be very difficult to distinguish from the surrounding osseous tissue. Some authors advocate the use of methylene blue dye to aid in the identification of the periodontal ligament. A small amount of the dye is painted on the area in question and left for 1 to 2 minutes. When the dye is washed off with saline, the periodontal ligament will be stained with the dye making it easier to identify the location of the root.

Osseous tissue response to surgical removal is complicated and depends on a number of variables. One important factor is that bone in the surgical site has a temporary decrease in vascular supply due to the local anesthetic vasoconstrictor. This results in the osseous tissue being more heat sensitive and less resistant to injury. Of major importance in osseous tissue removal by burs is the generation of heat. Variables such as bur sharpness, rotary speed, flute design, and pressure applied will all have direct influence on heat generation.

The use of a liquid coolant is indispensable in controlling temperature increase during bone removal by dissipating the heat generated and by keeping the cutting flutes of the instruments free of debris. Osseous temperatures higher than 100°C have been recorded during bone removal with burs even when a liquid coolant is used.⁶⁸ Animal studies have shown that vascular changes occur in bone when temperatures exceed 40°C. Heating bone tissue in excess of 60°C results in inactivation of alkaline phosphatase, interruption of blood flow, and tissue necrosis.⁶⁹⁻⁷² The coolant will be most effective when it is directed on

Figure 21 Burs for gaining access to the bony crypt and for resection of the root apex (From left to right: No. 4 round bur; No. 6 round bur; No. 8 round bur; No. 57 fissure bur; multi-purpose bur; Endo-Z bur).

the head of the bur in order to prevent tissue debris from clogging the flutes.

The shape of the bur used for bone removal and the design of its flutes play a significant role in postsurgical healing. Cutting of osseous tissue with a #6 or #8 round bur (Figure 21) produces less inflammation, results in a smoother cut surface, and a shorter healing time than when a fissure bur or diamond bur is used.^{73,74} Burs with the ability to cut sharply and cleanly, with the largest space between cutting flutes, regardless of the speed of rotation, leave defects that heal in the shortest postsurgical time.^{75,76} The amount of pressure applied to the bone by burs during osseous tissue removal will have a direct effect on the frictional heat generated during the cutting process. Light “brush strokes” with short, multiple periods of osseous cutting will maximize cutting efficiency and minimize the generation of frictional heat.

No studies presently exist which support a biologic basis for the use of low speed over the proper use of a high speed handpiece for bone removal.⁶⁹ In most areas of the mouth, visual access is adequate while using a high speed handpiece and surgical length burs. In areas of restricted visibility, the use of a high speed handpiece with a 45° angled head significantly increases visibility. The Impact Air 45° high speed handpiece (Figure 22) offers the added advantage that the air is exhausted to the rear of the turbine rather than toward the bur and the surgical site. Case reports of surgical emphysema resulting in subcutaneous emphysema of the face including fatal descending necrotizing mediastinitis from the use of a high speed dental handpiece have been published.⁷⁷ Clinicians should be aware of the spectrum of this potential

Figure 22 Air Impact 45 Handpiece.

problem and specifically of the potential hazards of pressurized nonsterile air blown into open surgical sites by the dental drill.⁷⁸

When performing periradicular surgery, inexperienced endodontic surgeons, in their attempt to be conservative in the removal of osseous tissue, often create too small a window through the cortical plate to expose the tooth root. As a result, both visual and operative access is impaired for the most delicate and critical part of the surgery—root-end resection and root-end filling. While it is advisable to limit osseous tissue removal to no more than is necessary, failure to achieve sufficient visual and operative access results in extending the time required for the surgical procedure, increasing the stress level of the surgeon, trauma to adjacent tissues, and postsurgical patient morbidity.

Once the root and the root apex have been identified and the surgical window through the cortical and medullary bone has been properly established (Figure 23), any diseased tissue should be removed from the periradicular bony lesion (Figure 24). This removal of periradicular inflammatory tissue is best

Figure 23 Bony window of adequate size to perform periapical surgery on a mandibular premolar.

Figure 24 Soft tissue lesion on mesiobuccal root of maxillary first molar after reflection of a full thickness mucoperiosteal flap.

accomplished by using various sizes and shapes of sharp surgical bone curettes and angled periodontal curettes (Figure 25). The choice of specific curettes is very subjective, and endodontic surgeons will develop a preference for curettes that work best for them. It is advisable, however, to have a wide assortment of curettes available in the sterile surgery pack to use should the need arise.

Prior to periradicular curettage, it is advisable to inject a local anesthetic solution containing a vasoconstrictor into the soft tissue mass. This will reduce the

Figure 25 Variety of spoon excavators and curettes for removal of soft tissue from the bony crypt.

possibility of discomfort to the patient during the debridement process and will also serve as hemorrhage control at the surgical site. Additional injections of local anesthetic solution may be necessary if the amount of soft tissue needing to be removed is extensive and hemorrhage control is a problem.

Curettage of the inflammatory soft tissue will be facilitated if the tissue mass can be removed in one piece. Penetration of the soft tissue mass with a curette will result in increased hemorrhage, and shredding the tissue will result in more difficult removal. To accomplish removal of the entire tissue mass, the largest bone curette, consistent with the size of the lesion, is placed

between the soft tissue mass and the lateral wall of the bony crypt with the concave surface of the curette facing the bone. Pressure should be applied against the bone as the curette is inserted between the soft tissue mass and the bone around the lateral margins of the lesion. Once the soft tissue has been freed along the periphery of the lesion, the bone curette should be turned with the concave portion toward the soft tissue and used in a scraping fashion to free the tissue from the deep walls of the bony crypt (Figure 26A,B,C,D). Once the tissue has been detached from the walls of the crypt, it can then be easily removed by grasping it with a pair of tissue forceps. The tissue should be

Figure 26 **A**, Curettage of soft tissue lesion allows for visualization of mesiobuccal root apex. Tissue removed should be submitted for biopsy; **B**, Root end exposed and more visible following curettage; **C**, Soft tissue lesion overlying apex; **D**, Root-end exposed following curettage and osseous removal.

immediately placed in a bottle containing 10% buffered formalin solution and submitted for biopsy. While the majority of periradicular lesions of pulpal origin are granulomas, radicular cysts, or abscesses, all tissue removed during periradicular curettage should be sent for histopathologic examination to ensure that no potentially serious pathologic condition exists.⁷⁹ Lin and Gaengler⁸⁰ state that it is not always necessary to completely curette all of the inflammatory tissues so long as the etiology is apparent and eliminated.

Root-End Resection

When endodontic surgery is performed in the area around a root apex, root-end resection (Figure 27) is almost always a component of the surgical procedure. It has been reported that resection of the apical 3 mm of the root apex will eliminate 98% of the apical ramifications and 93% of the lateral canals which could contain material that would contribute to the periradicular disease.¹¹ Performing periradicular curettage without root-end resection is generally indicated when the surgical procedure is being performed solely to obtain the periradicular soft tissue lesion for biopsy purposes. Even in these cases, the root end may have to be resected to provide adequate access so the entire periradicular lesion can be removed.⁵⁷ The root-end resection allows the surgeon to evaluate the adequacy of the orthograde root canal therapy and determine if a root-end filling is necessary.⁵⁷

Figure 27 Root-end resection with a plain fissure or multi-purpose bur.

INDICATIONS

Root end resection is indicated for different reasons. Removal of the root apex will aid in eliminating anatomical variations, resorptive defects, ledges, perforation defects, canal obstructions, and separated instruments that may be present in this area of the root.^{11,57} Removal of the root apex also will allow the operator to better visualize the seal created by the orthograde obturating material, the need for a root-end seal, and to gain access for the removal of pathologic tissue that may be trapped along the lingual surface of the root.⁵⁷

El-Swiah and Walker⁸¹ classified the indications as being either biological or technical. In their retrospective study, they evaluated the clinical factors involved in deciding the need to perform root-end resections on 517 teeth from 392 patients. Of the total, 60% of the root-end resections were necessary because of biological factors and 40% because of technical reasons. The most common biological factors were persistent symptoms and continued presence of a periradicular lesion. The most common technical factors were the presence of post and core restorations, crowned teeth without posts, irretrievable root canal obturating materials, and procedural accidents.

Three important factors that must be considered prior to performing a root-end resection include the type of bur or laser energy used for the resection procedure, how much root end should be removed, and the angle at which the root end should be beveled.

BUR/LASER SELECTION

The bur type (see Figure 21) and choice of either a hi- or slo-speed handpiece are important considerations in performing root-end resections. Ingle et al.⁸² recommended using a #702 tapered fissure bur or a #6 or #8 round bur in a slo-speed straight handpiece for this procedure. They stated that a large round bur was best because it could be easily controlled and would prevent gouging and the formation of sharp line angles. Gutmann and Harrison⁵⁷ stated that root-end resection with a slo-speed handpiece could be very difficult unless a good finger rest is obtained and a sharp bur is used. They suggested using a surgical length straight or tapered plain fissure bur in a hi-speed handpiece. Gutmann and Pitt Ford⁸³ stated that even though various types of burs have been recommended for root-end resections, there is no evidence to support any advantage of one bur type over another with regard to tissue healing response. In

spite of this, clinicians continue to favor a smooth, flat resected root surface.

In an *ex vivo* study, Nedderman et al.⁸⁴ used the scanning electron microscope (SEM) to examine the resected root face and gutta-percha fillings following root-end resection with a variety of bur types using both hi- and slo-speed handpieces. They reported that the use of round burs at both speeds resulted in scooping or ditching of the resected root surface. Crosscut fissure burs at both speeds produced the roughest and most irregular resected root surfaces with the gutta-percha being smeared across the root face. The plain fissure bur, both at hi- and slo-speed, produced the smoothest resected root surface, and the plain fissure bur at slo-speed resulted in the least distortion of the gutta-percha.

Morgan and Marshall⁸⁵ compared the topography of resected root surfaces using a #57 fissure, Lindeman, or Multi-purpose burs. Additional comparisons were made after refinements to the cut root surface were made with either a multi-fluted carbide or an ultra fine diamond-coated finishing bur. The resected root surfaces were examined for smoothness and irregularities using a stereomicroscope at $\times 20$ magnification. Their results indicated that the surface produced by multi-purpose bur was smoother and more uniplanar than that produced by the #5 fissure bur, but it was not significantly different from the surface produced by the Lindeman bur. There was less damage to the root with the multi-purpose bur as compared to either the #57 fissure or Lindeman burs. The resected root surface smoothness was improved when multi-fluted carbide was used while the ultra fine diamond tended to roughen the surface.

Many investigators⁸⁶⁻⁹¹ have studied or reported on the *ex vivo* and *in vivo* effects of the application of laser energy to perform root-end resections. Investigators⁸⁶ from the Tokyo Medical and Dental University in Japan reported the results of an *ex vivo* study using the Er:YAG laser for root-end resections. They reported that there was no smear layer or debris left on the resected root surfaces prepared using the Er:YAG laser. A smear layer and debris were left on the root surfaces of the group where the root end was prepared with a fissure bur.

Komori and associates⁸⁷ studied root ends resected with Er:YAG and the Ho:YAG lasers. They reported that the Er:YAG laser produced smooth, clean resected root surfaces free of any signs of thermal damage while the Ho:YAG laser produced signs of thermal damage to the cut root surface and large voids between the gutta-percha root canal filling and the root canal walls.

In an evaluation of the carbon dioxide (CO₂) laser, Moritz et al.⁸⁸ reported that the use of the CO₂ laser as an adjunct following root-end resection with a fissure bur resulted in decreased dentin permeability. The dentin permeability was measured by dye penetration, and sealing of dentinal tubules was determined by SEM examination. They concluded that the CO₂ laser treatment optimally prepared the resected root surface by sealing the dentinal tubules, eliminating the niches for bacterial growth and sterilizing the root surface.

The connective tissue healing response adjacent to the surface of dentin cut by a Nd:YAG laser was compared to dentin cut with a fissure bur by Maillet and associates.⁸⁹ Disks of human root dentin 3.5 mm thick were prepared by the two techniques and then implanted in the dorsal subcutaneous tissue of rats for 90 days. The disks and surrounding soft tissue were recovered at various periods of time. Using light microscopy, the tissue adjacent to the prepared dentin surfaces was assessed for inflammation and fibrous capsule thickness. The results indicated a statistically significant increase in inflammation and fibrous capsule thickness adjacent to the dentin surfaces cut with the Nd:YAG laser as compared to the surfaces cut with the fissure bur.

Reports on the clinical use of lasers for root-end resection is very limited. In a case report by Miserendino,⁹⁰ a CO₂ laser was used to perform a root-end resection and to sterilize the unfilled apical portion of the root canal space. He stated that the rationale for laser use were improved hemostasis which improves visualization of the operative field, potential to sterilize the contaminated root apex, a potential reduction in permeability of cut root surface dentin, reduction of postoperative pain, and a reduced risk of contamination of the surgical site through the elimination of a need for aerosol-producing air turbine handpieces. He concluded that the initial results of the clinical use of the CO₂ laser for endodontic periradicular surgery confirmed the previous *ex vivo* findings but that further clinical studies of the application of lasers for microsurgical procedures in endodontics is needed. Komori and associates⁹¹ reported on 8 patients with 13 teeth in which the Er:YAG laser was used for root-end resections. All of the procedures were performed without the use of a hi- or slo-speed dental handpiece and even though the cutting speed of the laser was slightly slower than the use of burs, the advantages of the laser use included the absence of discomfort and vibrations, less chance for contamination of the surgical site, and reduced risk of trauma to adjacent tissue.

Regardless of the technique used for root-end resection, the cut root surface must be carefully examined for

possible cracks, anatomical variations, and the adequacy of the orthograde obturating material.^{11,57,92,93} Kim and Kratchman¹¹ noted that the only way that the anatomical detail of the resected root apex can be accurately assessed is with the operating microscope at a high power of magnification and the root end stained with methylene blue dye. In an *ex vivo* study,⁹² cracks were artificially created in the root face of 50 maxillary central incisors after 3 mm was resected from the root end. The Orascope at a magnification of $\times 35$ was found to be superior in identifying the cracks when compared to the operating microscope at $\times 10$ power, loupes at $\times 3.3$ power, and unaided/corrected vision. In another study,⁹³ a combination of different dyes, transillumination, and the operating microscope at $\times 8$ power were used, and the best discrimination of cracks in the cut root surface was found with a combination of methylene blue dye, transillumination, and the operating microscope. All of the techniques and combinations were more effective than a random chance of detecting the cracks.

EXTENT OF THE ROOT-END RESECTION:

There is no agreement on how much of the root end should be resected.¹¹ The extent of root end resection will be related to what is to be accomplished with the surgical procedure and a number of variable factors that must be evaluated on an individual case-by-case basis.⁵⁷ There is no predetermined amount of root-end removal that will be appropriate for all clinical situations. Routinely removing the entire root end apical to the most coronal extent of the bony crypt is not valid.⁵⁷ In some instances, more of the root end may have to be sacrificed in order to visualize and gain access to roots and other structures that lie lingual to the root in question (Figure 28A,B,C,D). The shape of the root and the number and location of canals within the root may dictate the amount of root resection. When a root-end filling is required, enough of the root end must be resected so that the root-end filling material is surrounded by sound dentin. The amount to be resected may also be dictated by the location of perforation defects, ledges, separated instruments, and the apical extent of posts and orthograde obturating materials. The level of the crestal bone and the presence of periodontal defects will be major factors in determining how much root end can or should be resected. The

conservation of root length should not compromise the goals of the surgical procedure.

ANGLE OF ROOT-END RESECTION

Historically, endodontic text books and other literature have recommended that the angle of root-end resections, when used in periradicular surgery, should be 30° to 45° from the long axis of the root facing toward the buccal or facial aspect of the root. The purpose for the angled root-end resections was to provide enhanced visibility to the resected root end and operative access to enable the surgeon to accomplish a root-end preparation with a bur in a slo-speed handpiece.^{11,57,83,3,4,94-98} Kim and Kratchman¹ noted that there is no biological justification for creating a steep bevel on the resected root end. They noted that the steeper the bevel, the more potential there is for damage to the buccal supporting bone. In the past, the bevel was placed strictly for the convenience of the surgeon, but with modern microsurgical instruments and use of the surgical operating microscope, this need is no longer justified.^{11,57}

Several authors⁹⁹⁻¹⁰⁴ have presented evidence indicating that beveling of the root-end results in opening of dentinal tubules on the resected root surface that may communicate with the root canal space and result in apical leakage, even when a root-end filling has been placed. Ichesco and associates,¹⁰⁰ using a spectrophotometric analysis of dye penetration, concluded that the resected root end of an endodontically treated tooth exhibited more apical leakage than one without root-end resection. Beatty,¹⁰¹ using a similar dye penetration analysis, examined apical leakage at different root-end resection angles. He reported that significantly more leakage occurred in those roots where the root-end filling did not extend into the prepared root-end preparation to the height of the bevel. If infection were to persist within the root canal system in an area not sealed by the root-end filling, the likelihood of bacteria and/or bacterial byproducts spreading outside of the root canal system is likely to occur.¹⁰² In another study²⁷ using the fluid filtration method to determine leakage, it was found that there was a significant increase in leakage as the angle of the bevel increased.

Dye penetration was measured in another apical leakage study¹⁰⁵ using extracted teeth with root-end resections at 45° and 90° angles from the long axis of the root. There was a statistically significant increase in leakage extending to the root canal space through

Figure 28 **A**, Pretreatment radiograph of a maxillary right second molar. dentinal tubules in those teeth with 45° angled root-end resections as compared to those with 90° bevels. They concluded that by increasing the angle of the root-end resection, the number of exposed dentinal tubules would also increase. Tidmarsh and Arrow-smith¹⁰⁴ examined the root surface following root-end resections at angles between 45° and 60° approximately 3 mm from the root apex. Using scanning electron microscopy, they reported the presence of an average of 27,000 dentinal tubules per mm² on the resected root face midway between the root canal and the dentinocementum junction.

Regardless of the angle or the extent of the root-end resection, it is extremely important that the resection is complete and that no segment of root is left unresected. The potential for incomplete root end resection is especially high in cases where the root is broad in its labial-lingual dimension and where surgical access and visibility are impaired.^{11,57} Carr and Bentkover¹⁰⁶ stated that failure to completely cut through a root in a buccal-lingual direction is one of the most common errors in periradicular surgery. Once the desired extent and bevel of root-end resection has been achieved, the face of the resected root surface should be carefully examined to verify that complete circumferential resection has been accomplished. This can be accomplished by using a fine, sharp explorer guided around the periphery of the resected root surface.⁵⁷ If complete resection is in doubt, a small amount of methylene blue dye can be applied to the root surface for 5 to 10 seconds. After the area is then irrigated with sterile saline, the periodontal ligament will appear dark blue, highlighting the root outline (Figure 29).

Root-End Preparation

The purpose of a root-end preparation in periradicular surgery is to create a space into which a root-end filling can be placed (see Figure 28E,F,G). Root-end preparations were originally made with sections of hand files held in hemostats or specially designed root-end preparation file holders.¹⁰⁷ The next procedure employed a small round but in straight, sloped handpiece. The procedure improved when a small round or inverted cone bur was used in a sloped contra-angle handpiece. The most recent versions of handpieces to be used for this purpose were the miniature surgical slo-speed contra-angle or the hi-speed with a pediatric size contra-angle head.^{11,57}

Several problems were noted when rotary burs in any of the handpieces were used for the root-end preparation. The access to the root end was difficult due to the small size of the osteotomy, there was a high risk of lingual or proximal root perforation, only a minimal depth of the preparation could be achieved, more dentinal tubules were exposed because of the large root-end bevel that was necessary to visualize and perform the preparation, and it was difficult to remove an isthmus if one existed between the root canals in a single root.^{11,108} One of the major objectives of a root end preparation is that it be placed parallel to the long axis of the root. It is rare that sufficient access is present to allow a bur in a contra angle or straight handpiece to be inserted down the long axis of a root. These preparations are almost always placed obliquely into the root and do not follow the direction of the root canal.^{11,57,108-110} Mehlhaff et al.¹⁰⁹ found that the

Figure 29 Methylene blue dye used to stain PDL of resected root end.

Figure 30 Ultrasonic root-end preparation illustration.

average root-end bevel required when using rotary burs was 35.1° . Two other studies^{102,103} demonstrated that as the root-end bevel increased, the depth of leakage around the root-end filling also increased.

One of the most significant advances in periradicular surgery was the introduction of ultrasonic microsurgical tips for the root-end preparation (Figure 30). The need for creating severe root-end beveling was eliminated; the tip was able to stay centered in the root and follow the original root canal space thus decreasing the possibility of lingual or lateral root perforations and conserving a greater thickness of the remaining root canal wall; a smaller osteotomy was required to accommodate the ultrasonic tips; a

deeper root-end preparation could be achieved; and less dentinal tubules were exposed decreasing the chances of leakage around the root-end filling material (Figure 31A,B).^{11,102,108–112}

Several studies^{110–114} have also reported that the root-end cavity is much cleaner when ultrasonic tip preparations are compared to bur preparations. Zuolo et al.¹¹¹ found the walls of the preparation were smoother, contained less debris and smear layer when the root-end preparation was accomplished with a smooth ultrasonic tip versus a diamond-coated tip. Diamond tips cut faster than noncoated tips but also create a larger preparation because of the diamond coating.¹¹ Newer zirconium tips create a smaller space because the zirconium nitride is processed into the metal thus making it narrower in diameter. A reported drawback to the zirconium tips is their inability to remove gutta-percha.¹¹ Navarre and Steiman¹¹⁵ found that zirconium tips removed gutta-percha from the axial walls and created the apical preparation faster than stainless steel tips.

Controversy exists if microfractures are created in the dentin walls when ultrasonic tips are used to develop the root-end preparation.^{108,116–122} In an ex vivo study using extracted teeth, Abedi et al.¹¹⁶ found a significantly higher incidence of microfractures in root ends prepared with two ultrasonic units than those prepared with burs. In another study,¹¹⁷ the highest incidence of microfractures occurred when the ultrasonic unit was used at a high setting. There were significantly fewer infractions when the unit was set at a medium setting. In a matched pair ex vivo study¹¹⁸ where the ultrasonic energy was used at a low setting, no difference in crack formation was noted

Figure 31 **A**, Ultrasonic tip used for root-end preparation on maxillary second premolar; **B**, Ultrasonic tip used for root-end preparation on mesiobuccal root of a maxillary first molar. Note how the ultrasonic tip in each case follows the long axis of the root being prepared.

from those root ends that had just received a root-end resection. The same group¹¹⁹ also evaluated diamond-coated tips and found that their use did not result in significant root-end cracking. Rainwater et al.¹²⁰ also found no significant difference in microcrack formation between stainless steel and diamond tips used at low energy settings compared to preparations with a hi-speed #2 round bur. Calzonetti et al.¹²¹ used cadaver specimens and found that the ultrasonic root-end preparations did not cause any microfractures. A clinical study¹²² using human patients reported only one incomplete canal fracture in 25 teeth treated with both stainless steel and diamond-coated tips using the lowest ultrasonic unit energy setting, water spray and a light touch.

Topical/Local Hemostasis

Good visualization of the surgical field and of the resected root surface is essential in determining the optimum placement of the root-end preparation. The ability to visualize the fine detail of the anatomy on the resected root surface is dependent upon obtaining hemostasis within the bony crypt to provide a clean, dry surgical site.¹²³ Hemostasis provided by the presurgical local anesthetic solutions and vasoconstrictors was discussed earlier in this chapter, and their importance cannot be overemphasized. Frequently there is the need for additional hemostasis within the bony surgical site once the crypt has been curetted and the root end resected. The type of hemostasis required in this area is best achieved by using a variety of topical hemostatic agents.^{13,11,123-135} Ideally, these hemostatic agents should be placed into contact with the bone after root-end resection and prior to the root-end preparation and filling.³ These topical hemostatic agents have been broadly classified as either non-collagen-based or collagen-based agents.¹²³

BONE WAX

Bone wax was introduced as a hemostatic agent by Horsley in 1892.^{11,124} It is a nonresorbable material composed of approximately 88% highly purified beeswax and 12% isopropyl palmitate. The latter acts as a softening and conditioning agent.^{11,123,125} It plugs the vascular openings by a mechanical or tamponade mechanism of action when it is packed firmly into contact with the bone surface. It does not have any effect on the blood clotting mechanism.^{11,125}

When using bone wax the entire bony crypt is filled with the material under firm pressure. The excess wax is then removed with a curette to expose the root

apex. Root-end preparation and root-end filling procedures can then be accomplished in a dry field. Once these procedures are completed, all of the remaining bone wax must be removed from the bony crypt. If any remnants of the bone wax are left in contact with the bone, persistent inflammation, foreign body giant cell reactions, and delayed healing have been reported.^{11,123,125-128} von Arx et al.¹²⁹ recently reported that bone wax provided the weakest hemostasis when compared to hemostatic agents containing ferric sulfate and aluminum chloride. With the availability of more biocompatible materials for local hemostasis, bone wax is no longer recommended for use in periradicular surgery.^{3,11,123,126}

VASOCONSTRICTOR-IMPREGNATED COTTON PELLETS/SPONGES

Vasoconstrictors have been recommended as topical agents for hemorrhage control during periradicular surgery. Of these agents, epinephrine has been shown to be the most effective and the most often recommended.^{3,11} Cotton pellets containing racemic epinephrine hydrochloride (Epidri, Racellet, and Radri) are available commercially (Figure 32). The amount of epinephrine hydrochloride in each pellet varies. For example, each Epidri pellet contains an average of 1.9 mg of racemic epinephrine. Each Racellet #2 pellet contains an average of 1.15 mg and each Racellet #3 pellet contains an average of 0.55 mg of epinephrine. Radri pellets contain a combination of a vasoconstrictor and an astringent. Each Radri pellet contains an

Figure 32 Racellet container and pellets.

average of 0.45 mg of epinephrine hydrochloride and an average of 1.85 mg of zinc phenol sulfonate.¹¹

An impregnated pellet is placed into the bony crypt. Additional non-impregnated pellets are then placed on top of the first pellet and held under pressure for 2 to 4 minutes (see Figure 28E). All of the non-impregnated pellets are then removed, and the site is evaluated to determine if adequate hemostasis has been obtained. The process is repeated until hemostasis is achieved (see Figure 23). Once a dry field is obtained, the required root-end procedures can be performed. The impregnated pellets work both by mechanical and chemical actions. The pressure provides the mechanical action, and the epinephrine hydrochloride provides the chemical effect by causing immediate, local vasoconstriction of the blood vessels. The epinephrine hydrochloride acts on the α -1 receptors in the blood vessel wall to cause the vasoconstriction. The blood vessel wall contains approximately 95% α receptors and 5% β receptors.¹¹ In a study¹³⁰ of 39 ASA type I or II patients, #3 Racellet pellets were compared to 20% ferric chloride for adequacy of providing local hemostasis during periradicular surgery. Both methods were found to be equally effective in providing hemostasis. Another study¹³¹ found that in only 1 of 42 patients was there a failure to achieve local hemostasis when collagen pellets soaked with 2.25% epinephrine were used for local hemostasis. This compared to 5 of 6 cases where local hemostasis was not achieved when the collagen pellets were soaked with saline.

There are two areas of concern when using epinephrine-impregnated cotton pellets for topical hemostasis. The first is the potential for leaving cotton fibers in the surgical site and the second is the possible effect topical epinephrine hypochloride might have on the patient's cardiovascular system. Gutmann and Harrison³ state that loose cotton fibers left in the surgical site may affect the root-end seal by becoming trapped between the root-end cavity preparation and the root-end filling material. They also note that cotton fibers may serve as foreign bodies in the surgical site and result in impaired or delayed wound healing. Sterile Telfa pads or collagen sponges cut into small squares and saturated with epinephrine hydrochloride can be placed into and easily adapted to the shape of the crypt. They may be used in the place of the cotton products as they contain no loose fibers.^{3,131}

The concern about the topical use of epinephrine in periradicular surgical procedures causing systemic cardiovascular changes has been addressed by several studies.¹³⁰⁻¹³² Besner¹³² reported that the pulse rate of the patient did not change when a #2 Racellet pellet containing an average of 1.15 mg of epinephrine

hydrochloride was used during periradicular surgery. This finding was confirmed in another study¹³⁰ where 1 to 7 #3 Racellet pellets (average of 0.55 mg epinephrine hydrochloride per pellet) were left in place for 2 to 4 minutes. The blood pressure and pulse rate taken at five different intervals in 39 patients treated in this study did not vary significantly at any of the evaluation points. Vy et al.¹³¹ also found that the blood pressure and pulse rate did not change in 42 patients where collagen sponges were saturated with 2.25% racemic epinephrine and used for local hemostasis during periradicular surgery. Kim and Kratchman¹¹ state that when epinephrine is used topically it causes immediate local vasoconstriction; therefore, there is little absorption into the systemic circulation, reducing the chance of having an effect on the cardiovascular system.

FERRIC SULFATE

Ferric sulfate is a chemical that has been used as a hemostatic agent since it was first introduced as Monsel's solution (20% ferric subsulfate) in 1857.¹¹ It is a necrotizing agent with an extremely low pH (0.8 to 1.6).¹²³ Its mode of action results from a chemical reaction of blood with the iron and sulfate ions to form an agglutination of blood proteins. The coagulum that is formed plugs the capillary openings to create the resulting hemostasis.^{11,123}

Ferric sulfate is directly applied to the bone surface with hemostasis being achieved almost immediately. This agent is known to be cytotoxic and if not completely removed from the bone surface at the end of the procedure will result in severe inflammation and delayed healing of the surgical site.^{11,123,133,134} Lemon and associates,¹³³ using standardized osseous defects created in rabbit mandibles, reported a significant adverse effect on osseous healing when ferric sulfate was left in situ for the duration of the experiment. In a follow-up study¹³⁴ using the same rabbit model, there was no significant difference in healing between the experimental and untreated control groups when the surgical site was curetted and irrigated with saline following a 5 minute application of ferric sulfate. The surgical site was then thoroughly curetted and irrigated with sterile saline with the result being that there was no significant difference in osseous healing between this experimental group and the untreated controls. Ferric sulfate solutions appear to be safe hemostatic agents as long as they are used in limited quantities, and care is taken to thoroughly remove them from the surgical site prior to suturing.^{11,123,134,135}

THROMBIN

Topical thrombin was developed to provide hemostasis when wounds are oozing blood from small capillaries and venules. Thrombin acts to initiate the extrinsic and intrinsic clotting pathways and acts rapidly to clot blood fibrinogen directly.¹¹ It is designed only for topical application and may be life threatening if injected. Topical thrombin has been investigated as a hemostatic agent in abating bleeding in cancellous bone. While there was less bleeding than the control, thrombin was less effective than other topical hemostatic agents.¹²³ Even though topical thrombin has been used successfully in neurosurgery, cardiovascular surgery, and burn surgery, it is not being used in conjunction with periradicular surgery at this time. The main disadvantages in using the topical thrombin powder are difficult handling characteristics and high cost.^{11,123}

CALCIUM SULFATE

Even though calcium sulfate (plaster of Paris) has been used primarily in dentistry to fill large surgical bone defects, as a barrier material in guided tissue regenerative procedures and repair of furcation defects, it can also be used for hemostasis during periradicular surgery.^{136,137} It is a resorbable material that consists of powder and liquid components which can be mixed into a thick putty-like consistency and placed in the bony crypt using wet cotton pellets to press it against the walls. The mechanism of action is similar to bone wax in that it acts as a mechanical barrier to plug the vascular channels. In contrast to bone wax, calcium sulfate is biocompatible, completely resorbs in 2 to 4 weeks, and does not cause a long-term inflammatory response. It also has the advantage of being relatively inexpensive.¹³⁷

GELFOAM AND SPONGOSTAN

Gelfoam and Spongostan are gelatin-based sponges that are water insoluble and biologically resorbable.^{123,125,137} They are made of purified animal skin and become soft on contact with blood.¹³⁵ Gelatin sponges are thought to act intrinsically by promoting the disintegration of platelets with the subsequent release of thromboplastin and plasmin. This, in turn, stimulates the formation of thrombin and supports fibrin strands infiltration of the interstices of the sponge.^{123,125,137}

When these gelatin-based sponges are used to control bleeding during periradicular surgery, they swell and form a soft, gelatinous mass. This swollen, soft gelatinous mass may visually obscure the surgical site

making it difficult to complete the root-end preparation and root-end filling procedures. Because they become so soft, it is difficult to put pressure on the sponges without displacing them with the result being a continuation of bleeding. The primary use for gelatin-based sponges in periradicular surgery is placement into the bony crypt, after root-end resection and root-end filling have been completed, just prior to wound closure. Because they promote the formation of thrombin, they may be beneficial in the initial stages of clot formation.

Gelatin-based sponge material left in situ may result in a decrease in the osseous healing rate, but the inflammatory response seems to be minimal. The net result is a material that is totally resorbed and well tolerated by the surrounding tissues.¹²³ The study by Ibarrola et al.¹²⁵ compared the response of rat tibias to bone wax, Surgicel and Gelfoam. They found the best histological response was obtained in those sites where Gelfoam was used. At the end of the 120-day experiment, the Gelfoam was usually completely resorbed, and healing of the bone defects was complete. Other studies^{138,139} have reported on the use of Gelfoam in extraction sockets and the results have been varied. The Ibarrola study most closely relates to the type of clinical situation that would be encountered in periradicular surgery.

COLLAGEN PRODUCTS

Collagen-based products consist primarily of collagen of differing microstructures and densities and have been used extensively as surgical hemostatic agents. These products are believed to have four principal mechanisms of action involved in hemostasis: (1) stimulation of platelet adhesion, aggregation, and release; (2) activation of Factor VIII (Hageman Factor); (3) mechanical tamponade action; and (4) the release of serotonin.^{123,135,140-143} The collagen used for surgical hemostasis is obtained from bovine sources and is supplied in sheets and sponge pads. Both forms are applied dry, directly to the bleeding site while using pressure. Hemostasis is usually achieved in 2 to 5 minutes.¹³⁷

MICROFIBRILLAR COLLAGEN HEMOSTAT

Avitene and Instat are two popular forms of microfibrillar collagen. These products are derived from purified bovine dermal collagen, which is shredded into fibrils and then converted into a fine powder as an insoluble partial hydrochloric acid salt. They provide topical hemostasis by forming a collagen framework for platelet adhesion. This process initiates platelet aggregation and adhesion with the result being the

formation of a platelet plug.^{123,135} Haasch et al.¹⁴⁴ reported on their potential use in periradicular surgery. Another study,¹⁴⁵ using Avitene, found that new bone formation proceeded uneventfully without a foreign body reaction to the material.

The handling characteristics of these microfibrillar collagen products are not ideal. The materials have an affinity for wet surfaces and as such readily adhere to instruments and gloves. It has been recommended that they be applied to the surgical site using a spray technique that allows direct application of the agents to the bleeding points.¹⁴⁶ Other disadvantages of these products include being inactivated by autoclaving, increasing the chance of infection when used in contaminated wounds, and being much more expensive compared to other topical hemostatic agents.¹³⁷

SURGICEL

Surgicel is a material that resembles surgical gauze and is prepared by the oxidation of regenerated α -cellulose (oxycellulose).^{123,125} The preparation is spun into threads and then woven into gauze that is chemically sterilized with formaldehyde. Its mode of action is principally mechanical as it does not have an affect on the clotting cascade.^{123,125} When the gauze is initially placed into contact with surgical site it acts as a physical barrier to any bleeding points. As blood becomes entrapped in the gauze, the mixture

becomes tacky and forms an artificial coagulum or plug to provide hemostasis.^{123,125}

In an animal study¹²⁵ that compared the osseous response of three different hemostatic agents, Surgicel, when left in situ, retarded the rate of healing and caused the most intense inflammatory reaction of any of the materials. The same study also noted that due to the difficulty in removing all of the Surgicel from bony wounds, the small fragments left behind resulted in a prolonged inflammatory response and foreign body reaction. The implantation of Surgicel into a surgical wound is not recommended.^{123,125}

ROOT-END FILLING MATERIALS

The purpose of a root-end filling is to establish a seal between the root canal space and the periradicular tissues. An ideal root-end filling material should be (1) able to prevent leakage of bacteria and their byproducts into the periradicular tissues, (2) non-toxic, (3) non-carcinogenic, (4) biocompatible with the host tissues, (5) insoluble in tissue fluids, (6) dimensionally stable, (7) unaffected by moisture during setting, (8) easy to use, (9) radiopaque, (10) nonstaining, and (11) bioinductive (promote cementogenesis).¹⁴⁷ Numerous materials have been suggested for use as root-end fillings including gutta-percha, amalgam, Cavit, intermediate restorative material (IRM), Super-EBA, Diaket (Figure 33A,B,C), glass ionomers, composite resins,

Figure 33 **A**, Preop digital radiograph showing apical radiolucencies on both maxillary central incisors. **B**, Postop digital radiograph after nonsurgical retreatment on the maxillary left central incisor. **C**, Postop digital radiograph demonstrating root-end resections on both teeth and Diaket root-end filling on the right central incisor.

carboxylate cements, zinc phosphate cements, zinc oxide eugenol cements, and mineral trioxide aggregate (MTA). The suitability of these various materials has been tested by evaluating their microleakage (dye, radioisotope, bacterial penetration, and fluid filtration), marginal adaptation, cytotoxicity, and clinical testing in experimental animals and humans.

A large number of *in vitro* studies dealing with the marginal adaptation and sealing ability (leakage) of various root-end filling materials have been published. The results of these studies have often been inconsistent, contradictory and confusing, and have been questioned as to their clinical relevance. Factors such as the choice of storage solutions, the molecular size of the dye particles, and other variables can influence the outcome of *in vitro* studies.¹⁴⁸

In vitro cytotoxicity and biocompatibility studies using cell cultures have also been published. Owadally and associates reported on an *in vitro* antibacterial and cytotoxicity study comparing IRM and amalgam. Their results indicated that IRM was significantly more antibacterial than amalgam at all time periods of exposure, and amalgam was significantly more cytotoxic than IRM.¹⁴⁹ Makkawy et al. evaluated the cytotoxicity of resin-reinforced glass ionomer cements compared to amalgam using human periodontal ligament cells. Their results indicated that at 24 hours amalgam significantly inhibited cell viability as compared to resin-reinforced glass ionomer cement and the controls. At 48 and 72 hours, however, all materials tested exhibited a similar slightly inhibitory effect on cell viability.¹⁵⁰ Chong et al. compared the cytotoxicity of a glass ionomer cement (Vitrebond),

Kalzinol, IRM and EBA cements, and amalgam. Their results indicated that fresh IRM cement exhibited the most pronounced cytotoxic effect of all materials tested. Aged Kalzinol was the second most cytotoxic material with no significant difference being reported between Vitrebond, EBA cement and amalgam.¹⁵¹

Zhu, Safavi, and Spangberg evaluated the cytotoxicity of amalgam, IRM, and Super-EBA cements in cultures of human periodontal ligament cells and human osteoblast-like cells. Their results indicated that amalgam was the most cytotoxic of the materials tested and showed a reduction in total cell numbers for both cell types. IRM and Super-EBA, however, were significantly less cytotoxic than amalgam and demonstrated no reduction in total cell numbers for both periodontal ligament and osteoblast-like cells (Figure 34A,B).¹⁵²

Several authors have published results of *in vivo* tissue compatibility studies of various root-end filling materials using an experimental animal model. Harrison and Johnson reported on a study designed to determine the excisional wound healing responses of the periradicular tissues to IRM, amalgam, and gutta-percha using a dog model. Healing responses were evaluated microscopically and radiographically at 10 and 45 days postsurgically. They reported no evidence of inhibition of dentoalveolar or osseous wound healing associated with amalgam, gutta-percha, or IRM. Statistical analysis showed no difference in wound healing between the three materials tested.¹⁵³

Pitt Ford, Andreasen et al. examined the effects of IRM, Super-EBA, and amalgam as root-end filling materials in the roots of mandibular molars of monkeys.

Figure 34 **A**, Preop digital image of maxillary premolar following nonsurgical retreatment; lesion still persists after one year. **B**, Postop digital image following curettage, root-end resection, and root-end filling with Super-EBA.

They reported that the tissue response to IRM and Super-EBA was less severe than that to amalgam. No inflammation was evident in the bone marrow spaces adjacent to root-end fillings of IRM and Super-EBA. In contrast, however, inflammation was present in the alveolar bone marrow spaces with every root end filled with amalgam.^{154,155}

Maeda et al. reported the results of a histological study comparing the effects of various root-end filling materials including a 4-META-TBB resin (C&B Meta-bond) using a rat model. The materials tested were amalgam, light-cured glass ionomer cement, IRM, a 4-META-TBB resin, and light-cured composite resin. The 4-META-TBB resin and light-cured composite resin root-end fillings showed the most favorable histological response among the materials tested. These materials did not provoke inflammation and did not appear to inhibit new bone formation as seen with the other materials.¹⁵⁶

Torabinejad and others developed MTA (ProRoot) at Loma Linda University. The main molecules present in MTA are calcium and phosphorous ions, derived primarily from tricalcium silicate, tricalcium aluminate, tricalcium oxide, and silicate oxide. Its pH, when set, is 12.5 and its setting time is 2 hours and 45 minutes. The compressive strength of MTA is reported to be 40 MPa immediately after setting and increases to 70 MPa after 21 days. The results of solubility testing of MTA (ADA specification #30) indicated an insignificant weight loss following testing.¹⁵⁷

Another study by Torabinejad et al. was designed to examine and compare the tissue reaction to several commonly used root-end filling materials and MTA.

Their study involved the implantation of amalgam, IRM, Super-EBA, and MTA in the tibias and mandibles of guinea pigs. The presence of inflammation, predominant cell type, and thickness of fibrous connective tissue adjacent to each implanted material were evaluated. The tissue reaction to implanted MTA was the most favorable observed at both implantation sites; in every specimen, it was free of inflammation. MTA was also the material most often observed with direct bone apposition (Figure 35A,B).¹⁵⁸

MTA has been extensively evaluated for microleakage (dye penetration, fluid filtration, and bacterial leakage), marginal adaptation (SEM), and biocompatibility (cytotoxicity, tissue implantation, and in vivo animal histology). The sealing ability of MTA has been shown to be superior to that of Super-EBA and was not adversely affected by blood contamination. Its marginal adaptation was shown to be better than amalgam, IRM, or Super-EBA. MTA has also been shown to be less cytotoxic than amalgam, IRM, or Super-EBA. Animal usage tests in which MTA and other commonly used root-end filling material were compared have resulted in less observed inflammation and better healing with MTA. In addition, with MTA, new cementum was observed being deposited on the surface of the material.¹⁵⁹⁻¹⁷⁰

Many prospective and retrospective human clinical usage studies have been reported assessing the outcome of periradicular surgery involving the placement of various root-end filling materials. It is difficult to compare the results of these studies because the authors have used differing evaluation criteria and observations periods. It is important, however, to

Figure 35 **A**, Preop digital image of mandibular molar following nonsurgical retreatment; extrusion of filling material occurred on both roots. **B**, Postop digital image following curettage, root-end resection, and root-end fillings with MTA.

consider some of the more significant of these clinical usage reports.

In 1978, Oynick and Oynick reported on the clinical use of a resin and silicone reinforced zinc oxide and eugenol cement (Staline Super-EBA, Staines, England) as a root-end filling material in 200 cases over a period of 14 years. Radiographic evaluations following periradicular surgical procedures using Staline indicated favorable healing. Histological and SEM evaluations of the root apex and adjacent periradicular bone, taken by block section, revealed newly formed bone in areas of previous resorption and collagen fibers growing into the filling material.¹⁷¹

Dorn and Gartner reported on a retrospective study of 488 periradicular surgical treatments in which three different root-end filling materials were used, IRM, Super-EBA, and amalgam. The evaluation period was from 6 months to 10 years. Outcomes assessment was conducted by evaluation of the most recent recall radiograph as compared to the immediate postsurgical radiograph. Analysis of the data indicated there was no significant difference in the outcome of healing rates between IRM and Super-EBA. There was a significant difference, however, in the outcome between IRM, Super-EBA, and amalgam, the latter being the worst.¹⁷² Pantshev and associates, however, reported on a prospective clinical study evaluating the outcome of periradicular surgical procedures using either EBA cement or amalgam. The minimum evaluation period was 3 years, and healing was based on clinical and radiographic analysis. Their data indicated no significant difference in the outcome between the two materials evaluated.¹⁷³

Rud et al. have reported on several prospective and retrospective human usage studies in an attempt to evaluate the acceptability of a composite resin (Retroplast), combined with a dentin bonding agent, as a root-end filling material. The placement is different from other root-end fillings in that no root-end preparation, other than root-end resection, is made. The material covers the entire resected root-end surface. They have shown that the creation of a leak-resistant seal is possible with this material; however, the process is very technique sensitive due to the need for strict moisture control. They have reported complete bone healing in 80% to 92% of cases using this technique. Their observation periods ranged from 1 to 9 years.¹⁷⁴⁻¹⁷⁸

Instrumentation of dentin results in the accumulation of a smear layer covering the dentinal surface and occluding the dentinal tubules. It has been shown that bacteria may colonize in the smear layer and penetrate the dentinal tubules.¹⁷⁹ Removal of this smear layer

seems desirable in the situation of root-end fillings that are placed in a bacterially contaminated root apex. Irrigation with tetracycline has been shown to remove the smear layer.¹⁸⁰ Smear layer removal from resected root ends and dentin demineralization by citric acid has been shown to be associated with more rapid healing and deposition of cementum on the resected root end.¹⁸¹

Tetracyclines have a number of properties of interest to endodontists; they are antimicrobial agents, effective against periodontal pathogens, they bind strongly to dentin, and when released are still biologically active. Root surfaces exposed to anaerobic bacteria accumulate endotoxin and exhibit collagen loss, which may suppress fibroblast migration and proliferation, thus interfering with healing. Root surface conditioning with acidic agents, such as tetracycline, not only removes the smear layer but it also removes endotoxin from contaminated root surfaces.¹⁸² Barkhordar and Russel reported on an *in vitro* study that examined the effect of irrigation with doxycycline hydrochloride, a hydroxy derivative of tetracycline, on the sealing ability of IRM and amalgam when used as root-end fillings. Their results indicated significantly less microleakage following irrigation with doxycycline involving both IRM and amalgam compared to the control irrigation with saline. They also suggested that, due to the long-lasting substantivity of doxycycline on root surfaces and its slow release in a biologically active state, their results support its use for dentin conditioning prior to placement of a root-end filling in periradicular surgery.¹⁸³

Based on a review of the currently available literature, there does not appear to be an "ideal" root-end filling material. MTA appears to be the currently available material that most closely meets the requirements, both physical and biological, for a root-end filling material, especially due to its regenerative potential. Its primary disadvantage is its handling characteristics, and multiple devices have been designed to assist in its delivery. In a 2003 prospective human clinical trial, Chong, Pitt-Ford, and Hudson demonstrated a high success rate with MTA over a 2-year period. Retroplast appears to be a "second-best" root-end material but is not yet available in the United States.¹⁸⁴

The method for placement of the root-end filling material will vary depending on the type of filling material used. Amalgam may be carried to the root-end preparation with a small K-G carrier that is sized for root-end preparations. Deeper lying apices may be more easily reached by using a mesing gun. Zinc

oxide–eugenol cements (IRM and Super-EBA) are best mixed to a thick clay-like consistency, shaped into a small cone, and attached to the back side of a spoon excavator or the tip of a plastic instrument or Hollenback carver and placed into the root-end preparation.

MTA is a unique root-end filling material with physical properties much different than other materials. It is a very fine, gray colored powder that is mixed with a sterile liquid, such as saline or local anesthetic solution, on a sterile glass slab. It cannot be mixed to a clay-like consistency, similar to IRM or Super-EBA, because, as more powder is added to the liquid, the mix becomes dry and crumbly. If the mix is too wet, it is runny and very difficult to handle due to its lack of form. The surgical area must be kept very dry during its placement, and care must be taken not to wash out the filling material by irrigation prior to closure of the soft tissue. The setting time of MTA is 2.5 to 3 hours. Properly mixed, MTA should be free of excess moisture, firm, but not crumbly. It can be delivered to the root-end preparation by placing a small amount on the backside of a small spoon excavator or by using a small amalgam-type carrier or the MAP system (Roydent), a micro-apical placement system very similar to a miniature messing gun (Figure 36 & 37). Recently introduced is white MTA with less potential for staining;

Figure 36 Placement of root-end filling material into preparation.

Figure 37 Microapical placement carriers used for placement of mineral trioxide aggregate into root-end preparations.

most of the research suggests that the gray and white have similar properties.¹⁸⁵

Root-end preparations using ultrasonic tips tend to be smaller in diameter and extend deeper into the root canal than those prepared with a bur. As a result, the need for specially designed root-end filling condensers has resulted in their availability from many different manufactures in various styles and shapes. It is important that the endodontic surgeon becomes familiar with the different shapes and styles of condensers to enable one to properly condense the root-end filling material to the full extent of the root-end preparation. The condenser should be small enough in diameter that it does not bind on the walls of the root-end preparation during condensation, resulting in the possibility of root-end fractures. It is also important that the condenser is long enough to properly condense the filling material into the deepest part of the root-end preparation.

Various techniques have been advocated for finishing root-end fillings in periradicular surgery. Fitzpatrick and Steiman reported on an *in vitro* study designed to evaluate the marginal interfaces between the dentin and root-end fillings of IRM and Super-EBA. Following placement of the root-end fillings, they were finished by either burnishing with a ball burnisher, a moistened cotton pellet, or with a carbide-finishing bur in a high speed handpiece with air/water spray. Their results indicated that root-end fillings finished with a finishing bur displayed significantly better marginal adaptation, with little evidence of flash, when compared to the other methods (Figure 38). There was no significant

Figure 38 Root-end preparation filled with root-end filling material.

difference between the other finishing techniques or between the materials tested.¹⁸⁶

Forte and associates reported on an in vitro study designed to compare microleakage, by the fluid filtration method, of root-end fillings of Super-EBA either unfinished or finished with a 30-flute high speed finishing bur. Their results indicated no significant difference in microleakage after 180 days between root-end fillings of Super-EBA, finished or unfinished.¹⁸⁷

Soft Tissue Management, Suturing, and Postoperative Care

After final inspection of the root-end filling and removal of all visible excess filling material and any surgical packing, a radiograph should be taken to evaluate the placement of the root-end filling and to check for the presence of any root fragments or excess root-end filling material. Thorough examination of the underside of the flap and in the depth of the fold between the mucoperiosteum and the alveolar bone should be done prior to repositioning the flap in order to remove any debris or foreign material that may be present. The final steps in the periradicular surgical procedure are wound closure and soft tissue stabilization.

Figure 39 Gauze sponge moistened with saline and applied to flap both before and after suturing.

REPOSITIONING AND COMPRESSION

The elevated mucoperiosteal tissue should be gently replaced to its original position with the incision lines approximated as closely as possible. The type of flap design will affect the ease of repositioning, with full mucoperiosteal flaps generally providing less resistance to repositioning than limited mucoperiosteal flaps. Using surgical gauze, slightly moistened with sterile saline, gentle but firm pressure should be applied to the flapped tissue for 2 to 3 minutes (5 minutes for palatal tissue) prior to suturing (Figure 39). Tissue compression, both before and after suturing, not only enhances intravascular clotting in the severed blood vessels but also approximates the wound margins, especially the dissectional wound. This reduces the possibility of a blood clot forming between the flap and the alveolar bone.

SUTURING

It is important to stabilize the reflected tissue to prevent dislodgement until initial wound healing has taken place. Multiple investigators have reported on studies in animals and humans designed to evaluate the effectiveness of medical grade adhesives, such as cyanoacrylate, for surgical wound closure and comparing them with sutures. Results of these studies have been mixed, and at this time, their use has not replaced that of sutures for wound closure in endodontic surgery.¹⁸⁸⁻¹⁹⁴

The purpose of suturing is to approximate the incised tissues and stabilize the flapped mucoperiosteum until reattachment occurs (Figure 40A,B,C). The placement of sutures in oral tissues, however, creates unique

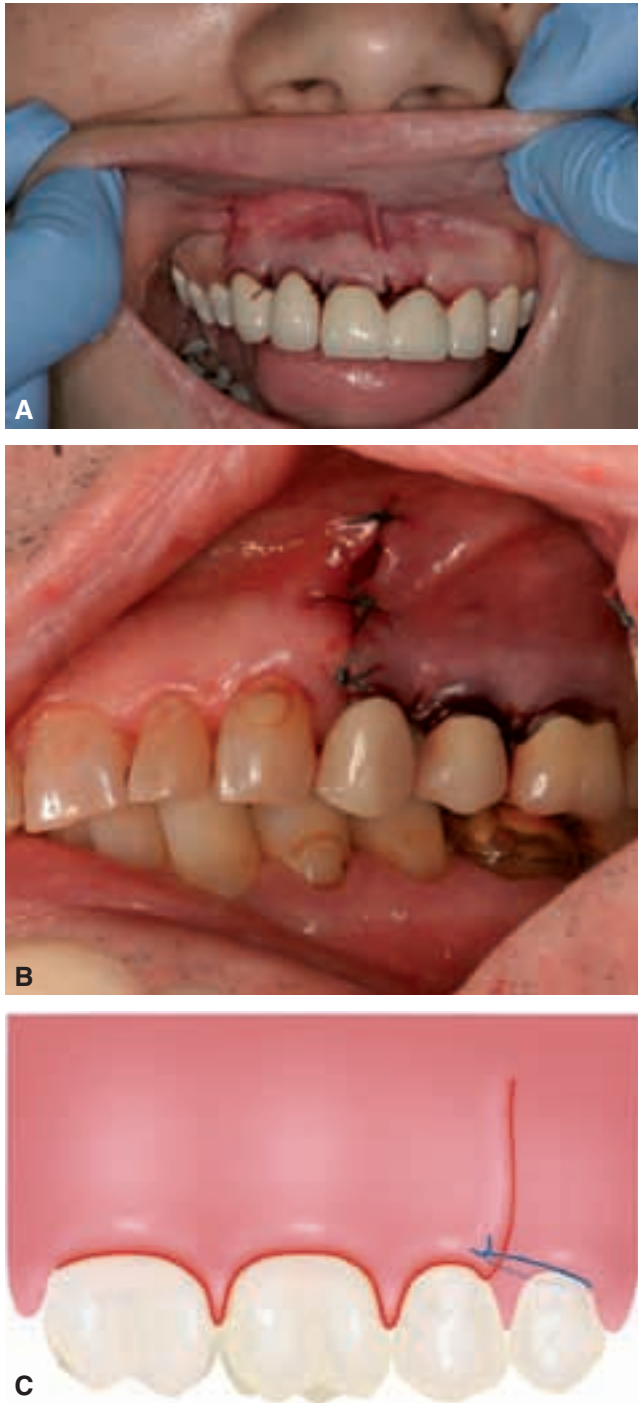

Figure 40 *A*, Proper flap repositioning and suturing. *B*, Large gap in vertical incision after suturing; another interrupted suture should have been placed. *C*, In cases of gapping, anchor sutures can be used to help pull repositioned flapped tissue towards the unreflected tissue by using a nearby tooth as an anchor.

problems. It is evident that incisional wounds in oral tissues heal more rapidly than in skin. However, sutures are better tolerated and interfere less with postsurgical healing in the skin. The major problem in oral tissues is the constant bathing of the suture material and suture tract with saliva containing a high concentration of microorganisms that may gain entrance to underlying tissues.

Sutures are available in many different materials, the most common being synthetic fibers [nylon, polyester, polyglactin (PG), and polyglycolic acid (PGA)], collagen, gut, and silk. Sutures are classified as absorbable or nonabsorbable, by size according to the manufacturer's minimum diameter, and by physical design as monofilament, multifilament, twisted, or braided. The classification of suture size is complicated by the existence of two standards, the United States Pharmacopeia (USP) and the European Pharmacopeia (EP). The USP size is designated by two Arabic numbers, one a zero, being separated by a hyphen (3-0, 4-0, 5-0, etc.). The higher the first number, the smaller the diameter of the suture material. The EP system is a number that represents the manufacturer's minimum diameter tolerance, in millimeters (1 = 0.10 mm, 1.5 = 0.15 mm, etc.) of the suture.

SILK

Silk sutures are made of protein fibers (fibroin) bound together with biological glue (sericin), similar to fibronectin, produced by silkworms. Silk sutures are nonabsorbable, multifilamentous, and braided (Figure 41). They have a high capillary action effect that enhances

Figure 41 High power view of a silk suture demonstrating that it is a multifilament and braided material.

the movement of fluids between the fibers (“wicking” action), resulting in severe oral tissue reactions.^{195–197} This tissue reaction results from the accumulation of plaque on the fibers that occurs within a few hours following insertion into the tissues.¹⁹⁸ Silk’s advantage is limited to its ease of manipulation. Due to the severe tissue reaction to silk, it is not the suture material of choice for endodontic surgery today.¹⁸⁹ If silk sutures are used, however, the patient should rinse with chlorhexidine during the postoperative period.

GUT

Collagen is the basic component of plain gut suture material and is derived from sheep or bovine intestines. The collagen is treated with diluted formaldehyde to increase its strength and is then shaped into the appropriate monofilament size. Gut sutures are absorbable; however, the absorption rate is variable and can take up to 10 days. Because of the unpredictability of gut suture absorption in oral tissues, a scheduled suture removal appointment should be made. Chromic gut sutures consist of plain gut that has been treated with chromium trioxide. This results in a delay in the absorption rate. Because retention of sutures beyond a few days is not recommended in endodontic surgery, the use of chromic gut sutures offers no advantage. In addition, evidence indicates that plain gut is more biocompatible with oral soft tissues than chromic gut.^{195–197} Gut suture material is marketed in sterile packets containing isopropyl alcohol. When removed from the packet, the suture is hard and non-pliable due to its dehydration. Prior to using, gut sutures should be hydrated by placing them into sterile, distilled water for 3 to 5 minutes. After hydration, the gut suture material will be smooth and pliable with manipulative properties similar to silk.¹⁹⁹

COLLAGEN

Reconstituted collagen sutures are made from bovine tendon after it has been treated with cyanoacetic acid and then coagulated with acetone and dried. Collagen sutures offer no advantage over gut for endodontic surgery as their absorption rate and tissue response is similar. They are available only in small sizes and used almost exclusively in microsurgery.

PGA

Sutures made from fibers of polymerized glycolic acid are absorbable in mammalian tissue. The rate of absorption is about 16 to 20 days. PGA sutures consist of multiple filaments that are braided and share hand-

ling characteristics similar to silk. PGA was the first synthetic absorbable suture and it is manufactured as Dexon.

PG

In 1975, Craig and coworkers²⁰⁰ reported the development of a copolymer of lactic acid and glycolic acid called PG 910 (90 parts glycolic acid and 10 parts lactic acid). Sutures of PG are absorbable and consist of braided multiple filaments. Their absorption rate is similar to that of PGA. They are commercially available as Vicryl.

Many studies have been reported evaluating the response of the oral soft tissues to gut, collagen, PGA, and PG sutures, with conflicting results. As a result, there is insufficient evidence at this time to make a strong recommendation between these materials. The important factor to remember regarding sutures, regardless of the material, is that they should be removed as early as the clinical situation will permit.

NEEDLE SELECTION

Surgical needles are designed to carry the suture material through the tissues with minimal trauma. For that reason, a needle with a reverse cutting edge (the cutting edge is on the outside of the curve) is preferable (Figure 42). The arc of the surgical needle selected should match the optimum curvature needed to penetrate the tissues in and out on both sides of the incision, 2 to 3 mm from the wound margins. Suture

Figure 42 Conventional cutting needles are not recommended because the cutting edge on the inside curvature tends to pull through the flap edge; reverse cutting suture needles prevent suture material from tearing through surgical flaps.

needles are available in arcs of one-fourth, three-eighths, one-half, and five-eighths of a circle, with the most useful being the three-eighths and one-half circle. The radius of the arch of the needle is also an important consideration. The smaller the radius of the arch, the more conducive the needle is to quick turnout. For vertical incision lines and anterior embrasure suturing, a relatively tight arc is necessary to allow for quick needle turnout. Suturing in posterior areas, however, requires less curvature and a longer needle to reach through the embrasure. The final selection of an appropriate surgical needle is based on a combination of factors including the location of the incision, the size and shape of the interdental embrasure, the flap design, and the suture technique planned.

SUTURING TECHNIQUES

There is a wide variety of suture techniques designed to accomplish the goals of closure and stabilization of flaps involving oral mucoperiosteal tissues. All suturing techniques should be evaluated on the basis of their ability to accomplish these goals. Several authors have compared the effects of continuous and interrupted suture techniques. Their findings indicate that the interrupted suturing technique provides for better flap adaptation than the continuous and, therefore, is the recommended technique, and the most commonly used, for endodontic surgery.^{201,202} Sutures are holding mechanisms and should not pull or stretch the tissue as a tear in the flap margin may result. Sutures that close an incision too tightly compromise circulation and increase chances for the sutures to tear loose upon swelling. Before placing sutures, bleeding should be controlled to prevent the formation of a hematoma under the flap. A hematoma will prevent the direct apposition of the flap to the bone and can act as a culture medium for bacterial growth. The suturing techniques that are most conducive to rapid surgical wound healing are the single interrupted suture, the interrupted loop (interdental) suture, the vertical mattress suture, and the single sling suture.

SINGLE INTERRUPTED SUTURE

The single interrupted suture is used primarily for closure and stabilization of vertical releasing and relaxing incisions in full mucoperiosteal flaps and horizontal incisions in limited mucoperiosteal flap designs (Figure 43). The initial needle penetration should be through the independent (movable) tissue. The point of needle entry should be from the buccal or facial and 2 to 3 mm from the incision margin in order to provide sufficient tissue to minimize suture tear-out.

Figure 43 Single interrupted sutures can be used for both the horizontal incision and the vertical incision.

The needle should then enter the under surface of the mucoperiosteum of the dependent (immovable) tissue and penetrate through the mucoperiosteum at a point 2 to 3 mm from the incision margin. In order to accomplish this, it is often necessary to elevate the attached mucoperiosteum from the underlying bone for a distance of a few millimeters at the point of needle insertion. It is important that the periosteum is included with the tissue bite otherwise the suture will most likely tear out of the fragile attached gingiva.

After the suture needle has been passed through the mucoperiosteum on both sides of the incision, the suture material should be drawn through the tissue until the end opposite the needle is approximately 1 to 2 inches from the tissue. The suture should be tied with a secure knot. A surgical knot is the most effective and least likely to slip. The surgeon's knot is best tied by wrapping double loops or throws of the long end (end with the needle attached) of the suture around the needle holder. By then grasping the short end of the suture with the needle holder and slipping the throws off, the first half of the surgical knot is tied. After adjusting the tissue tension, the second half of the knot is tied by repeating the same process, only wrapping the loops of suture around the needle holder in the opposite direction from the first tie, like a square knot. Suture knots should be placed to the side of the incision. Suture knots collect food, plaque, and bacteria, thus resulting in localized infection and a delay in healing when placed directly over the incision.

INTERRUPTED LOOP (INTERDENTAL) SUTURE

The interrupted loop, or interdental suture, is used primarily to secure and stabilize the horizontal

component of full mucoperiosteal flaps. The surgical needle is inserted through the buccal or facial interdental papillae, then through the lingual interdental papillae, and then back through the interdental embrasure. It is tied on the buccal or facial surface of the attached gingiva. This suture technique highly predisposes the fragile interdental tissue and col to inflammation and retarded healing, resulting in a loss of the outer gingival epithelium, with possible blunting or formation of double papillae.

A modification of the interrupted loop suture described above is as follows. After the surgical needle has been passed through the buccal and lingual papillary gingiva, the suture is passed over the interdental contact and secured with a surgeon's knot. This modification eliminates the presence of suture material in the interdental embrasure, thus reducing postsurgical inflammation to this delicate tissue. In clinical situations where the horizontal component of a full mucoperiosteal flap involves a tooth or teeth with full coverage crowns, this modification allows for a slight incisal or occlusal repositioning of the mucoperiosteal flap. This can be accomplished by placing slight tension on the suture over the interdental contact and may compensate for a loss of gingival height resulting from the sulcular incision.

VERTICAL MATTRESS SUTURE

The vertical mattress suture has the advantage that it does not require needle penetration or suture material being passed through tissue involved in the incisional wound (Figure 44). The surgical needle enters and exits the flapped mucoperiosteum some distance apical from the incision line. The suture is then passed through the interdental embrasure, directed to the lingual of the

Figure 44 Vertical mattress suture avoids penetration of tissues in the incisional wound and supports the interdental papilla in a coronal direction.

adjacent tooth, and passed back through the opposite interdental embrasure. The needle then enters and exits the flapped mucoperiosteum again, is passed through the embrasure and again, lingual to the tooth and through the opposite interdental embrasure to be tied on the buccal surface with a surgeon's knot. This suture technique also provides for the opportunity to return the flapped tissue to a slightly incisal or occlusal position from its original in order to compensate for a loss of gingival height.

SINGLE SLING SUTURE

The single sling suture is similar to the vertical mattress suture (Figure 45A,B). The surgical needle is passed through the attached gingiva of the flap, through the interdental embrasure but not through the lingual soft tissue. It is then directed lingual to the tooth and passed through the opposite interdental embrasure and over the incisal or occlusal margin of the flap. The needle is then passed through the attached gingiva of the flap, from the buccal or facial, back through the embrasure, passed lingual to the tooth, through the opposite embrasure, passed over the flap margin and tied with a surgeon's knot (Figure 46A,B). This suture technique is particularly effective for achieving the maximum incisal or occlusal level when repositioning the flap. Because the lingual anchor is the lingual surface of the tooth and not the fragile lingual tissue, tension can be placed on the flapped tissue to adjust the height of the flap margin.

POSTOPERATIVE CARE

Postsurgical management of the patient is equally as important as the surgical procedure itself. An important component of postsurgical care is a genuine expression of concern and reassurance to the patient regarding both their physical and emotional experience. It is well known that the emotional state of a patient has a direct relationship on the level of morbidity following a surgical procedure. The patient's awareness that the surgeon cares and that he/she is readily available, should they have a problem, is a priceless adjunct to healing. A telephone call to the patient, the evening following or the morning after endodontic surgery, is very reassuring and helps to build a strong doctor-patient relationship. This also allows any patient anxieties to be dealt with before they become major concerns.

Another important component of postsurgical care is good patient communication. It is the endodontic surgeon's responsibility to properly communicate to

Figure 45 *A*, Sling suturing technique; *B*, Single sling suture used following surgery on a maxillary second premolar.

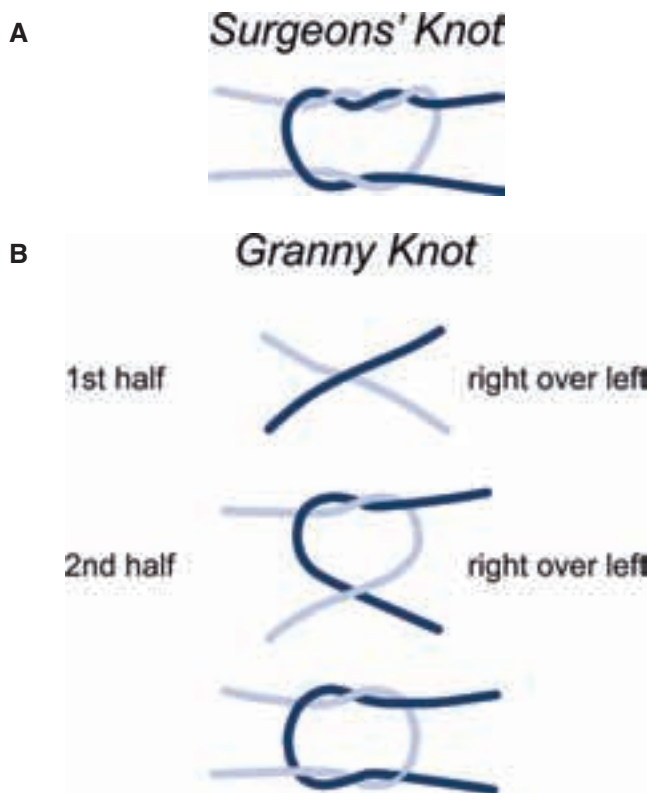

Figure 46 *A*, Surgeons' knot is a modified square knot in which the first overhand knot is doubled; the doubling prevents slippage especially when flaps are under tension; *B*, Granny knots result when a throw (complete twist of two strands) is followed by another throw in the same sequence. Granny knots result in knot slippage with less security than a surgeon's knot.

the patient the expected and normal postsurgical sequelae as well as detailed home care instructions. These are best conveyed both verbally and in writing.

Alexander stated that without written reinforcement, the understanding and retention of verbal instructions could not be assured. He also advised that written materials should be presented after oral instructions have been given rather than before. Because up to 20% of Americans are functionally illiterate, written instructions should use simple words (preferably 1 to 2 syllables) and short sentences of no more than 10 words.¹⁰⁵ Normal postsurgical sequelae include the possibility of slight bleeding from the surgical area for a few hours, pain that may persist for a few days, and swelling and soft tissue discoloration (ecchymosis) in the surgical area that may be evident for as much as 8 to 10 days. An example of written postsurgical instructions, which should be reviewed verbally with the patient before they are dismissed, is provided in Table 2.

Bleeding, swelling, discoloration, pain, and infection are the most likely untoward sequelae following endodontic surgery. These should be thoroughly discussed with the patient during the presurgical consultation and should be reinforced at the time of surgery, prior to dismissal of the patient.

BLEEDING AND SWELLING

Slight oozing of blood from severed microvessels may be evident for several hours following surgery. When a little blood is mixed with saliva, it often appears to the patient as a lot of blood. If the patient is forewarned of this possibility, it goes a long way to reducing their anxiety. Slight swelling of the intraoral and extraoral tissues is a normal consequence of surgical trauma and leakage of blood from the severed microvessels. Proper compression of the surgical flap both before

Table 2 Sample Instructions for Postoperative Care Following Endodontic Surgery

1. Limit physical activity for the first 24 hours. Easy activity is OK but be careful and do not bump your face where the surgery was done. You should not drink any alcohol or use any tobacco (smoke or chew) for the next 3 days.
2. It is important that you have a good diet and drink plenty of liquids for the first few days after surgery. Juices, soups, and other soft foods, like yogurt and puddings, are suggested. Liquid meals, like Sego, Slender, and Carnation Instant Breakfast, can be used. You can buy these at most food stores. Avoid carbonated beverages.
3. Do not brush in the area of the incision for first 3 days, then use a soft brush very carefully; use warm salt water rinses (dilute 1/8 teaspoon salt per 8 oz glass of water) and rinse for 1 minute swishing the surgical area every 2 hours during the day. Continue rinses until 2 days after sutures removed.
4. Do not lift up your lip or pull back your cheek to look where the surgery was done. This may loosen the stitches, causing them to tear the gum tissue and start bleeding.
5. A little bleeding from where the surgery was done is normal. This should only last for a few hours. You may also have a little swelling and bruising of your face. This should only last for a few days.
6. Place an ice bag (cold) on your face where the surgery was done. You should leave it on for 20 minutes and take it off for 20 minutes. You should do this for 6 to 8 hours. After 8 hours, the ice bag (cold) should not be used. The next day after surgery, you can put a soft, wet, hot towel on your face where the surgery was done. Do this as often as you can for the next 2 to 3 days.
7. Discomfort after the surgery should not be bad but the area will be sore. You should use the pain medicine you were given or recommended to you, as needed.
8. Rinse your mouth with one tablespoon of the chlorhexidine mouthwash (Peridex) you were given or prescribed. This should be done two times a day (once in the morning and once at night before going to bed). You should do this for 5 days.
9. The stitches that were placed need to be taken out in a few days. You will be told when to return. It is important that you come in to have this done!!
10. You will be coming back to the office several times during the next few months so we can evaluate how you are healing. These are very important visits and you should come in even if everything feels OK.
11. If you have any problems or if you have any questions, you should call the office. The office phone number is xxx-xxxx. If you call after regular office hours or on the weekend, you will be given instructions on how to page the doctor on call.

and after suturing greatly reduces postoperative bleeding and swelling (Figure 39).

Additional supportive therapy is the application of an ice pack, with firm pressure, to the facial area over the surgical site. Pressure and reduction of temperature slows the flow of blood and helps to counteract the rebound phenomenon, which occurs following the use of a vasoconstrictor in the local anesthetic. Application of cold also acts as an effective analgesic due to its reduction in sensitivity of the peripheral nerve endings. The ice pack should be applied in a 20 minutes on and 20 minutes off cycle. This regimen

should be repeated for 6 to 8 hours and should preferably be started in the clinician's office with the use of a disposable instant chemical cold pack. Continuous application of cold should be avoided. This will initiate a physiologic mechanism that will result in an increase in blood flow to the site of cold application.²⁰³

If minor bleeding should persist for more than 12 hours following surgery, this can usually be managed by the patient with proper home care. At the time of surgery, the patient should be given several 2 × 2 gauze pads in a sterile pack. The patient should be instructed to slightly moisten one of the sterile gauze pads and to place it over the bleeding site while applying firm pressure. Pressure should be applied to the area for 10 to 15 minutes. Should the bleeding problem persist, the patient should be instructed to place a moist tea bag or one of the gauze pads soaked in tea over the bleeding area and apply pressure in the same manner as before. Tannic acid, contained in tea, is known to be an effective hemostatic agent. If home treatment fails, the patient should be seen in the dental office where the dentist can inject a local anesthetic agent containing 1:50,000 epinephrine and apply tissue compression to the bleeding area. Unless there is an undisclosed or undiagnosed bleeding disorder, this should resolve the problem. The patient should be warned not to take aspirin for pain prior to surgery or after, but rather acetaminophen or ibuprofen.

Application of moist heat over the surgical site is recommended; however, it should not begin until 24 hours following the surgery. Heat promotes blood flow and enhances the inflammatory and healing processes. The application of moist heat is best accomplished by the use of a small cotton towel that has been wet with hot tap water. The hot, moist towel should be applied to the surface of the face over the surgical area for about 30 minutes. The towel should be re-heated with hot tap water every 5 to 10 minutes to maintain the temperature.

Discoloration of the mucoperiosteal and/or facial tissues following surgery is the result of the breakdown of blood that has leaked into the surrounding tissues. The patients should be made aware of the potential for postsurgical discoloration at the presurgical consultation visit and again reinforced at the time of surgery. This ecchymosis can last for up to 2 weeks and is observed more in the elderly and fair-complexioned patients (Figure 47). This is an esthetic problem only and requires no special treatment. In patients with ecchymosis, applications of moist heat may be beneficial for up to 2 weeks following surgery.

Figure 47 Bilateral ecchymosis following endodontic surgery on multiple maxillary anterior teeth.

Heat promotes fluid exchange and speeds resorption of discoloring agents from the tissues.

In the majority of patients, pain following periradicular surgery is surprisingly minimal. Postsurgical pain is usually of short duration and most often reaches its maximum intensity about 6 to 8 hours following surgery. A significant reduction in pain can usually be expected on the first postoperative day followed by a steady decrease in discomfort each day following surgery. It is unusual for a patient to experience pain that cannot be managed by mild to moderate analgesics.²⁰⁴

Another method of postsurgical pain control is the use of long-acting local anesthetic agents, such as bupivacaine (Marcaine) or etidocaine (Duranest), which provide 6 to 8 hours of local anesthesia and up to 10 hours of local analgesia.^{205,206} Because these long-acting anesthetic agents contain a low concentration of vasoconstrictor (1:200,000), they are not suitable to be used alone in periradicular surgery. They can either be used prior to surgery, in conjunction with lidocaine containing 1:50,000 epinephrine or at the conclusion of the surgical procedure prior to dismissal of the patient. The return of sensation is more gradual with the long-acting anesthetics than with the short acting; therefore, the onset of discomfort is less sudden.

Endodontic surgery is performed in an area that is heavily populated with microorganisms; however, postsurgical infections are rare. For this reason, pretreatment systemic antibiotic therapy is seldom required and is not considered part of routine postsurgical care in healthy patients. The most common causes of postsurgical infections following periradicular surgery are the result of inadequate aseptic tech-

niques and improper soft tissue reapproximation and stabilization. These are under the direct control of the endodontic surgeon. The clinical signs and symptoms of a postsurgical infection are usually evident 36 to 48 hours after surgery. The most common indications are progressively increasing pain and swelling. Suppuration, elevated temperature, and lymphadenopathy may or may not be present. Systemic antibiotic therapy should be initiated promptly when indicated. The antibiotic of choice is penicillin V, and the recommended dosage is 1 gram as an initial dose followed by a maintenance dose of 500 milligrams. The dosing interval should be every 3 to 4 hours, preferably without food. In patients allergic to penicillin, the antibiotic of choice is clindamycin with an initial dose of 600 milligrams followed by a maintenance dose of 150 to 300 milligrams depending on the age and weight of the patient. The dosing interval should be every 8 hours, preferably without food. The patient should be monitored every 24 hours and antibiotic therapy withdrawn as soon as the clinical condition indicates that the patient's host defenses have regained control of the infection and that the infection is resolving or has resolved.

Oral hygiene often presents a postsurgical problem for many patients. A toothbrush should not be used as an aid to oral hygiene in the area of surgery until the day following surgery and then only on the occlusal or incisal surfaces of the teeth. Use of a toothbrush in the surgical area may dislodge the mucoperiosteal flap and lead to serious postsurgical complications. A cotton swab soaked with chlorhexidine oral rinse (Peridex) or 3% hydrogen peroxide may be used to gently remove oral debris from the surgical area. A regimen of twice daily (morning and evening) rinsing with chlorhexidine oral rinse will provide an effective means for reduction of debris, decreasing the population of the oral microbial flora, and inhibiting plaque formation. Chlorhexidine oral rinses should continue for 4 to 6 days following surgery (2 to 3 days following suture removal).

According to Gutmann and Harrison,³ the key to preventing sutures from having a negative effect on wound healing following surgery is their early removal. The primary purpose for placing sutures following endodontic surgery is to approximate the edges of the incisional wound and provide stabilization until the epithelium and myofibroblast–fibronectin network provides a sufficient barrier to dislodgment of the flapped tissues. This usually occurs within 48 hours following surgery. It has been recommended that sutures should not be allowed to remain longer than 96 hours. A suture removal kit should contain a cotton

swab, 2" × 2" gauze sponges, suture scissors, cotton pliers, and a mouth mirror. The sutures and surrounding mucosa should be cleaned with a cotton swab containing a mild disinfectant followed by hydrogen peroxide. This helps to destroy bacteria and remove plaque and debris that have accumulated on the sutures, thus reducing the inoculation of bacteria into the underlying tissues as the suture is pulled through. A topical anesthetic should also be applied with a swab to the surgical site. This greatly reduces the discomfort associated with the placement of the scissors blade under the suture, a procedure that is particularly painful in areas of persistent swelling and edema, commonly seen in the mucobuccal fold. Sharp-pointed scissors are used to cut the suture material followed by grasping the knotted portion with cotton pliers and removing the suture. Various designs of scissors are available and can be selected according to specific access needs in different areas of the mouth. It has been suggested that a No. 12 scalpel blade be used to sever the suture. The advantages are stated to be a predictably sharp cutting edge and less "tug" on the suture.²⁰⁷

Corrective Surgery

Corrective surgery can be defined as the surgical procedure required to repair defects that occur in root or furcation areas as a result of therapeutic misadventures or pathologic processes. These defects are located in areas of the root other than the apex and are not amenable to nonsurgical repair. When a periodontal pocket is associated with a defect located in the cervical one-half of the root, it will be necessary to reflect a mucoperiosteal flap to insure proper repair of the root defect and correction of the periodontal defect. Furcation defects are generally repaired nonsurgically, but there are situations where a periodontal component is present and can only be corrected via a surgical approach. Therapeutic misadventures requiring corrective procedures include, but are not limited to, perforations that occur during complicated endodontic access, root canal location, and preparation procedures or as a result of misdirection of burs during the preparation of post space. Pathological processes that may cause some of these defects include caries, periodontal lesions, external resorption, and perforating internal resorption. Traumatic injuries that result in fractures of the root may require a surgical approach to treatment in order to retain the remaining root or combination of root and crown structures. Corrective surgical procedures include periradicular surgery

where access is gained through a flap procedure to repair the root and periodontal defects. Root amputation is also a possibility when a defect can only be corrected if an entire root of a multirrooted tooth is removed and the remaining crown of the tooth is recontoured and retained. In mandibular molars, a hemisection procedure may be required to remove the entire crown and root on the side of the tooth where the defect is present. An intentional replantation procedure is only a treatment option when all other nonsurgical and surgical procedures have already been attempted and failed or have been deemed impossible to perform.²⁰⁸ In these cases the tooth is extracted, the defect repaired, and the tooth repositioned back into its original socket.

PERFORATION REPAIR

Perforations in the floor of the pulp chamber in multirrooted teeth may occur during endodontic access preparation, post space preparation, or in conjunction with extensive caries or resorption lesions. The multirrooted teeth with the greatest potential for furcation perforations are the maxillary and mandibular molars. When a perforation occurs in this area of the tooth, the initial attempt at repair should be from an internal, nonsurgical approach. Corrective surgery is reserved for those teeth where nonsurgical repair is not a treatment option or the attempted nonsurgical repair has failed. When surgery is necessary, a buccal mucoperiosteal flap is reflected, the furcation bony defect is cuvetted to remove any pathologic tissue, and the perforation site is repaired.

In an animal study by Dean et al.,²⁰⁹ it was reported that when the perforation defect was repaired surgically, the associated bone defect filled with decalcified freeze-dried bone and the window in the bone was covered with a periodontal membrane, the percentage of osseous healing was 75% to 100%. In those cases where the perforation was repaired, the bone defect was allowed to fill with blood and the bone window was covered with a periodontal membrane, the percentage of osseous healing was 92% to 100%. When only the perforation was repaired and the other two procedures were not done, the osseous healing was only 52% to 70%. In the remaining three groups, the same blood clot, membrane and osseous fill were performed on the bone defect, but none of the perforations in these three groups was repaired. The amount of osseous repair for these three groups ranged from 0% to 15%. The results suggest that, in this particular model, repair and sealing of the perforation site was necessary to achieve significant osseous healing.

Strip perforations in the cervical one-third of the root occur most frequently in the thin distal aspects of the mesial roots of mandibular molars and the mesio-buccal roots of maxillary molars. Nonsurgical repair should be the first treatment option in these cases. If surgical repair is deemed necessary, the perforation must be accessed and visualized through a window created in the buccal bone. In many cases, surgical repair will be very difficult, if not impossible, and the bony window may be so large that a periodontal defect is created. If neither the nonsurgical nor surgical options are feasible, other possible treatment options include root amputation, hemisection, intentional replantation, or extraction followed by the placement of a bridge or osseointegrated implant.

If an external cervical root defect is present as a result of root caries or external resorption, the treatment approach may be different from that proposed for a perforation defect in the same area. If the carious or resorptive defect does not penetrate into the pulp canal space, a surgical approach to treatment is the first choice. A limited envelope soft tissue flap is generally adequate to visualize, cleanse, and repair the affected area. If the defect is in a cosmetic area, an appropriate composite resin or glass ionomer material will be the material of choice. Amalgam, MTA, and Ketac materials might also be choices if the defect is in an area where cosmetics are not an issue. Periodontal pocketing is often associated with these cervical defects so crown lengthening or vertical root extrusion may also have to be performed in order for the area to be properly restored and cleansed.

Perforations occurring at the mid-root level are usually the result of burs being misdirected or over-thinning of the root canal walls during post space preparation. If possible, these defects should be immediately sealed via an internal approach. If surgery is necessary (Figure 48A,B,C,D), the same steps are followed as for the other areas that require surgical repair. If there is cortical bone covering the root surface coronal to the level of the mid-root repair site, there will be less chance of creating a chronic periodontal problem. A perforation located in the apical third of the root is treated surgically by removing that portion of the root apical to the perforation site and, if necessary, placement of a root-end filling.

The management of external root resorption lesions located apical to the cervical area will depend on whether the defect communicates or does not communicate with the pulp canal space. Those lesions that do not communicate with the pulp canal space will need to be corrected surgically in order to arrest the

active resorptive process. The location of the resorptive defect on the root surface will be a key factor in determining whether a successful surgical repair can be accomplished. If the lesion is located on the distal of lingual surface of the root, it may be impossible to visualize and correct the defect from a surgical approach. In these situations, intentional replantation for a single-rooted tooth or root amputation or hemisection may be the only treatment choices if an attempt is to be made to retain the tooth. Otherwise, extraction may be the only option.

When these external resorptive defects are approached surgically, a full thickness mucoperiosteal flap is reflected, the bony window over the defect site is enlarged for visualization, the resorptive defect is curetted, and the site is repaired with MTA or an appropriate bonded resin material. If there is no bone covering the root surface coronal to the defect, a periodontal regenerative procedure may also be performed in conjunction with the corrective surgical procedure.

When an external root resorptive defect communicates with the pulp canal space or an internal resorptive defect communicates with the external root surface, a combination of nonsurgical and surgical approach to treatment may be required. The first step in either of these situations is to cleanse and shape the root canal system and place an internal dressing of calcium hydroxide. At a subsequent visit the calcium hydroxide is removed, the root canal dried, and that portion of the root canal system apical to the perforating defect is obturated with an appropriate obturating material. The external portion of perforation defect is then packed with a matrix/barrier material, and the repair site is repaired internally. If it is impossible to adequately dry the root canal system so that root canal obturation can be performed or the external resorptive process remains active, then a combination treatment must be performed.

With a combination treatment a mucoperiosteal soft tissue flap is reflected, the pathologic defect on the root surface is curetted, the root canal space can then be dried, and the portion of the root canal space apical to the defect can be obturated. The perforation defect on the root surface and into the root canal space is then repaired with an appropriate repair material. Another technique which has been suggested is to place a tight fitting gutta-percha cone into the root canal space without sealer, repair the external defect, and let the repair material set and then remove the gutta-percha cone and proceed with the internal root canal obturation procedure. The inherent danger with this latter

Figure 48 **A**, Periodontal probe placed into lingual defect; **B**, Point of periodontal probe exits via sinus tract on the buccal gingival tissues; **C**, Radiograph depicts perforation of post at mid-root level on mesial surface of root; **D**, Flap reflected to demonstrate root and bony defects that required sealing the perforation site and then periodontal bone grafting and membrane placement to resolve the problem and retain the tooth.

technique is that the compacting forces required to perform the obturation procedure may displace the external repair material. Once the soft tissue flap is sutured, the access opening is closed with a tem-

porary sealing material. Any additional nonsurgical treatment can be completed at a subsequent visit after the soft tissue flap has healed. If there is extensive bone loss over the external root surface,

a periodontal regenerative procedure may also be required. If the defect is found to be so extensive that the root cannot be retained, one of the alternative treatment options noted above must be considered.

TRAUMATIC ROOT FRACTURE REPAIR

The clinical management of teeth with traumatic root fractures will be discussed in detail in Chapter 31, “Endodontic Treatment Outcome: The Potential for Healing and Retained Function.” Corrective surgical procedures will only be required in those cases where periradicular pathology develops at the fracture site and the apical segment of the root must be removed surgically.

ROOT AMPUTATION

Root amputation procedures may be indicated when a multirrooted tooth has one root that cannot be retained and the other roots have adequate periodontal support and the remaining crown structure can be restored (Figure 49). These procedures are most frequently indicated when one root of a maxillary molar must be eliminated. This is considered a corrective endodontic surgical procedure when the root that must be sacrificed is the result of a vertical root fracture, a pathologic resorptive or dentistogenic defect that cannot be repaired. If the root to be removed has inadequate bone support as a result of chronic periodontal disease, the root amputation procedure may be one of the treatment options considered by the dentist performing the periodontal therapy. The root removal must allow access for proper home care and plaque control so that a chronic periodontal problem is not created. Retention of the remaining tooth structure may also be necessary for prosthetic reasons such as to retain an abutment tooth for a long-span fixed or removable partial denture. Case selection is an important factor in success because the strategic value of the tooth must be critical to the patient’s overall dental treatment plan. Because the prognosis for long-term retention of teeth with root amputations is guarded, there is a tendency in today’s dental practice to extract these teeth and replace them with osseointegrated implants. A root amputation procedure may also be contraindicated if the

Figure 49 If the space between the roots of two maxillary molars is so narrow (illustrated by the two arrows), new bone cannot be regenerated in this area if a periodontal pocket develops between the two roots.

remaining roots do not have adequate periodontal osseous support, the root to be removed is fused to an adjacent root, the remaining roots cannot be successfully treated endodontically, or the patient has poor home care and oral hygiene.

Nonsurgical root canal therapy should be completed on the roots to be retained before performing the amputation procedure (Figure 50A,B,C). The root canal system in the root to be amputated should be cleansed and shaped in the usual manner. The apical half of this root may or may not be obturated with gutta-percha. The entire root canal or at least the coronal one-half should be filled with either amalgam or MTA. A bonded core or post and core restoration is placed into the pulp chamber and the occlusion is adjusted to eliminate any excessive forces during lateral excursive movements. Once the restorative materials have set, the surgical procedure can be performed.

Before reflecting a soft tissue flap, the amputation procedure is started by recontouring the crown of the tooth to provide for cleansing and good home care of the resected area, to direct occlusal forces along the long axis of the remaining roots, and to expose the coronal portion of the root that is to be removed. This technique was recommended by Kirchoff and

Figure 50 **A**, Radiograph depicts a defect between the distobuccal root of a maxillary first molar and the mesiobuccal root of the maxillary second molar; **B**, Root canal therapy is completed and an amalgam core is placed into the root to be amputated; **C**, The same case 4 years after the amputation procedure, note the presence of a well-contoured crown and the health of the interproximal periodontal tissues.

Gerstein²¹⁰ and is best performed by using a combination of smooth fissure and diamond burs. A surgical length bur may be required for the resection of the mesiobuccal root of a maxillary molar because this root is generally very broad in a buccolingual dimension and may extend one-half the distance to the palatal root. The distobuccal root is generally conical in shape and may be resected with a normal length bur. Palatal root amputations are rarely performed because of the poor prognosis of retention of these teeth with just the two retained buccal roots. It is also rare that both buccal roots will be amputated to leave a single palatal root to provide all of the support for the remaining coronal tooth structure.

Performing the majority of the root amputation and crown contouring prior to extraction of the root will

prevent debris from collecting in the open extraction socket. Either a limited or full mucoperiosteal flap is then reflected to facilitate completion of the amputation procedure (Figure 51A,B), removal of the resected root, and to allow for recontouring of the bone in the area where the root was removed. A limited lingual flap may also be required to complete the osseous recontouring. After these procedures are completed, the flap is repositioned and sutured. At a subsequent visit after the coronal portion of the socket has healed, any refinement to the contour of the remaining coronal tooth structure can be accomplished and the appropriate final restorative procedure can be completed (see Figure 50C).

Root amputation is not the treatment of choice when only a portion of a mandibular molar must be removed.

Figure 51 **A**, Curved periodontal probe illustrates the periodontal defect that exists between the distobuccal and palatal roots of this maxillary first molar; **B**, The root amputation procedure has been completed and the distobuccal root is now ready for extraction. The arrow notes the presence of the amalgam core in the distobuccal root canal.

This procedure is normally only indicated in mandibular molars when the tooth is acting as an abutment for a well-fitting, serviceable fixed partial denture or a single crown with good proximal contact with the adjacent tooth. As with the maxillary molar, the majority of the crown contouring and amputation procedure must be accomplished with surgical length fissure or diamond burs prior to reflection of the soft tissue flap. The recontoured portion of the tooth should resemble a sanitary pontic. This will allow the patient to be able to adequately clean the undersurface of that portion of the crown in the area where the root was amputated. Delivery of the resected root in mandibular molars is much more difficult than for maxillary molars because the root is as broad as the tooth in a buccolingual dimension. After reflection of a limited soft tissue flap, the resected root will be reduced in length in a coronal to apical direction so that it can be removed from the

socket without compromising the stability of the remaining root and coronal tooth structure. Once the root is removed, the bone surrounding the socket will be smoothed and the soft tissue flap will be sutured. Once the coronal portion of the socket is adequately healed, the final recontouring and polishing of the crown can be completed.

HEMISECTION

When root removal is indicated in a mandibular molar because of a vertical root fracture, therapeutic misadventure, or pathologic resorptive process, hemisection is usually the treatment of choice. Due to the difficulties noted above in attempting to perform a root amputation procedure on mandibular molars, removal of one-half the tooth is a more predictable treatment procedure. This procedure is also falling out

of favor as a treatment procedure today because the prognosis for success with osseointegrated implants is much better than that for hemisected teeth. The ideal situation for performing a hemisection procedure is when one-half of a mandibular second molar can be retained to occlude with and prevent the supereruption of a maxillary second molar. The root and crown structure that is retained can be restored as a premolar. This procedure is only indicated if the remaining root has adequate periodontal support and the crown can be restored. The mesial root of a mandibular molar has more surface area so it will be more stable periodontally, but because there is generally a concavity present on the distal surface of this root, it is more difficult to restore and cleanse with dental floss and a toothbrush. The distal root is generally more conical in shape and is easier to restore and maintain. The procedure is contraindicated if the roots are fused; there will be inadequate bone support for the remaining root or if the tooth cannot be adequately restored.

As with a tooth being prepared for root amputation, nonsurgical endodontic therapy is completed first and then core material or a post and core restoration is placed into the coronal aspect of the root to be retained and pulp chamber (Figure 52A,B). Once the core material is set, the location of the buccal and lingual furcations is identified and selective occlusal adjustments are made so that the retained portion of tooth will not be in occlusion. The majority of the sectioning procedure is accomplished with a surgical length fissure bur using rubber dam isolation. This prevents debris from accumulating in the mucobuccal fold and possibly getting under the soft tissue flap once it is reflected or into the open extraction socket. The initial resection should begin on the buccal surface and move in a lingual and apical direction until the furcation area is reached. The sectioning should be accomplished at the expense of that portion of the crown that is scheduled for removal. A sufficient amount of tooth structure

Figure 52 **A**, Mandibular second molar with a fracture across the distal marginal ridge extending to the midroot level; **B**, Amalgam core has been placed; **C**, Hemisection procedure has been completed and the distal root is ready for extraction; **D**, Mesial half of the tooth has been retained as a bicuspid to form an occlusal stop to prevent the extrusion of the opposing maxillary molar.

should be left in the furca area of the portion of the tooth that is to be retained so that a restorative finish line can be established in that area of the tooth. Once the resection has reached the furcation area, the rubber dam is removed and the final separation of the roots is completed with a fissure or tapered diamond bur (see Figure 52C).

The gingival tissue attached to the portion of the tooth to be extracted is loosened. A limited soft tissue envelope-type flap may also be reflected to facilitate removal of the root. The portion of the tooth to be removed should be gently elevated so that the retained root is not disturbed. Using the appropriate forcep, hemostat or rongeur, the loosened root is removed from the socket (see Figure 52D). The socket walls are compressed, the bone margins smoothed, and the soft tissue is repositioned and sutured. If any additional contouring of the remaining tooth is required at this time, the socket should be covered with sterile gauze to prevent particles of tooth and restorative materials from falling into the open extraction socket. Once the healing of the socket has progressed to a point that the coronal portion of the socket is completely covered, restorative procedures can be initiated.

Bicuspidization refers to a procedure that was once recommended for mandibular molars when a hemisection procedure was performed but both roots were to be retained. The purpose of this procedure was to create a situation in a molar tooth with a furcation defect that would be more favorable for cleansing and maintenance. The procedure was found to have a very poor long-term prognosis and is rarely recommended as a treatment option today.

The results of several studies^{211–220} report success rates ranging from 62% to 100% with follow-up periods of 1 to 23 years. The combined data from these studies indicates an overall success rate of approximately 88% can be expected when these procedures are performed. The long-term prognosis for teeth with roots amputations or hemisections will depend on a number of factors: the quality of the root canal therapy in the retained root or roots, the contouring and quality of the final restoration, and the ability to maintain the health of the supporting periodontal soft and hard tissues. Any one, or combination, of these factors may result in failure of the case.

PERIODONTAL REGENERATIVE PROCEDURES

In the previous sections dealing with corrective surgical procedures, it was noted that situations might be encountered that will require periodontal regenerative

procedures in addition to the corrective root surgery. These regenerative procedures may include, but are not limited to, placement of decalcified freeze-dried bone allograft or calcium sulfate materials^{209,221,222} into large bone defects and guided tissue procedures^{223–233} using either resorbable or nonresorbable membranes. It is beyond the scope of this chapter to detail every periodontal regenerative procedure. A selected bibliography^{209,221–223} dealing with the utilization of these procedures in conjunction with endodontic procedures is provided. For more detail about the clinical techniques involved in the utilization and placement of these materials, the reader is referred to any number of excellent periodontal textbooks.

INTENTIONAL REPLANTATION

Intentional replantation may be defined as the purposeful extraction of a tooth to repair a defect or cause of a treatment failure and then returning the tooth to its original socket.^{234,235} The individual first credited with the principle of extraction and replantation was an Arabian physician by the name of Abulcasis who practiced in the eleventh century.²³⁶ Since that time there have been many published reports of studies and case reports dealing with the technique and results of the intentional replantation procedure.^{234–245}

Weine²⁴⁵ has stated that intentional replantation is only indicated when all other endodontic nonsurgical and surgical treatments have been performed and failed or were deemed impossible to perform. This procedure is generally an acceptable treatment alternative when periradicular surgery will not allow visualization of the area on the root to be repaired or there is danger of damaging adjacent vital structures such as the contents of the mandibular canal or mental foramen.^{234,235} Specific indications^{234,235,239} may include but are not limited to the following situations where nonsurgical and surgical endodontic procedures have been deemed impossible and the patient desires all possible efforts be made to retain the natural tooth: limited mandibular opening that prevents the performance of nonsurgical or periradicular surgical endodontic procedures; root canal obstructions; nonsurgical and surgical treatments have failed and symptoms and/or periradicular disease persists; resorptive or perforation root defects that exist on areas that are not accessible via the usual surgical approach without excessive loss of root length or alveolar bone; and to allow thorough examination of all surfaces of the root in order to identify or rule out the presence of a root defect, such as a crack or root perforation.

Contraindications^{234,235,245} may include the following: teeth with long, curved roots that require a surgical extraction procedure for removal from the socket; advanced periodontal disease that has resulted in poor periodontal support and mobility of the tooth; mutirooted teeth with roots that diverge making extraction and replantation impossible; teeth with nonrestorable caries; and teeth that are amenable to additional nonsurgical and surgical endodontic procedures.

To provide the best long-term prognosis for a tooth intentionally reimplanted, the tooth should be kept out of the socket for the shortest time possible, the periodontal ligament attached to the root surface should be kept in moist saline or in Hanks Balanced Salt Solution during entire time the tooth is out of the socket, and the extraction of the tooth should be accomplished as atraumatically as possible to minimize damage to the cementum and periodontal ligament.^{234,235} Part of the success of the procedure will also depend on the ability to extract the involved tooth without fracturing the root or roots (Figure 53). The patient should always be advised that fracture of the tooth is possible during the extraction procedure, and if this occurs, the pieces of the tooth will be removed and discarded.

Kingsbury and Wiesenbaugh²⁴⁰ reported a 95% success rate with 151 mandibular premolar and molar teeth that were intentionally reimplanted over a 3-year period. In another study²⁴¹ involving 192 intentionally reimplanted teeth with evaluation periods of between 6 and 51 months, a success rate of 82% was reported. In a more recent report, Bender and Rossman²³⁵ had 80.6% success with 31 intentional reimplantation cases with observation periods of up to 22 years. Raghoobar and Vissink²⁴² had only 72% success in 29 cases after a 5-year observation period. Intentional replantation is not a completely predictable procedure, but under favorable conditions, some fairly acceptable success have been reported.²³⁹⁻²⁴⁴

Once the decision has been made and accepted by the patient to perform the intentional replantation procedure, any nonsurgical endodontic procedures should be completed to the best degree possible (Figure 54A). The pulp chamber and coronal access are then restored to help stabilize and reinforce the coronal tooth structure during the extraction procedure. Intentional replantation is best accomplished as a team effort because each member of the team will be assigned, trained, and skilled to perform a specific function. This team approach will minimize the extra-oral time for the tooth, facilitate the removal of any diseased tissue from the apical portion of the

Figure 53 An attempt to perform an intentional replantation on a mandibular second molar failed because the tooth fractured during the extraction process.

socket, and accelerate the repair of the root surface defect or the placement of a root-end filling. Another method to minimize the time the tooth is out of the socket is to plan so that all necessary instruments and materials necessary to accomplish the entire procedure are out and readily available in the operating area.

Once adequate local anesthesia is obtained, the periodontal fibers in the gingival crevice area are detached with a scalpel blade of an appropriate size in order to loosen the gingival tissues attached to the tooth in this area. A surgical elevator should either not be used or used only minimally to loosen the tooth in the socket. If the use of the elevator results in damage to the cementum or periodontal ligament on the root surface, it may compromise the success of the case. If possible all the loosening of the tooth should be accomplished with the extraction forcep as the tooth is slowly and gently loosened

Figure 54 **A**, The mandibular second molar remained symptomatic after an unsuccessful attempt was made to negotiate the apical portion of both mesial canals and to retrieve the separated instrument from one of the canals. Due to the close proximity of the mandibular canal to the apices of the roots of the second molar, an intentional replantation procedure was recommended rather than periapical surgery; **B**, Forcep extraction; **C**, Root ends resected; **D**, Tooth reimplanted; **E**, Acrylic splint placed; **F**, Immediate postoperative radiograph; **G**, Soft tissues are healthy and tooth is asymptomatic at the 6-month follow-up; **H**, There has been a reduction in the size of the periapical radiolucent defect on the 6-month follow-up radiograph.

and removed from the socket (see Figure 54B). It is crucial to remove the tooth and roots in one piece.

Following extraction, the crown of the tooth should be wrapped in gauze moistened with saline or Hanks Balanced Salt Solution and held with the beaks of the

forceps. It is also extremely important that the root surfaces be constantly bathed with one of these solutions during the entire extra-oral time. The roots are then thoroughly examined with magnification and a fiber optic light to evaluate for the presence of root fractures or periradicular perforation or resorptive defects. Sterile methylene blue dye may be applied to the root surfaces in order to enhance the visualization of root defects.

If no root fractures are found and the prognosis for replantation appears to be positive, any root defects noted should be repaired with an appropriate material. If root-end resection is indicated, it should be accomplished perpendicular to the long axis of the root with the same bur and in the same manner as if the tooth was still in the socket (see Figure 54C). After root-end resection, the appropriate ultrasonic tip is used to create the small 3-mm-deep Class I root-end preparation. An appropriate root-end filling material will then be placed. If a team approach is being used, one operator repairs the root defect while the second operator gently removes any diseased tissue from the extraction socket. Once the repair/root-end filling material is placed, the extraction socket is irrigated with normal saline and gently suctioned to remove any blood clot that may have formed. The tooth is then carefully reinserted back into its socket (see Figure 54D). Reinsertion of the tooth into the socket may be difficult at times so care must be taken to assure the tooth is returned to the socket in its proper orientation.

After the tooth has been inserted back into the socket, the patient is asked to bite so that the occlusion can be checked to assure the tooth is fully seated back into the socket. In some cases, posterior teeth are well retained in their sockets and stabilization with a splint may not be required. If excessive mobility is present, splinting will be necessary (see Figure 54E). The recommended splinting type and length of time are the same as those for replantation of the traumatically avulsed tooth as discussed in Chapter 31, "Endodontic Treatment Outcome: The Potential for Healing and Retained Function." In the case of a posterior tooth, stabilization may be achieved by placing a figure-8 suture over the occlusal surface of the tooth or by using a prefabricated acrylic splint. Stabilization may also be achieved by using a flexible wire or monofilament line bonded to adjacent teeth with an acid-etch composite resin system.^{234,235}

The patient should be re-evaluated 7 to 14 days following the intentional replantation to remove any stabilization that was placed and to evaluate tooth mobility. Other follow-up visits should be scheduled

1, 3, 6, and 12 months following the procedure (see 54F,G,H).

Implant Surgery

OSSEOINTEGRATED IMPLANTS

It is important to emphasize that while the surgical placement of osseointegrated implants is within the scope of endodontics, it is a very technique-sensitive procedure. Attention to detail is required in the alignment of the implant so that it can be properly restored and maintain the health of the supporting periodontal tissues. Dentists who plan to incorporate this procedure into their practice should participate in advanced training programs in order to gain knowledge in diagnosis, treatment planning, and placement of osseointegrated implants prior to implementing their use in clinical practice. This topic is covered in detail in Chapter 34, "Osseointegrated Dental Implants."

ENDODONTIC ENDOSSEOUS IMPLANTS

This type of implant is rarely ever used in today's practice of dentistry and will only be mentioned from a historical perspective. It seemed like a good idea when the procedure was introduced because the rigid implant would be contained within the confines of the root canal system, extend into the apical bone to stabilize the tooth, and not have any direct communication with the oral cavity. Orlay²⁴⁶ was one of the first to use and advocate this type of implant. Al Frank^{247,248} is credited with developing the instruments and matching implants along with standardizing the clinical nonsurgical and surgical techniques. It was reported²⁴⁹ that these implants were accepted by the periradicular tissue and that healthy fibrous connective tissue surrounded the metal implant and separated it from the alveolar bone. In 1993 Weine and Frank²⁵⁰ reported that while many of the cases they had placed over a 10-year period failed, some had resulted in long-term successes. Their recommendation was that endodontic endosseous implants be used only in carefully selected cases. With the advent of the true osseointegrated implants, the endodontic implant is no longer considered a treatment option.

Emergency Surgical Procedures

Emergency surgical procedures are indicated when drainage must be established to evacuate purulent

and/or hemorrhagic exudate that has formed within the soft tissue or the alveolar bone as a result of a periradicular abscess. These procedures decrease the pressure and pain that result from the buildup of byproducts of the inflammatory and infective process present within the area of the abscess. The length of the morbidity will also be decreased resulting in more rapid healing. If swelling is present in the soft tissues, an incision and drainage procedure will be the treatment of choice. The result of the incision and drainage procedure will be most dramatic if the swelling is fluctuant and the incision results in a productive flow of purulent exudate. If severe pain is present and there is no soft tissue swelling, a cortical trephination procedure may be required to establish drainage and relief of the painful symptoms. The clinical techniques for performing these two procedures are discussed in more detail in Chapter 21, "Treatment of Endodontic Infections, Cysts, and Flare-ups."

Surgical Outcomes (Success/Failure)

Outcomes assessment of endodontic surgical procedures must be addressed from a historical prospective. The techniques, armamentarium, and materials used when performing endodontic surgical procedures today are dramatically different from those being used when some of the early modern era endodontic surgical outcomes studies^{251–253} were published. Today the surgeon is able to visualize the surgical field with a surgical operating microscope equipped with an excellent light source. Ultrasonic surgical tips used to prepare the resected root for a root-end filling decrease the need for creating severe beveling of the root end and conserve a greater thickness of dentin and cementum of the root canal walls. This results in greater strength to the remaining root structure. Root-end filling materials used today have proven to be more biocompatible and to have better sealing capability than some of those used in the past. Not only will new cementum cover the resected root end, but it will also grow into contact with certain of these materials so that the entire root end and material is capable of being covered with new cementum.

The results of the studies dealing with outcomes of endodontic surgical treatment are based upon clinical signs and symptoms along with radiographic interpretation at varying follow-up periods of time. The criteria and classification generally used for reporting surgical outcomes are either those proposed by Rud et al.^{251,252} or some modification of their original suggestions. Their four classifications for outcomes included a category of "complete healing" which

denoted complete radiographic bone fill of the surgical crypt. The second classification was "incomplete healing" which indicated that the surgical crypt had healed with fibrous connective tissue (scar). Radiographically the surgical defect would have significantly reduced in size, but a small radiolucency would still be present. Some studies combine these two categories into one "healing" classification as they both would note a successful result as long as there were no signs and symptoms still associated with the case. The "uncertain healing" category notes there has been little, if any, reduction in the size of the radiolucent surgical defect but that there are no adverse signs or symptoms present at the time of the follow-up. With a longer follow-up period, cases in this category could either end up in one of the healing classifications or in the "unsatisfactory healing" category. This latter category denotes failure of the treatment. In the "failure" category, there will either be no evidence of any reduction in the size of the radiographic surgical defect or the radiographic defect will have enlarged in size. The presence of adverse clinical signs and symptoms can also denote failure even though there are no significant changes radiographically.

Using their established criteria, Rud et al.²⁵¹ reported complete healing in 18%, incomplete healing in 23%, and uncertain healing and unsatisfactory healing in 36% of 120 surgical cases with a minimum of a 1-year follow-up period. In a more extensive study²⁵² of 1,000 surgical cases, they reported on the outcomes at 1 year and then at longer follow-up times. They noted that with the longer follow-up periods there were increases in the complete (66% to 81%) and unsatisfactory categories (2% to 4%) and a decrease in the incomplete (15% to 9%) and uncertain categories (17% to 6%). In another study²⁵³ from this same time period, the complete healing results of 71% were very similar to those reported in the second Rud et al. study²⁵².

In the 1980s, some changes began to take place with regard to the type of materials being used for root-end fillings. In 1990, Dorn and Gartner¹⁷² reported that in a clinical study of 488 cases, the success rate obtained with Super-EBA cement as a root-end filling material was 95% and 91% for IRM root-end fillings. The results obtained when these two materials were used were significantly better than the 75% success they reported for the cases with amalgam root-end fillings. Frank et al.²⁵⁴ in 1992 reported on the success of 104 surgical cases with a minimum of a 10-year follow-up period. All 104 teeth had amalgam root-end fillings placed at the time of surgery and had been considered as treatment successes at earlier follow-up evaluations. The success rate in the

long-term cases was only 57.7%, suggesting that cases with amalgam root-end fillings would result in short-term successes but might not result in long-term successes. In other reports^{255,256} from the early 1990s, the reported surgical success rates are not significantly different from those reported in the 1970s.

The 1990s brought about a revolution in the management of endodontic surgical cases. With the introduction of the surgical operating microscope to endodontics, the ability to better visualize and illuminate the surgical site was changed. Microsurgical instruments were developed and surgical tips were designed for ultrasonic and sonic units. MTA and a dentin-bonded resin composite material (Retroplast) were introduced as potential root-end filling materials. The primary goal of all of these changes was to improve the chances of obtaining a successful outcome for patients requiring endodontic surgical procedures.

Rud et al.¹⁷⁶ reported 97% success in 33 of 34 cases with an 8- or 9-year follow-up where a dentin-bonded resin composite had been used as the root-end filling material. They¹⁷⁸ then reported complete healing in 92% of 551 infected roots treated with the same material and followed for 2 to 4 years. In a 2001 report²⁵⁷ using the same material, they noted complete healing in 92% of 834 roots after follow-up periods of 6 months to 12.5 years.

Rubinstein and Kim²⁵⁸ were one of the first to report on success when the endodontic surgical procedure had been performed using the operating microscope. At the 1-year and 2-month follow-up evaluation of 94 cases treated with the microscope and root end filled with Super-EBA cement, they reported a success rate of 96.8%. Of the cases that were considered to be healed after 5 to 7 years, 59 cases were available for follow-up evaluations and the success rate was still very high (91.5%).²⁵⁹ In another study of 120 teeth treated using the microscope, ultrasonic root-end preparation and Super-EBA root-end filling, an overall success of 92.5% was obtained at the 3-year follow-up evaluation.²⁶⁰ Von Arx et al.²⁶¹ reported an overall success of 83.8% for 191 teeth with a short-term, 1-year follow-up period. Their clinical technique varied in that an endoscope was used rather than an operating microscope, sonic rather than ultrasonic root-end preparation, and three different root-end filling materials were selected for use in a nonrandomized, uncontrolled manner. In a prospective clinical study²⁶² that specifically assessed surgical success when root-end preparations were accomplished with ultrasonic surgical tips, 42 of 46

cases (91.3%) were judged to be successful at the end of 1 year.

Several prospective clinical studies^{184,261,263} have compared success rates when different root-end filling materials have been used. Chong et al.¹⁸⁴ compared MTA and IRM when used as root-end filling materials and reported no statistically significant difference in success between MTA (92%) and IRM (87%) after a 2-year follow-up period. In a study²⁶³ comparing the same two materials, complete healing was found to occur in 64% and incomplete healing in 28% of the 50 teeth root-end filled with MTA after just a 1-year follow-up. In the 50 teeth in this study with IRM root-end fillings, 50% of the teeth were judged to have complete healing and 36% with incomplete healing. If the two healing categories were to be combined, the reported success would be almost identical to that of Chong et al.¹⁸⁴ The success with MTA (90.2%), Retroplast (84.7%), and Super-EBA (76.4%) were compared, but this prospective clinical study²⁶¹ failed to control the randomization usage of the three root-end filling materials.

In a systematic review²⁶⁴ of the endodontic literature, it was found that 330 of 2,788 teeth in 2375 patients required a resurgery procedure. Of these 330 teeth, only 35.7% were found to have successfully healed at the end of 1 year. Thirty-eight percent were determined to be failures and 26.3% were classified in the uncertain healing category at this same time period. In a longitudinal 5-year study²⁶⁵ first-time versus resurgery cases, the success at 5 years for the resurgery cases was only 59% compared to an 86% success for the first-time surgery cases. A much higher success rate of 77.8% for resurgery cases evaluated at the end of 1 year was reported by von Arx et al.²⁶¹ The predictability of achieving successful healing with resurgery cases is significantly less than what we have come to expect with first-time surgery using modern armamentarium, techniques, and materials.

CHAPTER 34

OSSEOINTEGRATED DENTAL IMPLANTS

JAIME L. LOZADA, ALEJANDRO KLEINMAN

Implant Dentistry in the Endodontic Practice

One of the main objectives in dentistry is prevention of oral disease and the preservation of the natural dentition, frequently achieved by root canal treatment.¹ When this is not possible, osseointegrated implants can play a significant role in the rehabilitation of patients who have lost their teeth or have hopeless teeth because of periodontal or restorative concerns.² Implants are increasingly being used to replace missing teeth in a variety of situations, including the **missing single tooth**.

There is, however, considerable variation in treatment planning philosophy among clinicians encountering patients with pulpally involved teeth with a questionable prognosis.³⁻⁷ The decision between retention of endodontically involved teeth versus extraction and implant placement is a clinical decision that requires careful evaluation of all of the factors influencing the outcome of the proposed treatment.^{8,9}

The treatment decision depends on the following variables: the quality of the support the tooth will provide for planned restorations, predicted longevity, and its role in the overall rehabilitation, functionally, esthetically, and financially.^{2,10} Before a definitive treatment decision is made, it is important to assess the quality of tooth support compared with that provided by implants.

Dental implants have by no means constituted the only significant recent advance in dentistry. In endodontics, for instance, the use of microscopes, nickel titanium files, electronic apex locators, and ultrasonic instruments are but a few of the developments enabling practitioners to perform endodontic treatment with greater precision and efficiency, fewer errors, and better success rates than ever before.¹¹ Of course, success in endodontic treatment is not solely dependent on instruments and technique. It is also

affected by such factors as the level of disease progression (i.e., the presence of apical pathosis), case selection, restoration quality, iatrogenic errors, and, very importantly, postendodontic control of coronal microleakage.^{12,13}

The determination of success is usually based on clinical parameters, including cessation of symptoms and complete repair of periapical tissues. Success for a patient, however, may simply be to have a tooth that is in function, one that may not be totally comfortable to chew on but otherwise is clinically sound. Endodontic therapy alone does not guarantee successful retention of a tooth or prevent its future loss as most failures associated with endodontically treated teeth are not endodontic in nature. Recurrent dental caries, root fractures, and periodontal disease, in conjunction with recurring apical periodontitis, have been associated with these failures.^{9,14,15} These studies also suggest that such factors are indications for tooth extraction more frequently than endodontic failure itself. The loss of tooth structure is directly related to the ability of a tooth to resist fracture.¹⁶ More specific data regarding the success and survival of endodontically treated teeth are described in Chapter 31, "Outcomes of Endodontic Treatment."

As with conventional endodontic therapy, the long-term success of implant-based treatment varies, depending on the experience of the clinician, implant location, surgical and prosthetic technique, and type of implants used.¹⁷ However, long-term implant survival rates better than 90% are well supported by the literature.^{14,18-21} Modern implant surfaces provide more predictable integration (measured by bone-implant contact, removal torque, and Resonance Frequency Analysis) at all time intervals, making implants a predictable treatment foundation for the long-term restoration of missing teeth.

When one compares the predictability of endodontically treated teeth versus implants as foundations for

restorative dentistry, the literature provides some advantages for implants. This is most likely related to their obvious resistance to dental caries, periodontal disease, and structural deficiencies. The clinical literature reports survival rates up to and exceeding 97% depending on the location in the arch and bone density.²²⁻²⁴

Single-rooted teeth with structural integrity and **intact coronal structure** are the best candidates for traditional endodontic treatment, especially in instances in which the esthetic outcome is important to the patient. The loss of vitality in these teeth is often caused by trauma. In contrast, teeth requiring endodontic therapy that have a significant caries and restorative history end up with substantial loss of coronal structure. Most of these teeth require additional restorative care, and this further compromises the retained structure and periodontal and caries status. Correctly placed implants, positioned in idealized sites, with the use of appropriately timed provisional restorations to shape the surrounding soft tissue, can be associated with esthetic results comparable (and often superior) to fixed prosthodontic restoration on natural teeth.²⁵

Extraction and immediate placement of dental implants to support replacements of single teeth, even in esthetic sites, are now very predictable.²⁶⁻²⁸ Immediately placed implants have numerous advantages over delayed placement techniques, including maintenance of the existing gingival embrasure form, any marginal contour, preservation of the existing bone, reduced surgical procedures, and shorter treatment times.^{28,29}

When the diagnosis of endodontic failure has been made,³⁰⁻³³ three treatment options exist to resolve the problem: conservative retreatment, apical surgery, or extraction.³⁴ The literature indicates that the success of retreatment is higher than surgical treatment when access to the root canals is feasible.³⁰ Retreatments, however, should be avoided in teeth that cannot be satisfactorily restored (Figure 1). Additionally, in cases with periodontal involvement, the prognosis of combined therapy should be assessed before proceeding with the endodontic retreatment.³⁵ Several factors may dictate surgical endodontics as the treatment of choice. These factors include failure of conventional endodontic treatment, difficulties in performing conventional endodontic treatment, root fractures, root perforations, and endodontic-periodontal complications. A poor prognosis with an increased probability of failure may be associated with any of those factors.

When a tooth is considered to be in a hopeless condition, extraction is indicated. Immediate placement of

Figure 1 An endodontically treated tooth is failing because of vertical root fracture of the mesial root. This is a situation in which replacing the tooth with an implant is a good option.

an implant following extraction has been suggested by several investigators to take advantage of the present osseous dimensions and to minimize further osseous resorption.^{29,36}

Immediate placement has several advantages, including the following: decreased operator time with less trauma to the tissues and less discomfort to the patient; easier implant orientation and better restorations can be achieved; crestal bone loss can be minimized; through the use of a longer implant, the long-term prognosis can be increased; and greater support can be obtained for guided bone regeneration procedures in cases of bone-implant deficiency to maintain or enhance the bone width and height.³⁶

Contraindications to immediate implant placement include the presence of active infection, if bone regeneration is important, or if there is difficulty in obtaining primary closure.

Immediate implant placement is a predictable and a widely practiced procedure with demonstrated efficacy for long-term restoration of missing teeth. The clinician now has an additional choice of treatment in cases in which tooth extraction is inevitable. The decision to either maintain an endodontically involved tooth or do the extraction and place an implant can be a very complex issue and must be based on a number of factors, not the least of which is the long-term predictability of treatment outcome. According to Bader, there is no generic answer to this clinical issue, and every patient, indeed every site, must be examined and evaluated on an individual basis.⁸

Historical Background

Over the past 40 years, endosseous dental implantation has been established as a creditable method of oral rehabilitation. The replacement of teeth by implantation techniques was started a long time ago by our ancestors. Skeletal remains from ancient Egyptian and South American cultures give evidence of these efforts.³⁷ Gold and ivory dental implants were used in the sixteenth and seventeenth centuries.³⁸ Since then, until the 1960s, multiple materials and surgical techniques were used without any major breakthroughs in replacing teeth.

Root replacement by allogenic tooth transplantation became popular in seventeenth century England, France, and the Americas and continued well into this century. Metal implant devices of gold, iridium, tantalum, stainless steel, and cobalt alloy were developed in the early twentieth century.³⁹

Classic Dental Implant Devices

BLADE-FORM IMPLANTS

This type of implant also is known as a plate-form implant. It is a type of endosseous implant with the geometric shape of a rectangle, with a narrow buccal-lingual dimension designed, once inserted, to be restored and splinted to a natural tooth abutment (Figure 2).

The endosteal blade implant was introduced independently in 1967 by Leonard Linkow and by Ralph

Figure 2 An example of a blade-form implant. These implants were typically splinted to natural teeth.

and Harold Roberts. In 1979, the National Institutes of Health Office of Medical Applications of Research (OMAR) scheduled a consensus development conference titled “Dental Implants: Benefits and Risks.” For blade-form implants in the free end application that primarily involves bridges or one pontic and two or more natural abutments, the data suggested that the 5-year survival rate may have been as high as 90%. However, data presented at the meeting suggested a 5-year survival rate as low as 65%. The device is not as popular today as it was 20 years ago.⁴⁰

SUBPERIOSTEAL IMPLANTS

One of the earliest designers of a subperiosteal implant was the Swedish practitioner Gustav Dahl, who placed his first subperiosteal implant in 1940.⁴¹ Aaron Gershkoff and Norman Goldberg of Providence, Rhode Island, were leading American pioneers in subperiosteal implant designs and techniques. They brought the technique of Dahl to the United States and performed their first surgical placement in 1948. Their work consisted of making a complete mandibular impression of the soft tissues covering the edentulous jaw. They estimated the thickness and character of the mucosa using radiographs and palpation. They then scraped a cast to remove the appropriate amount of stone to reflect the tissue thickness. From the modified cast, they fabricated a vitallium casting. The tissues were then reflected, and the implant was fitted on the bone and held in place with screws.

Another American, Nicholas Berman of Seattle, Washington, altered Goldberg and Gershkoff's early technique. Recognizing that the bone must be exposed to accurately determine its morphology, Berman fabricated a stone cast from a modeling plastic impression of the mandible after the soft tissue had been reflected. Two or three weeks after the initial impression, he again uncovered the bone and fitted the meshwork under the periosteum and over the bone.⁴²

In 1980, Philip Truit, a graduate student in implant dentistry at Loma Linda University School of Dentistry, using computed tomography (CT), produced a morphologic replication of the mandible. His work consisted of comparing actual measurements with CT measurements on dry skulls and subsequently on cadavers. Adequate accuracy was not obtained on the first attempt, and certain regions of the jaw were not accurately recorded when 18 separate anatomic landmarks were evaluated.⁴³

Subsequent research and improvements produced frameworks that fit with gaps that were generally less

Figure 3 **A**, An example of a subperiosteal implant on a duplicate of the tridimensional model of a patient's alveolar arch. **B**, Panoramic radiograph of the subperiosteal implant in the patient's mouth.

than 0.5 mm. The results, using this process, showed sufficient accuracy to apply to clinical patient treatment. Over 200 subperiosteal implants were subsequently fabricated and placed at Loma Linda using the three-dimensional modeling protocol that eliminated the need for a bone impression (Figure 3).

ENDODONTIC IMPLANTS

The concept behind endodontic implants is that if a rigid implant can safely extend out through the apex of the tooth into sound bone, and by so doing stabilize a tooth with weakened support, the patient is well served and perhaps can avoid replacement for some time. Unfortunately, a high failure rate of endodontic implants developed, and the profession backed off from their use. Weine and Frank, however, retrospectively "revisited" their endodontic implant cases placed over a 10-year period.⁴⁴ While admitting to "many that did fail," they "noted some remarkable long-term successes with the technique." Their recommendation was that endodontic implants not be discarded totally but used only in carefully selected cases (Figure 4).

Orlay may have been among the first to use and advocate endodontic implants.⁴⁵ Frank is credited, however, with standardizing the technique, developing the proper instruments, and matching implants.^{46,47} Frank and Abrams were also able to show that a properly placed endodontic implant was accepted by the apical tissues and that a narrow "collar" of healthy fibrous connective tissue, much like a circular periodontal ligament, surrounded the metal implant and separated it from the alveolar bone.⁴⁸

Placing endodontic implants is a technique-sensitive procedure. A **perfectly round preparation** must be reamed out through the root apex and into the alveolar bone. Failure to accomplish this, results in leakage around the implant-dentin interface at the apex and eventual failure results.

ENDOSSEOUS ROOT FORM IMPLANTS

It has been proposed that the term *root-form implant* be avoided since it perpetuates a faulty concept that cylindrical implants resemble the roots of natural teeth. However, an alternate term that differentiates the endosseous implants approximating the form of a tooth from those that are plate-like in form has not emerged. Therefore, the term *endosseous root-form implant* continues to be widely used (Figure 5).

OSSEOINTEGRATION

In the 1950s and 1960s, Professor Per-Ingvar Brånemark and his colleagues completed experimental work that was started in 1952. Their research led to the development and introduction of titanium root-form implants.⁴⁹ His work revolutionized the approach to and acceptance of implants as a treatment modality. This type of endosseous root-form implant has become the most widely used implant in the world.

After the validation of osseointegration, which is now a clinical reality, the root-form implant once again has become implant dentistry's most dominant design. A multitude of solid and hollow screw and press-fit forms have been developed with and without

Figure 4 Examples of the use of endodontic implants. **A**, Eight-year follow-up of treatment of a tooth with an endodontic implant for a horizontal root fracture in which the apical segment had been removed. **B**, An example of a tooth with extensive periodontal bone loss, one of the indications for an endodontic implant. **C**, The tooth in **B** 2 years after implant placement. **D**, An endodontic implant after 6.5 years. **E**, An endodontic implant in place after 32 years. *3D* and *E* are courtesy of Dr. Pabla Barrientos, Santiago, Chile.

Single-Implant Restorations

DIAGNOSIS AND TREATMENT PLAN

Endodontic clinicians repeatedly face decision making in providing the best form of treatment for compromised teeth. From endodontic retreatment, tooth extraction, and alveolar preservation to simultaneous dental implant placement, endodontists today are preparing themselves to be well equipped to provide all of these forms of treatment.

Several diseases, medications, treatments, and habits affecting implant success have been evaluated and reported in the literature. Some have been definitively correlated with increased implant failure rates; others have been evaluated, but no correlation with increased failure has been noted. Data about other factors are limited and do not permit conclusions to be drawn. These factors investigated have included smoking, radiation therapy, diabetes, chemotherapy, osteoporosis, hormone replacement therapy, scleroderma, Sjögren syndrome, Parkinson disease, multiple myeloma, and a human immunodeficiency virus (HIV)-positive status.⁵⁰

An important part of diagnosis is determining if sufficient bone is available for the placement of an implant. When teeth approximate edentulous areas, it is important to determine if the teeth and bone are free from disease. It is also important to locate vital anatomic structures that can interfere with implant placement, such as the maxillary sinus, inferior alveolar canal, mental foramin, and approximating roots.

Radiographic images are necessary to assess available bone sites for implant placement. The number, angulation, and dimensions (length and width) of implants are dependent on available bone volume. Radiographs are also used to identify bone quality. To aid in the treatment planning of implant patients, a classification system has been developed for both the maxilla and the mandible related to the degree of resorption and morphology of the residual ridge. The bone quality noted radiographically has also been classified (Figure 7).

The faciolingual dimensions of residual bone have also been measured using bone sounding and ridge mapping. With bone sounding, a periodontal probe is pushed through anesthetized mucosa to locate the depth of the bone beneath the facial and lingual mucosa. Special bone calipers with sharp points have

Figure 7 Bone quality can be measured and classified from the Cone Beam Computed Tomography.

Figure 8 Template in the diagnostic model with buccal and lingual perforations to guide the bone sounding.

Figure 9 Probing in the buccal area of the alveolar ridge to locate the depth of the bone beneath the facial mucosa.

also been developed for this purpose (Figures 8 to 10). The points more easily penetrate the anesthetized mucosa, and a measurement scale identifies the bone thickness.⁵¹

Using a radiograph template, the selected radiograph is made and analyzed. Bone dimensions are measured, and the location of the bone, relative to the prosthetic teeth, can be analyzed. The cone beam tomogram

Figure 10 The points will transfer the information to the model, and a measurement scale identifies the bone thickness.

Figure 11 Bone quantity can be measured with accuracy using computed tomography.

and CT scan are the two most common types of advanced radiographs used in conjunction with implant dentistry.

The effectiveness and accuracy of cone beam CT have been validated, and articles have described the clinical use of linear tomography in presurgical planning.⁵² The accuracy of cone beam CT has also been favorably compared with the accuracy of panoramic and periapical radiographs (Figure 11).

EXTRACTION AND ALVEOLAR PRESERVATION

The alveolar ridge, after dental extraction, undergoes resorption produced by a lack of stimulus. The stimulus is interrupted when exodontia is performed owing to the loss of periodontal ligament attached to surrounding bone. Maxillary ridge resorption occurs approximately four times more rapidly than mandibular ridge resorption; this is due to the loss of anatomic, mechanic, and biologic factors. The absence of stimulation of the alveolar bone plays an important role in the continuous resorption of the basilar cortical plates.⁵³

In the 1980s, replacing vital roots with synthetic roots was highly recommended for the preservation of alveolar bone for complete denture wearers.⁵⁴ Synthetic hydroxyapatite roots were advantageous in preservation of the alveolar ridge. Recent publications demonstrate that immediately postextraction, maintenance of the alveolar ridge minimizes residual ridge resorption and, thus, allows placement of an implant that satisfies esthetic and functional criteria. Recent advances in bone grafting materials and techniques allow clinicians to place implants in sites that were considered compromised in the past. The focus is on the healing pattern of sockets, with and without the use of regenerative materials, and the rationale for **preserving the dimensions of the extraction socket**. Histologic and clinical evidence provides an in-depth understanding of the logic behind and value of socket preservation (Figures 12 to 16).⁵⁵

Figure 12 Atraumatic extraction to preserve all of the bone walls and septum.

Figure 13 Socket filled with allograft hydroxyapatite to minimize residual ridge resorption.

Figure 14 Graft material covered with a collagen membrane. The suture will hold the membrane in place.

IMMEDIATE EXTRACTION AND IMMEDIATE IMPLANT PLACEMENT

When an implant is planned for an area currently occupied by a tooth that must be removed, it may be advantageous to immediately place the implant following tooth extraction. Immediate placement offers several potential advantages compared with

Figure 15 Healing wound 2 weeks after extraction at suture removal. The granulation tissue is growing, covering the membrane.

Figure 16 Four months later, ready for implant placement.

extracting a tooth, allowing the bone to heal and then subsequently placing the implant:

1. The bone that originally surrounded the tooth is more likely to be preserved. Thin bone (such as the facial bone of maxillary teeth) and interproximal bone can rapidly disappear after tooth extraction. Placing an implant at the time the tooth is extracted helps preserve the remaining bone and decreases the need for subsequent ridge augmentation procedures. This bone preservation is important in conjunction with maxillary posterior roots encased in a thin bony housing that extends into the sinus. Months after extraction, implant placement might not be possible without

sinus bone augmentation surgery owing to rapid bone loss and sinus pneumatization, which occurs after extraction.

2. More ideal implant positioning is possible. For single-rooted teeth, the implant is positioned where the root of the tooth was located, which is advantageous unless the position of the tooth prior to extraction was undesirable. When implants are centered beneath the crowns, there is more favorable loading. Also, screw access holes are more likely to be centrally located within the peripheral crown dimensions that facilitate the fabrication process.
3. The total treatment time is decreased.
4. The number of surgical procedures is reduced.
5. There is a shorter time period when the patient is subjected to the challenges of being edentulous and wearing a provisional removable prosthesis.
6. The overall cost is reduced.
7. Soft tissue contours and height are better preserved in esthetic zones.
8. There is better acceptance of the treatment plan by the patient.
9. The opportunities for osseointegration are better owing to the healing potential of fresh extraction sockets (Figures 17 to 21).^{56,57}

Figure 17 Hopeless tooth with horizontal root fracture.

Figure 21 Immediate implant placement after grafting the gaps between the implant and the bone walls.

IMMEDIATE LOADING PROTOCOL

Immediate loading, by placing the prosthesis on the implant immediately after implant placement, was developed because of the desire to reduce treatment time and provide patients with a stable, esthetic replacement either the same day or within a very short time. For patients who have been wearing dentures, a few more months of wearing a removable prosthesis usually produces little concern. However, the standard protocol requires that they not wear any prosthesis for the first 10 days following surgery or that the prosthesis be relieved extensively to ensure that there is no contact with the soft tissue overlying the implants. Both of these options produce a challenge or inconvenience to patients.

There are also patients who are losing teeth and have never worn a removable prosthesis. These individuals can experience significant psychological and functional difficulties throughout the submerged healing time when they have to wear an interim removable prosthesis. Therefore, modifications to the original two-stage protocol were developed. Immediate loading has the following advantages:

1. The implant and crown or prosthesis are placed the same day, thereby providing the patient with an esthetic and stable replacement for the missing tooth or teeth in one appointment.
2. The number of surgical procedures is reduced.
3. The total treatment time is reduced.

Minimal surgical insertion torque values have been used as a means of determining if implants

are suitable for immediate loading. It has been suggested that implants whose torque at placement was more than 40 Ncm are suitable for immediate loading, whereas those torqued to less than 27 Ncm should be submerged. Bicortical anchorage and primary implant stability up to a torque of 40 Ncm have been proposed as mandatory.⁵⁸ The minimum insertion torque for immediately loaded implants has been described as 32 Ncm (Figures 22 to 25).

Figure 22 Provisional abutment fixed to the implant.

Figure 23 Shaping the customized cervical collar of the temporary abutment to guide soft tissue healing.

Figure 24 Temporary abutment finished in the patient's mouth.

Figure 25 Provisional crown in place the same day as the surgery.

Additional requirements for immediate loading have been described as follows:⁵⁹

- Provisional restoration and diet
- No centric occlusal contact
- No eccentric occlusal contact
- Liquid diet for 2 weeks after surgery
- Soft diet for 2 months after surgery
- Regular diet initiated 2 months after surgery

PROVISIONAL RESTORATIONS ON IMPLANTS AND DENTAL IMPLANTS IN THE ESTHETIC ZONE

Kan et al. proposed that immediate placement of a single implant into the anterior esthetic zone is most predictable when the prospective implant site possesses certain characteristics prior to tooth extraction.⁵⁸ They indicate the dentogingival complex

Figure 26 Clinical situations after complete implant osseointegration (6 months). The provisional crown can be removed, and the patient is ready for the final impression.

dimensions (distance from free gingival crest to the osseous crest) should ideally be 3 mm on the facial surface of the tooth to be extracted and 4.5 mm on the interproximal surfaces of the adjacent teeth. Deviations from these dimensions will likely produce deficits in the soft tissue esthetics. The authors also reported a technique whereby the papilla can be retained between adjacent single implants. This inter-implant papilla preservation involves alternate immediate implant placement and provisionalization, one following the bone integration period of the other. The process involves extracting one of the two teeth, immediately placing the implant, attaching a provisional metal abutment with resin added to create the proper emergence profile, and provisionalization with a resin crown. In this way, the soft tissue around the implant is preserved in its normal location. After 6 months, the procedure is repeated for the adjacent tooth, thereby preserving the interimplant papilla. The authors reported highly satisfactory esthetic results when treating consecutive patients in this manner (Figure 26).

Complications

Complications have been defined as secondary conditions that develop during or after implant surgery or prosthesis placement.⁵⁰ The occurrence of complication does not necessarily indicate that substandard dental care has been provided and also does not necessarily mean that clinical failure has occurred. Complications and failures in relation to dental implants with association of surgical and prosthetic stages are multifactorial, caused by inadequate planning, surgical insult,

systemic factors, and early and late failures. Late failures occur during the prosthodontic and maintenance phases after initial successful osseointegration. Early failures may be due to undiagnosed systemic diseases, systemic factors such as traumatic surgical technique, bacterial contamination, smoking, infection, premature loading, or inadequate home care.

Improper implant placement location and angulation can be due to a lack of bone in the preferred location for the implant owing to bone resorption, disease, or trauma. It can also occur owing to a lack of planning, failure to evaluate the location, angulation identified by the surgical template, or inadequate surgical technique.⁵⁰

HEMORRHAGE

Minor bleeding, hematomas, and ecchymosis are somewhat common surgical complications that are expected side effects associated with surgery. Lengthy surgeries or excessive trauma can lead to more hemorrhage-related complications, such as penetration of the lingual cortex, inadvertent bleeding on raising the buccal flap, intraosseous hemorrhage, and arteriovenous malformation.⁵⁰

NEUROSENSORY DISTURBANCE

A modestly high percentage of paresthesia of the mental nerve follows placement of implants in the area of the mental foramen. If the surgery is without incident and the mental nerve exiting the foramen is well identified during the placement of implants, paresthesia can still result owing to inadvertent stretching of the mental nerve or to implants placed into the inferior canal; implants anterior to the mental nerve can also damage some incisive nerve branches, retard formation of reparative bone, and exert pressure from a removable prosthesis.⁵⁰

ADJACENT TOOTH DEVITALIZATION

The pulps in adjacent teeth can be devitalized when an implant is placed too close to a tooth or invades the periodontal ligament space of adjacent teeth. It is best to place the implant so that the edge of the implant is greater than 1 mm away from the root of the adjacent tooth. The anatomy of an adjacent tooth root can often be visualized so that care is taken to avoid encroaching on this apical space. Periapical radiographs can be taken during surgery to assess the initial drill direction before completing the entire osteotomy.⁵⁰

PERIAPICAL LESIONS ON ADJACENT TEETH

It has been noted that endodontic pathosis in teeth adjacent to recently placed titanium implants can lead to implant failure.⁵⁰

PERIAPICAL LESION ON THE EXTRACTION SITE

Sites where teeth with apical lesions are to be extracted and implants immediately placed must be meticulously managed. After extraction, the socket must be carefully curetted and thoroughly rinsed with saline solution to ensure elimination of the lesion. The use of topical antibiotics may be indicated before implant placement, as well as the use of systemic antibiotics preoperatively and postoperatively.⁵⁰

SINUS TRACTS

Sinus tracts have been noted when there are loose and/or fractured screws that attach a crown, prosthesis, or prosthetic component to an implant. Sinus tracts are commonly located at the level where the mechanical deficiency is present. Sinus tracts have also been noted around cemented crowns or prostheses when excess cement is retained subgingivally. The problem occurs when deep subgingival margins make removal of excess cement difficult. In situations in which two-stage surgery is used, insufficient tightening of the implant cover screw may result in its loosening and the development of a sinus tract within a few days of surgery.⁵⁰

IMPLANT FRACTURE

Implant fractures have occurred owing to heavy occlusal forces and to the presence of substantial cantilevers on the crown or prosthesis. Fractures have also been found after improper surgical placement of root-form implants when excessive insertion torque is used, especially with small-diameter implants. When excessive force is used to insert an implant into dense bone that should have been tapped, the implants can fracture.⁵⁰

ESTHETIC COMPLICATIONS

Esthetic complications have been reported in conjunction with fixed complete dentures, fixed partial dentures, and single crowns. Contour, shade, embrasure spaces, and gingival recession have been identified as sources of esthetic challenges that are related to malpositioning of implants. Bone resorption prior to implant placement, preventing the ideal placement of implants, can produce open cervical embrasures between single crowns. Achieving ideal soft tissue form and interdental

papilla height can be a challenge when placing implants into highly visible edentulous areas. The marginal tissue may be thicker than the gingival margin present around adjacent teeth, interdental spaces may be present, the apical location of the soft tissue margin may not be at the same height as adjacent or contralateral natural teeth, interdental papilla may not possess the most desirable form or height, or recession of the soft tissue may lead to crown length variations. Placement of implants in the esthetic zone in the wrong position (mesiodistal, buccolingual) creates substantial problems that cannot be overcome. When existing bone dimensions permit, implants should be placed slightly facial to the faciolingual center of the edentulous area.⁵⁰

Gingival recession can cause esthetic challenges; recession can continue for up to 1 year. Since most of the recession occurs within the first 3 months, a 3-month waiting period has been proposed, followed by abutment connection surgery, before making the definitive impression.⁵⁹ Currently, the tendency is to connect the final abutment at the time of implant placement and to build the temporary crown on top of this final abutment, thus avoiding the constant connection and reconnection of the different implant restoration components that produce an insult to the peri-implant tissues with esthetic consequences.⁶⁰

RELATED ENDODONTIC TREATMENT

CHAPTER 35

VITAL PULP THERAPY

GEORGE BOGEN, NICHOLAS P. CHANDLER

Healing is a matter of time, but it is sometimes also a matter of opportunity.

—Hippocrates

Vital pulp therapy is broadly defined as treatment initiated to preserve and maintain pulp tissue in a healthy state, tissue that has been compromised by caries, trauma, or restorative procedures. The objective is to stimulate the formation of reparative dentin to retain the tooth as a functional unit. This is particularly important in the young adult tooth, where apical root development may be incomplete. This chapter describes advances in direct pulp capping and pulpotomy, where the treatment has been redefined by newly developed materials and protocols that are rapidly replacing long accepted strategies. The focus is directed toward the preservation of the pulpally involved **permanent tooth**, based on the premise that pulp tissue has an innate capacity for repair in the absence of microbial contamination.¹

During the last decade, exceptional progress was made in the field of vital pulp therapy. Materials used in the past were both biologic and nonbiologic.² Since the concept of indirect pulp capping was first documented in the eighteenth century by Pierre Fauchard, clinicians have recognized the innate capacity of the pulp tissue to initiate repair after injury from trauma, caries, or mechanical exposure.³ The first documented instance of vital pulp therapy is attributed to Phillip Pfaff, who placed gold foil against an exposed pulp with the intention to promote pulpal healing.⁴ Since the beginning of modern dentistry, researchers have endeavored to better understand and expand their

knowledge of pulp physiology, microbiology, and caries progression. This has coincided with the quest to identify bioactive materials and physiologic mediators that consistently stimulate reparative dentin formation and protect the pulp against microbial ingress.

There is a long-held perception that pulp exposures in a carious field have an unfavorable prognosis and that more aggressive treatment, such as pulpotomy or pulpectomy, should be considered.^{5,6} These strategies are based on traditional treatment protocols and materials that did not provide a consistently suitable environment for pulpal repair and reparative bridge formation. Moreover, the diagnosis of the pulpal histologic condition is difficult to ascertain owing to the lack of a fundamental understanding of pulpal physiology, patient subjectivity, and the presence of inflammatory mediators that cannot be assessed clinically.⁷ Proper case selection, based on a new understanding of inflammatory mechanisms responsible for producing irreversible changes in pulpal tissue, can help identify teeth with a greater likelihood for favorable outcomes.

The challenge is to identify a reliable pulp capping or pulpotomy agent and a suitable delivery technique. The introduction of mineral trioxide aggregate (MTA) has opened a new frontier in vital pulp therapy and changed the perception that pulp capping in carious exposed teeth is unpredictable and therefore contraindicated. The outcome of vital pulp therapy will depend on the age of the patient, the size of the pulp, bacterial contamination, the pulp capping material, and the quality of the final restoration. The importance of establishing a differential diagnosis

and proper case selection cannot be overemphasized. The pulp status must be determined carefully, establishing a differential diagnosis using multiple tests. According to the American Academy of Pediatric Dentistry, “Teeth exhibiting provoked pain of short duration, that is relieved, upon the removal of the stimulus, with analgesics, or by brushing, without signs and symptoms of irreversible pulpitis, have a clinical diagnosis of reversible pulpitis and are candidates for vital pulp therapy.”⁸ The assessment of a definitive pulpal status prior to treatment is often difficult to establish; however, a diagnosis of reversible pulpitis increases the probability of a favorable outcome.⁷ A negative patient report, that is subjective and variable, does not always indicate that the pulp capping or pulpotomy procedure cannot be successful. Moreover, pain associated with cold testing prior to treatment or a pulp exposure during caries excavation does not necessarily mandate a poor prognosis for the involved tooth.

The Vital Dental Pulp

The pulp is a highly vascular tissue that has the unique distinction of being encased within a rigid chamber composed of dentin, cementum, and enamel.⁹ These hard tissues provide mechanical support and protection from the microorganisms associated with the oral cavity.¹⁰ The tissue performs several important functions, including dentinogenesis, immune cell defense, and nutrition and proprioceptor cognizance. The retention and maintenance of the dental pulp are crucial to the long-term function of the tooth since during the life of the tooth, the healthy pulp produces reparative, secondary, and peritubular dentin in response to various biologic and pathologic stimuli.¹¹

Since the vital pulp is capable of demonstrating competent immune defense mechanisms, it is desirable to preserve the vitality of an exposed pulp since its retention is crucial to the tooth's long-term survival. If the hard casing of the tooth is compromised and the pulp is subjected to microbial ingress, inflammatory changes can lead to pulp necrosis and further pathologic changes, including infection and its consequences.^{12,13} Circulating immunocompetent cells limit microbial challenges, and functioning proprioceptors and pressoreceptors guard against excessive occlusal loading. By contrast, structurally compromised teeth that have been endodontically treated and restored with various post and core systems are more susceptible to fracture and failure owing to the loss of protective mechanisms. Although studies show that the

loss of moisture from dentin after endodontic therapy is minimal,^{14,15} cumulative loss of tooth structure is implicated in the failure of root-treated teeth.¹⁶

The dental pulp is composed of four distinct zones: a cell-rich zone, a core composed of major vessels and nerves, a cell-free zone, and the odontoblastic layer at the periphery. The major cell populations found in the pulp include fibroblasts, undifferentiated mesenchymal cells, odontoblasts, macrophages, and other immunocompetent cells. The odontoblasts have the distinction of forming a single layer lining the periphery of the pulp and feature odontoblastic processes extending into the dentin, sometimes to the dentoenamel junction.^{17–19} When the dental pulp is injured by trauma or carious exposure, the mechanism of healing is similar to that observed in normal connective tissue (see Chapter 5, “Embryology, Histology, and Physiology of the Dentin-Pulp Complex”).

Wound healing is a continuous process, and a sequence of four phases of healing overlap, including hemostasis, inflammation, proliferation, and remodeling.²⁰ After an injury, the tissue adjacent to the exposure is characterized by inflammatory cells, extravasated erythrocytes, and potentially necrotic tissue. An acute response is mounted, dominated by neutrophils in the presence of exudated fibrinogen and blood coagulation. Vascular permeability is altered when proinflammatory cytokines are released by immunocompetent cells in response to both trauma and bacterial by-products. Chemotactic signals prompt adhesion molecule interactions between leukocytes and endothelium, enabling transmigration of inflammatory cells. These cell interactions form an adhesion cascade mediated by chemoattractant/activator molecules interacting with sets of cell adhesion molecules.²¹

Reparative Dentin Formation

The reformation of a protective dentinal bridge by tertiary dentinogenesis is a primary goal of vital pulp therapy. The repair of pulpodentinal defects is orchestrated by the migration of granulation tissue to the site from the cell-rich and deep pulp subodontoblastic layers that differentiate into new odontoblast-like cells. Although these progenitor cells are most likely derived from undifferentiated mesenchymal cells, other cell populations migrating via the bloodstream, such as bone marrow stem cells and perivascular cells, have been proposed as possible precursors.²²

The migration and proliferation of these cells were studied in nonhuman primates after direct pulp capping with calcium hydroxide (Ca(OH)₂).²³ At the

calcium hydroxide–pulp interface, a continuous influx of newly differentiating odontoblast-type cells with initial matrix formation was observed as early as day 8. Labeled odontoblast-like cells showed differences in cell types and grain counts between zones, indicating that at least two deoxyribonucleic acid (DNA) replications had occurred between initial treatment and differentiation. Studies have suggested that the mineralization of dentin bridges is more dependent on the extracellular matrix than the pulp capping or pulpotomy material.^{24–26}

In a transmission electron microscopic study by Hayashi, initial calcification during pulp healing, characterized by an abundance of extracellular matrix vesicles, was located between the amputated pulp surface and the forming cells that contained needle-like crystals and osmiophilic material.²⁷ After the disappearance of the vesicular membrane, a calcified front formed as crystals and aggregate accumulated. The presence of calcium and phosphate ions within the crystals suggested that they were produced during the calcification process, similar to the calcification in other biologically normal or diseased tissues. Dentin bridge formation can be seen after 1 month at the site of the surgical wound, although pulp healing defects can be associated with different pulp capping agents and include tunnel defects, operative debris, pulpal inflammatory cell activity, and bacterial microleakage.²⁸

Techniques for Generating Reparative Dentin

DIRECT PULP CAPPING

The most widely used vital pulp therapy techniques for permanent teeth include direct and indirect pulp capping and partial or complete pulpotomy. **Direct pulp capping** is defined as the “treatment of an exposed vital pulp by sealing the pulpal wound with a dental material placed directly on a mechanical or traumatic exposure to facilitate the formation of reparative dentin and maintenance of the vital pulp.”²⁹ The indications for direct pulp capping include exposures as a result of caries removal, tooth preparation, or trauma. Pulp tissue, jeopardized by a long-standing exposure to oral microorganisms and acute inflammation, may be unsuitable for direct pulp capping.³⁰ Direct pulp capping for carious exposures is discussed in detail later in this chapter.

INDIRECT PULP CAPPING

Indirect pulp capping is defined as “a procedure in which a material is placed on a thin partition of remaining carious dentin that, if removed, might expose the pulp in immature permanent teeth.”²⁹ This technique shows some success in teeth with an absence of symptomatology and with no radiographic evidence of pathosis.³⁰ It has been controversial for decades.³¹ The strategy involved various techniques in which caries removal was completed to a point near the pulp tissue without direct exposure. The potential for pulpal repair has been demonstrated in selected teeth with deep carious lesions where caries excavation was conservative and direct pulp exposures were avoided.^{32,33} Indirect pulp caps are completed using either Ca(OH)₂ or zinc oxide–eugenol (ZOE) in a one- or two-stage procedure. The major difficulty with the procedure (one or two stage) is to determine at what point excavation is halted. Moreover, voids under the restorative material result during the remineralization process, in which the carious dentin dries out and loses volume. Another complication is restoration failure and rapid reactivation of a dormant lesion.³⁴ Indirect pulp capping is not recommended as a predictable treatment for permanent teeth.

PULPOTOMY

Pulpotomy is a more extensive procedure defined as “the surgical removal of the coronal portion of a vital pulp as a means of preserving the vitality of the remaining radicular portion.”²⁹ After the complete removal of the coronal pulp, a material is placed over the canal orifices. A variety of dressing materials, with varying toxicity, have been used for this purpose. They include phenol, creosote, ferric sulfate, polycarboxylate cement, glutaraldehyde, ZOE, Ca(OH)₂, and formaldehyde, which mummifies the remaining tissue.³⁵ Although studies indicate that short-term success rates are favorable, this procedure is generally advocated for deciduous teeth. Pulpotomies in young adult teeth have been completed with formocresol, although the material has distinct disadvantages.³⁶ Aside from the issue of systemic sensitivity to the agent, experiments with primates have shown a high incidence of internal resorption.³⁷ Also, orthograde endodontic treatment can be difficult to complete owing to changes in the canal system apical to the formocresol.³⁸ In addition to pulpotomies performed on permanent teeth, recent studies have shown MTA to be a suitable replacement for formocresol in pulpotomy of primary molars.^{39,40}

PARTIAL PULPOTOMY

Partial pulpotomy (Cvek pulpotomy) is defined as “the surgical removal of a small portion of the coronal portion of a vital pulp as a means of preserving the remaining coronal and radicular pulp.”²⁹ In this instance, inflamed tissue is removed to expose deeper, healthy coronal pulp tissue.⁴¹ Direct pulp capping and partial pulpotomy are considered similar procedures and differ only in the amount of undestroyed tissue remaining after treatment.

Indications for Vital Pulp Therapy

Vital pulp therapy is indicated whenever the remaining pulp exhibits reversible pulpitis and can be selectively induced to produce a reparative barrier that protects the tissue from microbial challenges. In particular, direct pulp capping can be performed for teeth with deep caries, mechanical exposures, and traumatic injuries to maximize pulpal preservation. The outcome of treatment for direct pulp capping or pulpotomy will be determined by the initial diagnosis, which includes radiographic evaluation, pulp testing, clinical evaluation, and patient history. The intention is to postpone more aggressive therapies that could eventually lower the long-term prognosis for tooth retention and function. Teeth undergoing orthograde root canal therapy and placement of posts and cores, followed by full coverage or cuspal coverage restorations, show lower long-term survival rates than teeth with vital pulps.^{42–48}

Vital Pulp Therapy Materials

The search for the ideal vital pulp therapy material has led researchers to investigate many different materials. These include $\text{Ca}(\text{OH})_2$ compounds,^{49–52} zinc oxide, calcium phosphate, zinc phosphate and polycarboxylate cements, calcium-tetracycline chelate, antibiotic and growth factor combinations, calcium phosphate ceramics, Emdogain, Bioglass, cyanoacrylate, hydrophilic resins, hydroxyapatite, resin-modified glass ionomers, and, recently, MTA.^{53–63} Other studies have included Ledermix, glyceric acid–antibiotic mix, potassium nitrate, and dimethyl isosorbide.⁶⁴ Innovative methods have also been used to eliminate caries progression and stimulate the repair of affected pulpal tissue and include ozone technology, lasers, and bioactive agents that activate pulpal defenses.^{65–68} Favorable outcomes in direct pulp capping have varied depending on the techniques and materials, with human retrospective studies showing 30 to 85% success rates at 5

to 10 years.^{49–52} Researchers have strived for decades to identify and produce a pulp capping material that, ideally, would exhibit the following characteristics:⁶⁹

- Stimulate reparative dentin formation
- Maintain pulpal vitality
- Release fluoride to prevent secondary caries
- Bactericidal or bacteriostatic
- Adhere to dentin
- Adhere to restorative material
- Resist forces during restoration placement
- Must resist forces under restoration during lifetime of restoration
- Sterile
- Radiopaque
- Provide bacterial seal

CALCIUM HYDROXIDE

This material, long considered the “benchmark” for vital pulp therapy materials (Figure 1), has been shown to have some desirable properties, but long-term study outcomes have been variable.^{51,52} Beneficial characteristics include a bactericidal component owing to its high alkaline pH and the irritation of pulp tissue that stimulates pulpal defense and repair.⁷⁰ Conversely, $\text{Ca}(\text{OH})_2$ has been shown to be cytotoxic in cell cultures, does not exclusively stimulate reparative dentin formation, shows poor marginal adaptation to dentin, and induces pulp cell apoptosis.^{71–73} The material can be associated with primary tooth resorption, it can degrade and dissolve beneath restorations, and it can also suffer interfacial failure upon amalgam condensation.^{74–76} It produces a gap between the dentin interface when used with bonding resins.⁷⁷ Dentin bridges beneath $\text{Ca}(\text{OH})_2$ are associated with tunnel defects, and the material fails to provide a long-term seal against microleakage when used as a pulp capping agent.^{71,76} The disintegration of $\text{Ca}(\text{OH})_2$ under restorations associated with defects in the dentinal bridge can provide microorganisms with a pathway for penetration into pulpal tissue and the subsequent stimulation of circulating immune cells, inducing pulpal irritation and potential pulpal calcification and canal obliteration.

ADHESIVE RESINS AND RESIN-MODIFIED GLASS IONOMERS

The use of adhesive systems for direct pulp capping was first introduced by Japanese researchers in the early 1980s.^{78–80} Preliminary research with nonhuman primate models using ISO standards was encouraging.^{81–85} Exposed pulps directly capped with various resins and

Figure 1 Pulpotomy with calcium hydroxide and amalgam. **A**, A 10-year-old boy with a deep carious lesion of the maxillary molar; clinical symptoms and examination indicated reversible pulpitis. **B**, Complete pulpotomy of the coronal pulp was done, followed by placement of a calcium hydroxide hard-setting paste and amalgam restoration. **C**, One-year follow-up shows additional placement of a stainless steel crown. evaluated histologically for pulpal reaction, microbial presence, and the formation of reparative dentin formation showed favorable biocompatibility. Although these favorable results were observed in nonhuman primates, the transition was not paralleled in human subjects.^{86–90} Research by several investigators in humans showed unfavorable histologic reactions to the resins when placed directly against pulp tissue. Many histologic sections from these investigations were characterized by mononuclear inflammatory infiltrates, macrophages, polymorphonuclear leukocytes, multinuclear giant cells, and an absence of calcific bridge formation.^{86,87,90}

Two clinical studies on human subjects compared direct pulp capping with either resin-modified glass ionomer cement or with a hydrophilic resin.^{91,92} Histologic results showed that both Vitrebond (3M Espe Dental Products, St. Paul, MN) and Clearfil Liner Bond 2 (Kuraray Co., LTD, Osaka, Japan) resulted initially in a moderate to intense inflammatory response and did not stimulate reparative dentin formation at 300 days. Further investigations in nonhuman subjects have revealed the unpredictable nature of reparative dentin formation and the contamination of reparative dentin bridges by bacteria. In a study by Murray et al., in which the hierarchy of repair was measured against microbial contamination, 18.6% of resin-based composite, 22.2% of resin-modified glass ionomer, and 47.0% of $\text{Ca}(\text{OH})_2$ specimens showed bacterial contamination of the reparative dentin bridge.⁹³ This is an indication that these pulp capping materials do not allow for predictable pulpal healing, nor do they provide a favorable environment for reparative dentin formation and the exclusion of microorganisms.^{94,95} Repair should proceed successfully beneath the material when bacterial microleakage is precluded.

MINERAL TRIOXIDE AGGREGATE

MTA was introduced to endodontics by Lee et al. in the early 1990s.⁹⁶ This bioactive silicate cement was originally composed of tricalcium silicate, tricalcium aluminate, tricalcium oxide, silicate oxide, and other mineral oxides.⁹⁷ The product is currently marketed under several names around the world and in one form (ProRoot MTA, Tulsa/Dentsply, Tulsa, OK) has changed in composition since its introduction with the substitution of dicalcium silicate for tricalcium silicate and the addition of tetracalcium aluminoferrite, calcium sulfate dehydrate, and bismuth oxide; the latter was added to impart radiopacity.⁹⁸ Originally a gray powder, white MTA was produced for esthetic reasons with the reduction of ferrite (Fe_3O_3) with no detectable change in clinical performance.^{98–101}

Figure 2 Comparison of dentin bridge formation using mineral trioxide aggregate (MTA) or calcium hydroxide in dog pulps. **A**, After 1 week, a noticeable bridge has formed subjacent to MTA. **B**, A comparable bridge under calcium hydroxide after 2 weeks. **C**, A 4-week specimen with MTA shows excellent bridge formation. **D**, Consistently, the bridge formation under calcium hydroxide lagged behind MTA; an example of bridge formation under calcium hydroxide after 8 weeks. CH = calcium hydroxide; DB = dentin bridge; MTA = mineral trioxide aggregate. Reproduced with permission from Junn DJ.¹¹¹

The cement exhibits many favorable characteristics, which make it a superior material when used as a direct pulp capping material in adult teeth or as an agent in partial or complete pulpotomy in primary teeth.^{102,103} MTA is structurally similar to Portland cement, which physiochemically allows the material to set in the presence of blood and moisture.¹⁰⁴ It exhibits a superior marginal adaptation and is nonabsorbable, and when it cures in the presence of calcium ions and tissue fluids, it forms a reactionary layer at the dentin interface resembling hydroxyapatite in structure.^{104–106} Other biocompatible characteristics include a sustained alkaline pH after curing, small particle size, and a slow release of calcium ions.¹⁰⁷ Studies have also demonstrated that MTA stimulates cytokine release, induces pulpal cell proliferation, and promotes hard tissue formation.^{108,109} The high alkalinity of MTA and its calcium release and sustained pH at 12.5 is most likely responsible for preventing any further microbial growth of residual microorganisms left after caries excavation.

The high pH also extracts growth factors from adjacent dentin thought to be responsible for promoting dentinal bridging.^{108,110}

Direct pulp capping with MTA has proven to be effective in stimulating tertiary dentin formation in canine models (Figure 2) and primates.^{60,111,112} Recent investigations have shown favorable short-term outcomes in humans when pulpotomies (partial or complete) (Figure 3) or direct pulp capping using MTA was examined.^{113–117} According to Tomson et al., the bioactive properties of MTA that stimulate reparative bridge formation can be attributable to the material providing a biocompatible noncytotoxic antibacterial environment.¹¹⁸ MTA also provides a favorable surface morphology for cell attachment and has the ability to form hydroxyapatite on its surface in the presence of tissue fluid. They hypothesized that soluble components of MTA during and after setting on the dentin interface may cause the release of growth factors

Figure 3 Pulpotomy on young immature permanent teeth using mineral trioxide aggregate (MTA). **A**, Recurrent decay under a previous restoration (amalgam and stainless steel crown); clinical symptoms and examination indicated reversible pulpitis. Complete pulpotomy of coronal pulp using MTA and amalgam was done. **B**, Follow-up evaluation 18 months later shows continued root formation, and the tooth is asymptomatic. **C**, Radiograph of a maxillary molar in a 10-year-old girl shows extensive caries involvement; based on clinical symptoms and examination, the pulp was determined to be reversibly involved. After caries excavation, the coronal pulp tissue was removed and MTA was placed followed by amalgam. **D**, The 18-month follow-up shows normal periapical tissues, and the tooth was asymptomatic. Reproduced with permission from Lauer HH. Vital pulp therapy with MTA: an outcomes study [thesis]. Loma Linda (CA): Loma Linda University; CA, 2005.

and other bioactive molecules, such as transforming growth factor beta ($TGF-\beta_1$) and adrenomedullin. The increased presence of these dentine extracellular proteins as the result of MTA culminates in dentin bridge formation after stimulating reparative dentinogenic mechanisms.

A current observational study examined MTA as a direct pulp capping agent using a two-visit protocol in permanent teeth in which cold testing determined a pulpal diagnosis no more severe than irreversible pulpitis.¹¹⁹ Teeth were selected for treatment that exhibited no detectable pathosis based on radiographic evidence and no clinical signs of swelling, furcation defects, or sinus tracts. Teeth received caries removal under magnification using a caries detector dye. Hemostasis was provided by direct contact with 5.25 to 6.0% sodium hypochlorite (NaOCl) for periods of 5 to 10 minutes. MTA was placed over the exposure, and all surrounding

dentin of the pulpal roof or axial wall and teeth received interim restorations with a moist cotton pellet and unbonded Photocore (Kuraray Co., LTD).

On a second visit, after 5 to 10 days, the teeth were permanently restored with a bonded composite (Clearfil LinerBond 2 and Clearfil AP-X composite, Kuraray Co.), but only after confirmation that the MTA had set and normal responses to vitality testing were elicited. Radiographic recalls were evaluated for reparative dentin formation, pulpal calcification, continued normal root development, and the absence of pathosis. Forty-nine teeth were observed for a 1- to 9-year period, with an average observation time of 3.94 years. Favorable outcomes, based on subjective symptomatology and cold testing, was 97.96%. Pulpal calcifications were seen in 10.6% (5 of 49) of cases, and all teeth (15 of 15) in younger patients showed complete root formation (apexogenesis) when open apices were present initially.¹¹⁹

The remarkable outcomes for direct pulp capping with MTA are attributable to distinctive properties inherent to the material. The sustained alkaline pH of the set cement is bactericidal and most likely contributes with NaOCl to the elimination of many residual microorganisms left at the dentin-pulpal interface after exposure. MTA is hygroscopic and sets in the presence of moisture, so direct contact with tissue fluids or blood does not affect the curing properties. The close adaptation of the silicate cement produces a virtually gap-free interface owing to the small particle size and precludes microleakage and bacterial ingress. MTA may also act to entomb residual microorganisms at the dentin interface. The slow release of calcium ions also allows the material to stimulate growth factors from the dental pulp and promote signaling molecules (TGF- β , interleukin [IL]-1 α , IL- β , macrophage colony-stimulating factor (MCSF), that encourage hard tissue formation.¹⁰⁸ The compressive strength and surface texture of the set cement allow strong bonding with adhesive restorations and minimal compression under heavy loading when a final restoration is placed.

Diagnostic Criteria for Successful Outcome

Direct pulp capping and partial and complete pulpotomy are important treatment options for the immature permanent tooth. Whether the coronal pulp tissue is preserved in toto, partially removed, or removed to the base of the pulpal floor, the preservation of the radicular pulp tissue allows continuing development and apical maturation (apexogenesis) of teeth with open apices. Moreover, in cases of trauma, in which tooth development may be interrupted, induction of apexogenesis should be the clinician's primary goal, with the pulp protected and encouraged to remain vital.¹²⁰⁻¹²²

Before treatment can be initiated, the clinician must make a careful assessment of all available information. Important aspects of vital pulp therapy include a differential diagnosis based on medical history, radiographic evidence, patient report, percussion testing, and vitality testing. Clinical evaluation must also include assessment of mobility, periodontal probing, localized swelling, and the presence of sinus tracts. Radiographs (both periapical views and bitewings) must be assessed for the absence of periapical pathosis, furcation radiolucencies, internal or external resorption defects, and pulp calcification owing to previous restorations or trauma.

After the radiographic and clinical assessments indicate an absence of disease, subjective symptomatology must be

considered. Although most patients with deep carious lesions can often experience sensitivity to heat, cold, and certain acidic or sweet foods, the subjective response to cold testing can be variable, and a short, lingering response (1–2 seconds) may not be an indication that the pulp is irreversibly involved. Studies have shown that cold testing responses in primary teeth are unpredictable, and testing may also be confounded in some individuals in immature permanent teeth.^{123,124} Pain to percussion is most often associated with irreversible pulpitis. In teeth with open apices with irreversible pulpitis, pulpectomy is recommended using MTA as a root-end plug to promote root-end closure (apexogenesis).^{122,125}

All teeth that have previous restorations, or a history of trauma, have a lower prognosis for repair and tertiary dentin formation than teeth with initial caries alone.^{126,127} In mature permanent teeth receiving full coverage, only teeth with no previous history of restorative treatment should be considered for direct pulp capping. From a technical standpoint, pulp exposure on the occlusal surface of a full crown preparation may have the best prognosis. Pulp exposures on axial walls of full-coverage preparations are extremely difficult to treat clinically owing to the handling properties of MTA and the technical challenge of placing the material against an open vertical wall. In these cases, orthograde root canal therapy should be considered a more predictable and suitable treatment option.

The remaining tooth structure should also be considered when selecting an appropriate vital pulp treatment. In teeth exhibiting advanced caries and severe coronal breakdown, requiring full coverage, pulpotomy rather than direct pulp capping is recommended. In patients with rampant caries, pulpotomies are recommended rather than direct pulp capping since the majority of these patients will exhibit recurrent caries at a higher rate.¹²⁸⁻¹³⁰ Young patients who exhibit initial caries on all first molars can still be considered excellent candidates for direct pulp capping if the differential diagnosis indicates reversible pulpitis in all teeth evaluated. It is also evident that a favorable prognosis for vital pulp therapy diminishes with the increasing age of the patient.^{52,130}

The diagnosis can be further confirmed at the time of pulp exposure when the pulp is visualized and hemorrhage control is assessed. In cases without bleeding, then the tissue is most likely necrotic and should be removed to a point where bleeding is encountered. A partial pulpotomy is completed with a high-speed diamond round bur with direct placement of MTA against the entire wound after achieving hemostasis. In teeth with pulp exposures, where bleeding cannot be controlled with 3 to 6% NaOCl within a 10-minute contact period, the diagnosis must be changed to irreversible pulpitis, and

pulpotomy or pulpectomy is recommended. The type of vital pulp therapy delivered is based on the option that will best benefit the patient and secure the optimum prognosis for the long-term retention of the tooth.

Pulp sizes are underestimated on radiographs, possibly leading to a greater risk of an unexpected and sizeable pulpal exposure.¹³¹ The observation of Matsuo et al. that the size of an exposure has no influence on the outcome is important.¹³² Erroneously, clinicians probably assume that larger exposures have a poorer prognosis and may include size in their decision making. In a recent study involving the examination of simulated exposures (0.5–0.9 mm), dentists without a ruler or previous calibration overestimated exposure size by a mean of 26%.¹³³ There may also be differences in some pulp dimensions between the genders and among racial groups.¹³⁴

Caries Removal

Dental dam isolation, aided by a caries detector dye and optical magnification during caries removal may be critical implements in achieving favorable results for direct pulp capping. Fusayama et al. made considerable progress in caries research by redefining the carious process and presenting a technique for objectively removing infected tissue, thus contributing to pulpal protection and survival.^{135,136} They indicated that gram-positive bacteria, whose main by-product is lactic acid, first break down hydroxyapatite and collagen in the outer carious layer but spare banded collagen in the second layer, where the intermolecular cross-links are still intact.^{137,138} They also discovered that pulpal repair and preservation were possible in teeth sealed with bonded composites if

the upper layer of two distinctive carious layers could be selectively stained and carefully removed.

Preservation of the second (caries affected) layer allowed for the exclusion of the majority of necrotic dentin and invading bacteria at the deepest point of microbial penetration, responsible for the production of proinflammatory mediators at the pulp-dentin interface. Moreover, since restoration placement was no longer dependent on retentive cavity preparations, more tooth structure could be spared, with less resultant trauma to the dental pulp.

The development of caries staining using a propylene glycol solution of Acid Red 52 dye (a common food and cosmetic coloring dye) provides visible differentiation of the two carious layers and is a selective method to remove the necrotic and infected dentin.¹³⁸ The retained caries-affected layer of dentin, which contains banded, intact collagen, allows for the remineralization of the altered tissue by calcium phosphate secreted from the pulp via the dentinal tubules. In the dentinal tubules, calcium and phosphate ions induce the formation of whitlockite crystals, which block the tubules. This remineralization of caries-affected dentin has been confirmed in canine and primate models.^{139,140} Fusayama argued that conservative objective caries removal promotes pulpal preservation without injuring residual **caries-affected dentin** that is reparable and remineralizable when a bonded composite restoration is placed to prevent microbial leakage.¹³⁸ Although several studies have questioned the efficacy of caries removal using a caries detector dye, the material does allow the operator to visually inspect under magnification infected dentin that may have been overlooked and potentially compromise the outcome for direct pulp capping (Figure 4).^{141–144}

Figure 4 Caries removal procedure. **A**, Clinical appearance of a mandibular molar with extensive caries after dental dam placement. **B**, Occlusal view after caries removal, including the use of a caries detector dye, and hemostasis using 6.0% NaOCl for a 5-minute period. Hemostasis

Many different hemostatic agents and antimicrobial materials have been introduced into the field of vital pulp therapy. These include ferric sulfate, disinfectants such as Concepsis (Ultradent Products Inc., South Jordan, UT) and Tubulicid (Global Dental Products, North Bellmore, NY) epinephrine, and varying concentrations of hydrogen peroxide (H_2O_2) and NaOCl. The most commonly accepted technique has been direct pressure at the exposure site with cotton pellets moistened in sterile water or saline. Other techniques using electrosurgery and lasers have shown limited value in hemorrhage control.¹⁴⁵ NaOCl, widely regarded as the most effective antimicrobial irrigant in endodontic therapy during chemomechanical cleaning of the root canal system, has been advocated as an agent in direct pulp capping and pulpotomy since the early 1950s.^{146,147} The main advantages of NaOCl not only include excellent hemostasis at the pulpal wound site, but the solution also allows for the clearance of most dentin chips, biofilm removal, chemical amputation of the blood clot and fibrin, disinfection of the cavity interface, and the removal of damaged cells from the mechanical or traumatic exposure.^{145,148,149} The dissolving capacity of 5.25% to 6.0% NaOCl appears to affect only the peripheral pulp cells without impairing underlying pulp tissue.¹⁵⁰ Although concentrations of NaOCl greater than 0.025% have been shown to be adverse to wound healing as a fluid dressing in burn victims, the reaction to pulp tissue appears to be relatively benign.¹⁵¹

The importance of hemostasis in vital pulp therapy was demonstrated in an eloquent study by Matsuo et al., in which treatment outcomes revealed a 2-year success rate of 81.8%.¹³² Teeth were directly pulp-capped with a fast-setting $Ca(OH)_2$ material after pulp exposures occurred during caries removal. Caries removal was completed under the guide of a caries detector dye, and hemorrhage control was completed with 10% NaOCl. Statistical analysis showed that the age of the patients, type of teeth, responses to thermal stimuli and percussion, and diameter of the pulpal exposure had no bearing on the success rate. The one significant measurable variable that predicted a favorable outcome was the degree to which bleeding could be arrested at the exposure site. This observation underscores the importance of proper hemostasis in the success of direct pulp capping and pulpotomy procedures.

It has been shown that higher levels of inflammatory mediators, including immunoglobulin (Ig)M, IgG, IgA, prostaglandin E_2 , and elastase, are present in clinically inflamed pulps.¹⁵² This suggests that

greater levels of these mediators may affect the degree of intrapulpal pressure and the likelihood of securing pulpal hemostasis. In cases in which pulpal hemostasis cannot be achieved within 5 to 10 minutes, the diagnosis should be considered **irreversible pulpitis**, and pulpotomy or pulpectomy should be considered.

The use of undiluted NaOCl (5.25%) was investigated histologically in beagle dogs on vital pulp tissue exposed on freshly cut dentin prepared to a depth of 2 mm. After the cavities were sealed with Cavit, pulps examined at 1- and 4-week time periods were free of inflammatory cells. The use of NaOCl did not appear to cause any additional pulpal damage after the trauma of exposing dentin and vital dentinal tubules.¹⁵³ Similarly, NaOCl at varying concentrations did not affect positive outcomes in primates when pulps were capped directly with adhesive resins.^{148,149}

In a clinical evaluation by Demir and Cehreli, 1.25% NaOCl was used for 60 seconds to ensure hemorrhage control in human primary teeth that were pulp-capped with either $Ca(OH)_2$ or various adhesive bonding agents.¹⁵⁴ The teeth were evaluated clinically and radiographically over a period of 24 months, and the outcome revealed a 93% survival rate when exfoliations were excluded. Sodium hypochlorite hemostasis did not seem to impair the biologic repair and subsequent tertiary dentinogenesis. This was reaffirmed in a study by Vargas et al. in which pulpotomies were compared using either NaOCl or ferric sulfate ($FeSO_4$) on primary teeth that were then restored with Intermediate restorative material (IRM) base/stainless steel crowns.¹⁵⁵ Short-term evaluation at 1 year showed a 100% retention rate of all teeth in the NaOCl group and 79% radiographic success, higher than the $FeSO_4$ group. Although $FeSO_4$ is effective as a hemostatic agent and recommended as a replacement for formocresol in pulpotomies on deciduous teeth, its use is not recommended if bonded restorations are used since it interferes with the bond strength of adhesive resins.¹⁵⁶

In a study completed on human third molars, direct pulp caps were examined histologically at 30 and 90 days after pulp capping with either $Ca(OH)_2$ or a self-etching adhesive system after using 2.5% NaOCl for hemostasis.¹⁵⁷ Although $Ca(OH)_2$ appeared to perform better biologically, pulpal repair was not compromised by the use of NaOCl. When comparing hemostatic agents in healthy human pulp tissue, the exposure to 0.9% saline, 5.25% NaOCl, or 2% chlorhexidine digluconate did not incapacitate healing after direct pulp capping with $Ca(OH)_2$ at 90 days.¹⁵⁸ Clearly, the use of **NaOCl** in concentrations of 1.25 to 6.0% for direct pulpal exposures can

be recommended as a relatively safe and practical method to predictably achieve hemostasis in vital pulp therapy.^{154,155,157,158}

Another emerging potential hemostatic agent is MTAD (Biopure, Tulsa/Dentsply), an irrigant and an antimicrobial agent introduced for removal of the smear layer during nonsurgical initial endodontic treatment and retreatment.¹⁵⁹ The solution is a mixture of tetracycline isomer (doxycycline), an acid (citric acid), and a detergent (Tween 80). The irrigant shows many desirable properties and may be a suitable replacement for ethylenediaminetetraacetic acid in conjunction with NaOCl. The solution shows an antimicrobial effect against some strains of *Enterococcus faecalis*, cleans the dentin–pulp tissue interface, and does not affect the flexural strength and modulus of elasticity of dentin.^{160–162} Initial trials with MTAD indicate favorable results when used in direct pulp capping and partial pulpotomy (Dr. Mahmoud Torabinejad, personal communication, 2007).

Direct Pulp Capping

TREATMENT RECOMMENDATIONS

Recommended steps for direct pulp capping with MTA using a two-visit format (Figure 5):

1. Following diagnosis, the tooth has been identified as having either reversible pulpitis or a normal healthy pulp. After profound local anesthesia, the tooth is isolated with a dental dam, further sealed with an agent such as Oraseal (Ultradent Products Inc., South Jordan, UT) or a comparable product if required, and disinfected with either chlorhexidine or NaOCl. Working under magnification is highly recommended. The undermined enamel is removed with a diamond or carbide bur, and soft debris is removed with a spoon excavator.
2. After the carious dentin is air-dried, a caries detector dye is applied for 10 seconds, and the tooth is washed and dried. Caries removal is completed with slow-speed number 4–2 carbide round burs and spoon excavators until minimal (light pink) or no profound stained dentin is evident. The caries detector is again reapplied on air-dried dentin for 10 seconds, and the process is repeated carefully (possibly five to seven applications) until no or only light pink staining is evident.
3. If a pulpal exposure occurs during the caries removal, the bleeding can be controlled by the placement of a cotton pellet moistened with 3 to 6% NaOCl for 20 to 60 seconds, and the staining and removal process is continued carefully around the exposure site until little or no staining is visible.
4. After caries removal, the exposure(s) should be hemorrhaging to some degree. A cotton pellet moistened with 3% to 6% NaOCl is placed directly against the exposure(s) for a contact time of 1 to 10 minutes. If hemostasis is not achieved within 10 minutes, the diagnosis is changed to irreversible pulpitis and more aggressive treatment is indicated. Conversely, if bleeding is not evident after pulpal exposure, the tissue is most likely necrotic, and partial or complete pulpotomy or pulpectomy must be initiated using a high-speed diamond round bur. If, during the course of caries removal, the entire pulpal roof or axial wall is removed, a pulpotomy must be considered.
5. The MTA is mixed according to the manufacturer's instructions (3:1, MTA:H₂O) and will have the consistency of wet sand. The cement is brought to the site in bulk with either a hand instrument (Glick or spoon excavator) or an MTA carrier gun. The MTA should be placed directly over the exposed pulp tissue and all surrounding dentin. The material is gently patted down with a small moist cotton pellet or a dry pellet if the mixture is too wet, and when in place, it should be at least 1.5 mm thick. If MTA is pushed inadvertently into the pulp chamber, it will not impact the outcome negatively. A circumferential region of dentin and enamel measuring approximately 1.5 mm should be cleared around the MTA with a small (2 mm) moist cotton pellet placed at the end of an explorer. This will allow an adequate area for the future bonded restoration to provide an effective seal.
6. A custom-fabricated, flat (1–2 mm), moist cotton pellet is then placed over the entire area of the MTA. If the area involves a Class II preparation exposure including the axial wall, then the moist pellet may require placement in two sections. If the patient is willing to return within 4 hours, a large moist cotton pellet can be placed and the patient instructed not to eat or chew during the interim since this may disrupt the MTA placement.
7. After the cotton pellet placement, a strong interim restoration is provided, preferably an unbonded composite material that will facilitate removal during the second visit (e.g., Photocore, Kuraray). Unless amalgam is the designated restorative material, interim restorations such as

Figure 5 Radiographic and clinical sequence showing direct pulp capping of a mandibular left molar in a 7-year-old female patient. **A**, Pretreatment radiograph showing caries and the presence of immature apices. **B**, Clinical presentation following dental dam placement. **C**, Caries detector stain applied after removal of undermined enamel. **D**, Two-millimeter pulp exposure after caries removal and 5.25% NaOCl hemostasis. **E**, MTA of 2.5 mm thickness placed over the entire pulpal roof. **F**, Radiograph of MTA with a moist cotton pellet and unbonded Photocore as the interim restoration. **G**, Bonded composite restoration placed over cured MTA 10 days after direct pulp capping. **H**, Eight-year 4-month recall radiograph showing completed root formation. The tooth has a normal response to CO₂ ice testing. **A**, **F**, and **G**, reproduced with permission from Schmitt D et al.¹⁰²

IRM or ZOE (that are eugenol based) will interfere with adhesion and bond strengths of adhesive resins and should be avoided.¹⁶³

8. The second appointment can be scheduled 5 to 10 days after MTA placement. Before attaining profound anesthesia, the patient is questioned about sensitivity, mastication comfort, or the presence of pain. The tooth is then cold-tested (CO₂ ice or Endo-Ice, Hygienic Corp., Akron, OH) to confirm continued normal vitality. After injection of a local anesthetic, the tooth is isolated as before. The interim material is removed with a high-speed diamond or carbide bur under water spray. The cotton pellet is removed and the imbedded cotton fibers removed with a spoon excavator or similar hand instrument. Working with magnification is strongly recommended. The MTA is checked to ensure proper curing, and a bonded composite restoration is placed following the manufacturer's recommendations.
9. After the permanent restoration is placed, the occlusion is checked and adjusted as required. The patient is then recalled at 6 weeks, and subjective symptomatology and cold testing are evaluated. If it appears that the procedure was successful, radiographic follow-up, cold testing, and subjective symptomatology can be evaluated at 6 and 12 months. The patient can then be evaluated on a yearly basis thereafter.

ONE-STEP PULP CAPPING

According to the one manufacturer of MTA (ProRoot MTA), pulp capping can be completed in one visit. In some situations, treatment of the immature permanent tooth can be difficult, especially in young patients with challenging medical or behavioral problems that may require treatment under sedation. When one step is indicated, the manufacturer of MTA recommends the following protocol:⁹⁸

1. Under a dental dam, a cavity preparation outline using high-speed burs under constant water cooling is completed.
2. If caries is present, excavate using a round bur in a handpiece at low speed or use hand instruments.
3. Rinse the cavity and exposure site(s) with 2.6% to 5% NaOCl. Heavy bleeding may be controlled with a cotton pellet moistened with sterile saline.
4. Prepare ProRoot MTA according to the listed instructions.

5. Using a small ball applicator or similar device, apply a small amount of the material over the exposure.
6. Remove excess moisture at the site with a moist cotton pellet.
7. Apply a small amount of Dyract Flow flowable compomer (Dentsply International, York, PA) (or an equivalent light-cured resin, glass ionomer liner) to cover the MTA and light-cure according to its instructions.
8. Etch the remaining cavity walls with 34% to 37% phosphoric acid gel for 15 seconds. Rinse thoroughly.
9. Dry the cavity gently, leaving the dentin moist but not wet. Apply Prime and Bond NT material or an equivalent bonding material. Cure according to its instructions.
10. Place TPH Spectrum (Dentsply/Caulk, Milford, DE) composite material or an equivalent composite resin to complete the restoration.
11. At the next appointment, assess the pulp vitality. Pulp vitality and status should be assessed clinically and radiographically every 3 to 6 months or as needed.

We recommend that caries removal be completed under magnification with the aid of a caries detector dye (step 2). Also, during MTA placement against the exposure site (step 5), a larger bulk of MTA should be placed that includes the majority of surrounding dentin at a thickness greater than 1.5 mm.

Final Restoration

The quality of the final restoration can be critical to the long-term maintenance of pulp vitality and sustained normal function of the pulp-capped or pulpotomized tooth. Pulp inflammation is directly associated with bacterial microleakage around restorations, and the frequency varies according to the material used.¹⁶⁴ In the absence of microleakage, the pulp will have the highest probability for wound repair and survival.¹⁶⁵⁻¹⁶⁷ It has been suggested that leaking restorations may be more harmful to pulp tissue than cavity preparations that are unfilled and left open.¹⁶⁸ The clinician must determine an appropriate restorative material for each case that provides the best likelihood of a predictable seal against microleakage and deliver it with a high level of skill. Adhesive restorative materials are technique sensitive, and clinicians must execute treatment protocols following the manufacturer's guidelines. Specific composite

materials should be matched with their respective and recommended bonding resins.¹⁶⁹

Restorative procedures for immature permanent teeth include full-coverage restorations, composite resins, and bonded or unbonded amalgam restorations. The more conservative the restorative treatment, preserving the remaining healthy tooth structure, the higher the probability of pulp survival.¹³⁸ The age of the patient, the size and depth of the cavity preparation, and the choice of restorative material are all factors affecting repair mechanisms within pulp tissue.¹⁷⁰ Amalgam has proven to be a reliable material, inexpensive and relatively simple to place. It has disadvantages, which include esthetic concerns and potential health risks for dental providers. Restorations can be associated with coronal infractions or cuspal fracture, particularly if cusps are not protected.¹⁷¹⁻¹⁷³ Amalgam may exhibit less microleakage if placed in conjunction with a bonding resin or resin-modified glass ionomer liners.^{164,174,175} Although retention rates of composite restorations are improving as technology advances,^{176,177} amalgam restorations remain a reliable, safe, and predictable long-term treatment option.¹⁷⁸⁻¹⁸²

Postoperative Follow-Up

Clinical recall and radiographic evaluation are the most accurate predictors for measuring survival rates in vital pulp therapy. Recall compliance is generally more challenging with successful asymptomatic cases than teeth that become irreversibly inflamed or progress to acute apical periodontitis after treatment. The importance of follow-ups after vital pulp therapy cannot be overstated since the occurrence of recurrent caries, restoration failure, poor oral hygiene, or other conditions may be present, requiring attention. Compliance rates for follow-up with child patients can be mediocre as some parents lack basic oral health knowledge and do not practice preventive care.^{183,184} The time sequence necessary for proper follow-up assessment is based on the common practice of the 6-month recall, usually related to the oral examination and oral prophylaxis and has recently come into question.¹⁸⁵ Optimal recall rates should be established individually, based on the patient's need, caries index, periodontal status, symptomatology, and the need for observation of craniofacial development in younger patients.¹⁸⁶

In an investigation in which direct pulp capping was completed with Ca(OH)₂, it was determined that 3 months was an adequate time period for a tentative diagnosis of survivability.¹³² The same study also showed that an observation period of 21 to 24 months

was sufficient to establish a prognosis for long-term pulp survival. When MTA is used in the two-visit protocol (described earlier in this chapter), the clinician has the opportunity to examine the treated tooth at 5 to 10 days. If the treatment appears successful at that appointment, the provider can confidently schedule the next follow-up at 6 weeks if possible and then at 6 and 12 months.¹¹⁹

In direct pulp capping and pulpotomy, with **immature permanent teeth**, the most reliable prognostic indicator for success is the radiographic confirmation of root-end closure (apexogenesis). Apexogenesis of the immature adult tooth is one of the key objectives in vital pulp therapy. The process encourages physiologic development and formation of the root end and should advance successfully in healthy patients at the same rate after the application of MTA, whether direct pulp capping or pulpotomy was performed.^{114,115,187,188}

In vital teeth, this natural succession of tooth development should follow a predictable pattern viewed chronologically and compared radiographically with contralateral teeth.¹⁸⁹ Following contralateral tooth development is an excellent way to observe the success of vital pulp therapy. In teeth that have suffered trauma, with necrotic pulps and periapical pathosis, teeth are treated to stimulate apical barrier formation (apexification). The time required to barrier formation can be variable, with times from 5 to 20 months.¹⁹⁰ Similarly, MTA, which has been shown to be a suitable replacement for Ca(OH)₂ in pulpotomy and direct pulp capping treatments, can be expected to provide apical maturation at comparable time periods.¹⁹¹ The human pulp and surrounding tissue have extraordinary regenerative capacity when a **microbe-free environment** is provided.^{169,192} MTA is the first of many new bioactive substances that will potentiate the ability of the dental pulp to heal, thereby retaining and maintaining its natural evolutionary function and purpose.

Acknowledgment

We wish to thank Dr. Rajneesh Roy for his contributions to this chapter.

CHAPTER 36

ENDODONTIC CONSIDERATIONS IN DENTAL TRAUMA

MARTIN TROPE

Traumatic injuries to the teeth result in damage to many dental and periradicular structures. Therefore, the management and consequences of these injuries are multifactorial, and knowledge of the interrelating healing patterns of these tissues is essential.

The focus of this chapter is the dental pulp and how damage to the dentinopulpal complex can contribute to complications after a traumatic injury and how correct diagnosis and treatment can result in favorable healing after an injury. More information on management of dental trauma can be obtained by going on the Web site of the International Association of Dental Traumatology: <<http://www.iadt-dentaltrauma.org>>.

Unique Aspects of Dental Trauma

Most dental trauma occurs in the 7- to 10-year-old age group owing to falls and accidents near home or school.^{1,2} It occurs primarily in the anterior region of the mouth, affecting the maxilla more than the mandible.³

Thus, in many cases after a dental traumatic injury, endodontic therapy is provided to caries-free, single-rooted, **young** permanent teeth. Therefore, maintenance of the tooth is particularly important in these young individuals. Luckily, the potential for a successful endodontic outcome is very good if timely and correct treatment is provided soon after the injury.

Crown Fractures

The primary aim from an endodontic point of view is to **maintain pulp vitality** after fractures involving the crowns of teeth.

Crown Infractures—“Incomplete fracture or crack of enamel without loss of tooth structure”⁴ and **Uncomplicated Crown Fractures**—“Fractures of the enamel only or enamel and dentin without pulp exposure”⁴ are injuries that have little danger of resulting in pulp necrosis. In fact, the biggest danger to the health of the pulp is through iatrogenic causes during the esthetic restoration of these teeth. Therefore, meticulous follow-up over a 5-year period is an important endodontic preventive measure in these cases. Endodontic intervention should be considered at any follow-up time when reactions to sensitivity tests change, apical periodontitis develops, the root appears to have stopped development, or the pulp is obliterating.

COMPLICATED CROWN FRACTURES

By definition, complicated crown fractures involve enamel, dentin, and pulp⁴ and occur in 0.9 to 13% of all dental injuries.⁵⁻⁷ A crown fracture involving the pulp, if left untreated, will always result in pulp necrosis.⁸ However, the manner and time sequence in which the pulp becomes necrotic allow a great deal of potential for successful intervention in maintaining pulp vitality. The first reaction after an injury is

Figure 1 Histologic appearance of the pulp within 24 hours of a traumatic exposure. The pulp proliferates over the exposed dentinal tubules. There is approximately 1.5 mm of inflamed pulp below the surface of the fracture.

hemorrhage and local inflammation. Subsequent inflammatory changes are usually proliferative but can be destructive. A proliferative reaction is favored in traumatic injuries since the fractured surface is usually flat, allowing salivary rinsing with little chance of impaction of contaminated debris. Therefore, unless impaction of contaminated debris is obvious, it is expected that within the first 24 hours after the injury, a proliferative response with inflammation will extend no more than 2 mm into the pulp (Figure 1).⁹⁻¹¹ In time, however, bacterial infection will result in local pulp necrosis and a slow apical spread of pulpal inflammation.

TREATMENT

Treatment options are (1) **vital pulp therapy** comprising pulp capping, partial pulpotomy, and full pulpotomy or (2) **pulpectomy**. The choice of treatment

depends on the stage of development of the tooth, time between the accident and treatment, concomitant periodontal injury, and the restorative treatment plan.

STAGE OF DEVELOPMENT OF THE TOOTH

Loss of vitality in an immature tooth can have catastrophic consequences. Root canal treatment on a tooth with a “blunderbuss” canal is time consuming and difficult. Of more importance, however, is the fact that necrosis of an immature tooth leaves it with thin dentinal walls that are susceptible to fracture both during and after an apexification procedure.¹² Therefore, every effort must be made to keep the pulp vital at least until the apex and cervical root have completed development. Pulpectomy in a mature tooth has a high success rate,¹³ but vital pulp therapy (rather than removal) on a mature tooth performed under optimal conditions can also be carried out successfully.^{14,15} Therefore, vital pulp therapy can be an option under certain circumstances, even though a pulpectomy is the treatment affording the most predictable success. **In an immature tooth, vital pulp therapy should be attempted, if at all feasible, because of the tremendous advantages of maintaining the vital pulp.**

TIME BETWEEN THE ACCIDENT AND TREATMENT

For 48 hours after a traumatic injury, the initial reaction of the pulp is proliferative, with a depth of no more than 2 mm of pulpal inflammation (see Figure 1). After 48 hours, chances of direct bacterial contamination of the pulp increase as the zone of inflammation progresses apically.¹⁶ Thus, with time, the chance of success in maintaining a healthy pulp decreases.

CONCOMITANT ATTACHMENT DAMAGE

A concomitant periodontal injury will compromise the nutritional supply of the pulp. This fact is particularly important in mature teeth, in which the chance of pulp survival is not as good as for immature teeth.^{17,18}

RESTORATIVE TREATMENT PLAN

In a mature tooth, pulpectomy is a viable treatment option, unlike an immature tooth, in which the benefits of maintaining vitality of the pulp are great. However, if performed under optimal conditions, vital pulp therapy after traumatic exposures can be

successful. Thus, if the restorative treatment plan is simple, and a composite resin restoration will suffice as the permanent restoration, this treatment option should be given serious consideration. If a more complex restoration is to be placed (eg, a crown), pulpectomy would be the more predictable treatment method.

Vital Pulp Therapy for Traumatic Dental Injuries

REQUIREMENTS FOR SUCCESS

Vital pulp therapy in traumatically injured teeth has a very high success rate if the following requirements are adhered to:

1. **Treatment of a healthy pulp** has been shown to be an essential requirement for successful therapy.^{19,20} Vital pulp therapy of the inflamed pulp, on the other hand, affords a lower success rate.^{19,20} Therefore, the optimal time for treatment is within the first 24 hours,

when pulp inflammation is superficial. As time increases between the time of injury and therapy, pulp removal must be extended apically to ensure that noninflamed pulp tissue has been reached.

2. A **bacteria-tight seal** is the most critical factor for successful treatment.²⁰ Challenge by bacteria during the healing phase will cause failure.²¹ On the other hand, if the exposed pulp is effectively sealed from bacterial access, successful healing of the pulp with a hard tissue barrier will occur, independent of the dressing placed on the pulp.²¹

3. A **proper pulp dressing** is important, and, presently, calcium hydroxide is the most common dressing used for vital pulp therapy. Its advantages are that it is antibacterial^{22,23} and will disinfect the superficial pulp. Pure calcium hydroxide (pH 12.5) will cause necrosis of about 1.5 mm of the pulp tissue^{24,25} involving the superficial layers of inflamed pulp if present (Figure 2). The toxicity of the calcium hydroxide appears to be neutralized as the deeper layers of pulp are affected, causing coagulative necrosis at the junction of the necrotic and vital pulp, resulting in only a mild irritation. This mild

Figure 2 Pulp necrosis (1.5 mm) as a result of the high pH of calcium hydroxide.

Figure 3 Hard tissue barrier developed after calcium hydroxide partial pulpotomy. Histologic appearance of replacement odontoblasts and a hard tissue barrier.

irritation will initiate an inflammatory response and in the absence of bacteria²⁴ will heal with a hard tissue barrier (Figure 3).^{25,26} Hard-setting calcium hydroxide does not cause necrosis to the superficial layers of pulp but has been shown to initiate healing with a hard tissue barrier as well.^{27,28} A major disadvantage of calcium hydroxide is that it does not seal the fractured surface. Therefore, an additional material must be used to ensure that the pulp is not challenged by bacteria, particularly during the critical healing phase.

Other materials, such as zinc oxide–eugenol,²⁰ tricalcium phosphate,²⁹ and composite resin,³⁰ have been proposed as materials for vital pulp therapy. They have not afforded the predictability of calcium hydroxide used in conjunction with a well-sealed coronal restoration.

Mineral trioxide aggregate (MTA) has been reported to show promise as a pulp capping agent.³¹

It has a high pH, similar to calcium hydroxide, when unset³² and after setting will create an excellent bacteria-tight seal.³³ It also sets hard enough to act as a base for a final restoration.³⁴ MTA has not as yet gained popularity as a pulp capping agent, probably because of its need for a moist environment for 6 hours to set. Thus, what is normally a one-step procedure for other medicaments becomes a two-step procedure with MTA since a wet cotton pellet should be placed over it until it is set, and then later the permanent restoration can be fabricated.

Treatment Methods

PULP CAPPING

Pulp capping implies placing a dressing directly onto the pulp exposure. As indicated by the success rate of this procedure (80%) compared with that of partial pulpotomy (95%),³⁴ it appears that a superficial pulp cap should not be considered after traumatic pulp exposures. The lower success rate is not difficult to understand since superficial inflammation develops soon after the traumatic exposure. Thus, if the treatment is at the superficial level, a number of inflamed (rather than healthy) pulps will be treated, lowering the potential for success. In addition, a bacteria-tight coronal seal is much more difficult to achieve in superficial pulp capping since there is no cavity depth to create this bacteria-tight seal, as there is with a partial pulpotomy.

PARTIAL PULPOTOMY

Partial pulpotomy implies the removal of coronal pulp tissue to the level of healthy pulp tissue. In traumatic injuries, this level can be accurately determined owing to the knowledge of the reaction of the pulp after a traumatic injury. This procedure is commonly called the “Cvek pulpotomy.”

TECHNIQUE

Anesthesia, rubber dam placement, and superficial disinfection are performed. A 1 to 2 mm deep cavity is prepared into the pulp using a sterile diamond bur of appropriate size with copious water coolant

(Figure 4).³⁵ A slow-speed bur or spoon excavator should be avoided unless cooling of the high-speed bur is not possible. If bleeding is excessive, the pulp is amputated deeper until only moderate hemorrhage is seen. Excess blood is carefully removed by rinsing with sterile saline or anesthetic solution and dried

with a sterile cotton pellet. Care must be taken not to allow a blood clot to develop as this will compromise the prognosis.^{26,34} If the pulp is of sufficient size to allow 1 to 2 mm of additional pulp necrosis, a thin layer of pure calcium hydroxide is mixed with sterile saline or anesthetic solution and carefully placed. If

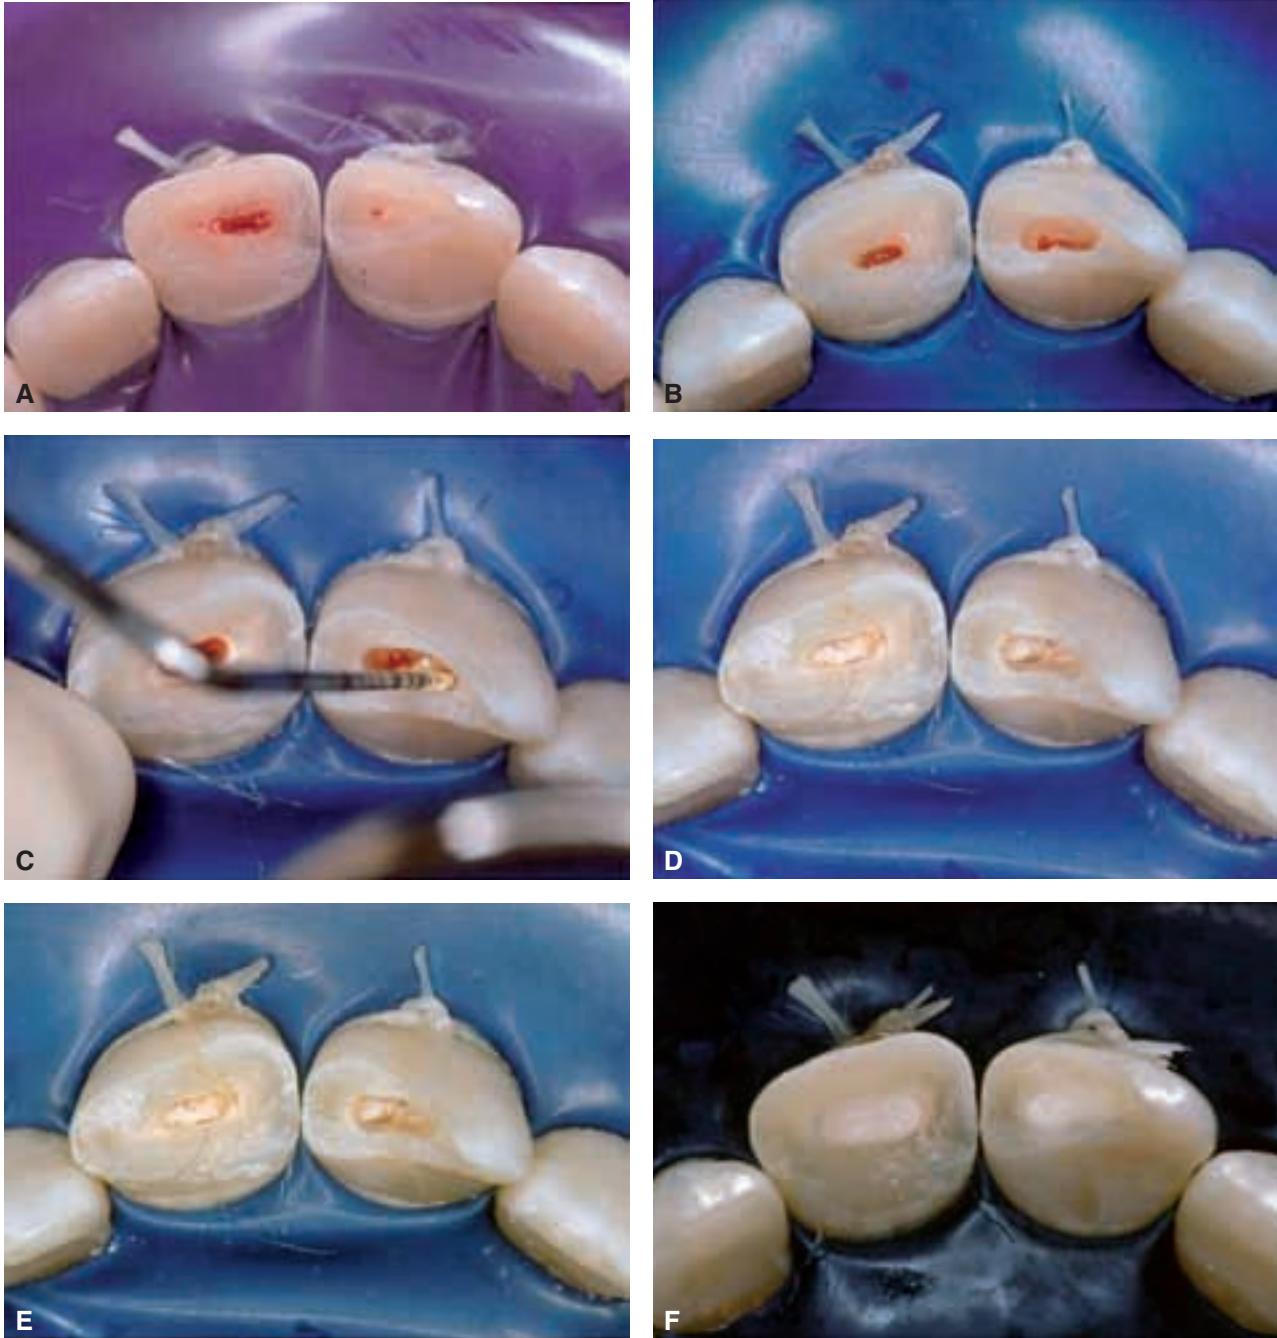

Figure 4 (Continued)

Figure 4 Cvek partial pulpotomy. **A**, The fractured teeth are cleaned and disinfected and a rubber dam is placed. **B**, Cavities are prepared at high speed with a round diamond bur that includes 1 to 2 mm of superficial pulp tissue. **C**, Calcium hydroxide is placed on a plugger and **D**, placed on the soft tissue of the pulp (only). **E**, Calcium hydroxide is removed from the walls of the cavities. **F**, The cavity preparations are filled with glass ionomer cement. **G**, The exposed dentin is etched, and **H**, the dentin is covered with composite resin. **I**, The radiograph taken 6 months later shows the formation of hard tissue barriers in both teeth. Courtesy of Dr. Alessandra Ritter.

the pulp size does not permit additional loss of pulp tissue, a commercial hard-setting calcium hydroxide can be used.³⁶ The prepared cavity is filled with a material with the best chance of a bacteria-tight seal (zinc oxide–eugenol or glass ionomer cement) to a level flush with the fractured surface. The material in the pulpal cavity, and all exposed dentinal tubules are covered with hard-setting calcium hydroxide. The enamel is then etched and restored with bonded composite resin, as in pulp capping. The use of MTA for

pulp capping and pulpotomies is described in Chapter 35, “Vital Pulp Therapy.”

Follow-up places the emphasis on maintenance of positive sensitivity tests and radiographic evidence of continued root development. Partial pulpotomy affords many advantages over pulp capping. Superficial inflamed pulp is removed in the preparation of the pulpal cavity. Calcium hydroxide disinfects dentin and pulp and removes additional pulpal inflammatory tissue. Most importantly, space is provided

for a material that will provide a bacteria-tight seal to allow pulpal healing with hard tissue development under optimal conditions. Additionally, coronal pulp tissue remains that allows sensitivity testing to be carried out at the follow-up visits. The prognosis is excellent (94–96%).^{34,37}

FULL PULPOTOMY

This procedure involves removal of the entire coronal pulp to the level of root orifices. This level of pulp amputation is chosen arbitrarily because of its anatomic convenience. Therefore, since the inflamed pulp sometimes extends past the canal orifices into the root pulp, many “mistakes” are made, resulting in treatment of an inflamed rather than a noninflamed pulp. This procedure is indicated when it is predicted that the pulp is inflamed to deeper levels of the coronal pulp. Traumatic exposures after 72 hours and a carious exposure are two examples in which this type of treatment may be indicated. Because of the fairly good chance that the dressing will be placed on an inflamed pulp, full pulpotomy is contraindicated in mature teeth. However, the benefits outweigh the risks for this treatment in immature teeth with incompletely formed apices and thin dentinal walls.

TECHNIQUE

Anesthesia, rubber dam placement, and superficial disinfection are done as described with pulp capping and partial pulpotomy. The coronal pulp is removed to the level of the root orifices. Calcium hydroxide dressing, a bacteria-tight seal, and coronal restoration are a part of the technique as described with partial pulpotomy. The follow-up is done as described with pulp capping and partial pulpotomy. A major disadvantage of this treatment method is that sensitivity testing is not possible owing to the loss of coronal pulp. Therefore, radiographic follow-up is extremely important to monitor for continuation of root formation and signs of apical periodontitis.

Since the cervical pulpotomy is performed on pulps that are expected to have deep inflammation, and the site of pulp amputation is arbitrary, more “mistakes” are made, leading to treatment of the inflamed pulp. Consequently, prognosis in the range of 75% is poorer than partial pulpotomy.³⁸ Because of the inability to evaluate pulp status after a full pulpotomy, some authors have recommended routine pulpectomy after the roots have fully formed (Figure 5). This philosophy is based on the fact that the pulpectomy procedure has a success rate in the range of 95%, whereas if apical periodontitis develops following pulpotomy, the prognosis of root canal treatment drops significantly to about 80%.^{13,39}

Time: 0 6m 18m 18m

Figure 5 Successful pulpotomy followed by a pulpectomy at 18 months. Courtesy of Dr. Leif Tronstad.

PULPECTOMY

Pulpectomy implies removal of the entire pulp to the level of the apical foramen. The indications are for complicated crown fracture of mature teeth (if conditions are not ideal for vital pulp therapy). This procedure is not different from root canal treatment of a vital, nontraumatized tooth.

Treatment of Nonvital Pulp

IMMATURE TOOTH: APEXIFICATION

Apexification is indicated for teeth with open apices and thin dentinal walls in which standard instrumentation techniques cannot create an apical stop to facilitate effective root canal filling.

BIOLOGIC CONSEQUENCES

A nonvital immature tooth presents a number of difficulties for adequate endodontic therapy. The canal is (often) wider apically than coronally, necessitating the use of a filling material that conforms to the shape of the apical part of the canal. Since the apex is extremely wide, no barrier exists to stop this material from moving into and traumatizing the apical periodontal tissues. Also, the lack of an apical stop and extrusion of material might result in a canal that is susceptible to leakage. An additional problem in immature teeth with thin dentinal walls is their susceptibility to fracture both during and after treatment. These problems are overcome by stimulating the formation of a hard tissue barrier to allow for optimal filling of the canal and reinforcing the weakened root against fracture both during and after apexification.^{12,40}

TECHNIQUE

Since in the vast majority of nonvital teeth are infected,^{41,42} the first phase of treatment is to disinfect the root canal system to ensure periapical healing.^{16,22} The canal length is estimated with a parallel preoperative radiograph and confirmed radiographically with the first endodontic instrument. Preparation of the canal (owing to the thin dentinal walls) is performed **very lightly** and with **copious** irrigation using 0.5% sodium hypochlorite.^{43,44} A lower strength and increased volume of NaOCl are used because of the increased danger of extruding sodium hypochlorite through the open apex in immature teeth. An irrigation needle that can passively reach close to the apical level is used in disinfecting the canals. The canal is dried with paper points, and a creamy mix of calcium hydroxide is spun into the canal with a lentulo-spiral. The calcium hydroxide is left in the canal for at least 1 week to be effective in accomplishing disinfection.²³ The continuation of treatment can take place any time after 1 week. Further treatment should not be delayed more than 1 month since the calcium hydroxide could be washed out by tissue fluids through the open apex, leaving the canal susceptible to reinfection.

Hard Tissue Apical Barrier

TRADITIONAL METHOD

The formation of a hard tissue barrier at the apex requires an environment similar to that required for hard tissue formation in vital pulp therapy, that is, a mild inflammatory stimulus, to initiate healing and a bacteria-free environment to ensure that inflammation is not progressive. As with vital pulp therapy, calcium hydroxide is used for this procedure.⁴⁵⁻⁴⁷ Pure calcium hydroxide powder is mixed with sterile saline (or anesthetic solution) to a thick (powdery) consistency. Ready-mixed commercial calcium hydroxide can also be used. The calcium hydroxide is packed against the apical soft tissue with a plugger or thick point to initiate hard tissue formation. This step is followed by backfilling with calcium hydroxide to completely fill the canal, thus ensuring a bacteria-free canal with little chance of re-infection during the 6 to 18 months required for hard tissue formation at the apex. The calcium hydroxide is meticulously removed from the access cavity to the level of the root orifices, and a well-sealing temporary filling is placed in the access cavity. A radiograph is taken, and the canal should appear to have become calcified, indicating that the entire canal has been filled with the cal-

cium hydroxide. Because calcium hydroxide washout is evaluated by its relative radiodensity in the canal, it is prudent to use a calcium hydroxide mixture without the addition of a specific material to enhance the radiopaque property of the medicament such as barium sulfate. These additives do not wash out as readily as calcium hydroxide, so if they are present in the canal, evaluation of washout is not possible.

At 3-month intervals, a radiograph is taken to evaluate whether a hard tissue barrier has formed and if the calcium hydroxide has washed out of the canal. This is assessed to have occurred if the canal can again be seen radiographically. If calcium hydroxide washout is seen, it is replaced as before. If no washout is evident, it can be left intact for another 3 months. Excessive calcium hydroxide dressing changes should be avoided if at all possible since the initial toxicity of the material is thought to delay healing.⁴⁸

When completion of a hard tissue barrier is suspected, the calcium hydroxide should be washed out of the canal with sodium hypochlorite and a radiograph taken to evaluate the radiodensity of the apical stop. A file that can easily reach the apex can be used to gently probe for a stop at the apex. When a hard tissue barrier is indicated radiographically and can be probed with an instrument, the canal is ready for filling (Figure 6).

MTA BARRIER

The creation of a physiologic hard tissue barrier using calcium hydroxide, although quite predictable, takes anywhere from 3 to 18 months. The disadvantage of this long time period is that the patient is

Figure 6 Successful apexification. The patient presented with an acute abscess. The canal was disinfected, and the wide apical lumen was closed with a long-term calcium hydroxide application. When a barrier was felt, the canal was filled with a permanent root filling.

required to present for treatment multiple times; also, the tooth may fracture during treatment, before the thin weak roots can be strengthened. In addition, one study has indicated that long-term treatment with calcium hydroxide may weaken the dentin of the roots and make them even more susceptible to fracture.⁴⁹

MTA has been used to create a hard tissue barrier quickly after the disinfection of the canal. Calcium sulfate can be pushed through the apex to provide a resorbable extraradicular barrier against which to pack the MTA. The MTA is mixed and placed into the apical 3 to 4 mm of the canal in a manner similar to the placement of calcium hydroxide. A wet cotton pellet is placed against the MTA and left for at least 6 hours, and then the entire canal is filled with a root filling material. The filling can also be placed immediately since the tissue fluids of the open apex will probably provide enough moisture to ensure that the MTA will set sufficiently. The cervical canal is then reinforced with composite resin to below the marginal bone level as described below.

A number of case reports have been published using this MTA apical barrier technique,^{50,51} and it has steadily gained popularity with clinicians. Presently, no prospective long-term outcome study is available comparing its success rate with the traditional calcium hydroxide technique.

FILLING OF THE ROOT CANAL

Since the apical diameter is larger than the coronal diameter in most of these canals, a softened filling technique is indicated. Care must be taken to avoid excessive lateral force during filling owing to the thin root walls. If the hard tissue barrier was “produced” by long-term calcium hydroxide therapy, it consists of irregularly arranged layers of coagulated soft tissue, calcified tissue, and cementum-like tissue. Included also are islands of soft connective tissue, giving the barrier a “Swiss cheese” consistency.^{52,53} Because of the irregular nature of the barrier, it is not unusual for cement or softened filling material to be extruded into the apical tissues (see Figure 6). Formation of the hard tissue barrier may also be some distance short of the radiographic apex. This is because it forms wherever the calcium hydroxide comes in contact with vital tissue. In teeth with wide open apices, vital tissue can survive and proliferate from the periodontal ligament a few millimeters into the root canal. The root canal filling should be completed to the level of the hard tissue barrier and not forced toward the radiographic apex.

REINFORCEMENT OF THE THIN DENTINAL WALLS

The apexification procedure has become a predictably successful procedure. However, the thin dentinal walls present a clinical problem. Should secondary injuries occur, teeth with thin dentinal walls are more susceptible to fractures, rendering them nonrestorable.^{54,55} It has been reported that approximately 30% of these teeth will fracture during or after endodontic treatment.⁵⁶ Consequently, some clinicians have questioned the advisability of the apexification procedure and have opted for more radical treatment procedures, including extraction followed by extensive restorative procedures such as dental implants. Recent studies have shown that intracoronally bonded restorations can internally strengthen endodontically treated teeth and increase their resistance to fracture.^{12,57} Thus, after root filling, the material should be removed to below the marginal bone level and a bonded resin filling placed.

Routine follow-up evaluation should be performed to monitor the outcome. Restorative procedures should be assessed to ensure that they do not promote root fractures. Periapical healing and the formation of a hard tissue barrier occur predictably with long-term calcium hydroxide treatment (79–96%).^{47,56} However, long-term survival is jeopardized by the fracture potential of the thin dentinal walls. It is expected that internal strengthening of teeth as described above will increase their long-term survivability.

Pulp Revascularization

Regeneration of a necrotic pulp has been considered possible only after avulsion of an immature permanent tooth. The advantages of pulp revascularization are the possibility of further root development, reinforcement of dentinal walls by deposition of hard tissue, and thus strengthening the root against fracture. After replantation of an avulsed immature tooth, a unique set of circumstances exists that allows regeneration to take place. The young tooth has an open apex and is short, which allows new tissue to grow into the pulp space relatively quickly. The pulp is necrotic but usually not degenerated and infected, so it will act as a matrix into which the new tissue can grow. It has been experimentally shown that the apical part of a pulp may remain vital and after replantation proliferate coronally, replacing the necrotized portion of the pulp.^{58–60} In addition, the fact that, in most cases, the crown of the tooth is intact and caries free ensures that bacterial penetration into the pulp space

through cracks⁶¹ and defects will be a slow process. Thus, the race between the new tissue and infection of the pulp space favors the new tissue.

Regeneration of pulp tissue in a necrotic infected tooth with apical periodontitis has been thought until now to be impossible. However, if it were possible to create a similar environment as described above for the avulsed tooth, regeneration should occur. Thus, if the canal is effectively disinfected, a matrix into which new tissue could grow is provided, and the coronal access is effectively sealed, regeneration should occur as in an avulsed immature tooth. A report by Banchs and Trope reproduced results in cases reported by others that indicate that it may be possible to replicate the unique circumstances of an avulsed tooth so as to revascularize the pulp in infected necrotic immature roots⁶² (Figure 7). The case presented describes the treatment of a maxillary central incisor with radiographic and clinical signs of apical periodontitis after a failed partial pulpotomy. The canal was disinfected without mechanical instrumentation but with copious irrigation with 5.25% sodium hypochlorite and the use of a mixture of antibiotics.⁶² A blood clot was produced to the level of the cementoenamel junction to provide a matrix for the ingrowth of new tissue, followed by a deep coronal restoration to provide a bacteria-tight seal. Clinical and radiographic evidence of healing was seen after 6 months;

Figure 7 A, Immature tooth with a necrotic infected canal with apical periodontitis. The canal is disinfected with copious irrigation with sodium hypochlorite and triantibiotic paste. After 4 weeks, the antibiotic is removed and a blood clot is created in the canal space. The access is filled with a mineral trioxide aggregate (MTA) base and bonded resin above it. **B**, At 7 months, the patient is asymptomatic and the apex shows some signs of healing of the apical periodontitis and closure of the apex. **C**, At 12 months, apical healing is obvious and root wall thickening has occurred, indicating that the root canal has been revascularized with vital tissue. Courtesy of Dr. Blayne Thibodeau.

the large radiolucency had disappeared, and at the 12-month follow-up, it was obvious that the root walls were thickening. Recent studies have confirmed the potent antibacterial properties of the triantibiotic paste used in this case,^{63,64} and studies are under way to find a synthetic matrix that will act as a more predictable scaffold for new ingrowth of tissue than the blood clot used in these previous cases. The procedure described in this section can be attempted in most cases, and if after 3 months no signs of regeneration are present, the more traditional treatment methods should be initiated.

MATURE TEETH

Traumatized mature teeth are routinely treated endodontically in the same manner as non-traumatized teeth.

Crown-Root Fractures

These fractures are first treated periodontally to ensure that a good margin for restoration is possible. If the tooth can be maintained from a periodontal point of view, the pulp is treated as a crown fracture.

Horizontal Root Fractures

This injury implies fracture of the cementum, dentin, and pulp. They are relatively infrequent injuries, occurring in less than 3% of all dental injuries.⁶⁵ Incompletely formed roots with vital pulps rarely fracture horizontally.⁶⁶ When a root fractures horizontally, the coronal segment is displaced to a varying degree, but, generally, the apical segment is not displaced. Because the apical pulpal circulation is not disrupted, pulp necrosis in the apical segment is extremely rare. Pulp necrosis develops in the coronal segment owing to its displacement but occurs in only about 25% of cases.⁶⁷ The clinical presentation is similar to that of luxation injuries. The extent of displacement of the coronal segment is usually indicative of the location of the fracture and can vary from none, simulating a concussion injury (apical fracture), to severe, simulating extrusive luxation (cervical fracture). Radiographic examination for root fractures is extremely important. Since root fractures are usually oblique (facial to palatal), one periapical radiograph can easily miss its presence. It is imperative to take at least three angled radiographs (45, 90, and 110 degrees) so that at least at one angulation the x-ray beam will pass directly through the fracture line to make it visible on the radiograph (Figure 8).

Figure 8 Radiographs showing the importance of an angled x-ray beam for diagnosis of root fracture. Three different vertical angled radiographs produce different radiographic images.

TREATMENT

Emergency treatment involves repositioning of the segments in as close proximity as possible and splinting to adjacent teeth for 2 to 4 weeks with a functional splint.⁶⁸ This splinting protocol has recently changed from the 2 to 4 months of rigid splinting that had been recommended for many years.⁶⁹ If a long time has elapsed between the injury and treatment, it will likely not be possible to reposition the segments close to their original position, compromising the long-term prognosis of the tooth.

Treatment of Root Fracture Complications

CORONAL ROOT FRACTURES

Historically, it had been thought that fractures in the cervical segment had a poor prognosis, and extraction of the coronal segment was recommended. Research does not support such treatment, and, in fact, if the coronal segment is below the attachment level and adequately splinted, the chances of healing do not differ from those of midroot or apical fractures.⁶⁷

MIDROOT AND APICAL ROOT FRACTURES

Pulp necrosis occurs in 25% of root fractures.^{67,70} In the vast majority of cases, the necrosis occurs in the coronal segment only with the apical segment remaining vital. Therefore, endodontic treatment is indicated in the coronal root segment only unless a periapical lesion is seen in the apical segment. In most cases, the canal lumen is wide at the apical extent of the coronal segment, so long-term calcium hydroxide treatment or an MTA apical plug is indicated. The coronal segment is root-filled after a hard tissue barrier has formed apically in the coronal segment and periapical healing has taken place (Figure 9). If MTA is used, the root filling will be placed before healing is seen, making follow-up visits essential in these cases.

In rare cases, when both the coronal and apical pulp areas are necrotic, treatment is more complicated. Endodontic treatment through the fracture is extremely difficult and should be avoided. Endodontic manipulations, medicaments, and filling materials all have a detrimental effect on healing of the fracture site. In more apical root fractures, necrotic apical segments can be surgically removed. This is a viable

Figure 9 The coronal segment (only) is root-filled after a hard tissue barrier has formed at the most apical part of the coronal segment.

treatment if the remaining root is long enough to provide adequate periodontal support. Removal of the apical segment in midroot fractures leaves the coronal segment with a compromised attachment, and the crown to root ratio must be assessed before the decision to maintain the tooth is made.

After the splinting period is completed, follow-up is conducted at the same intervals as all dental traumatic injuries: at 3, 6, and 12 months and yearly thereafter.

FACTORS INFLUENCING REPAIR

1. The degree of dislocation and mobility of the coronal fragment are extremely important in determining outcome.⁷¹⁻⁷³ Increased dislocation and coronal fragment mobility result in a decreased prognosis.
2. Immature teeth are seldom involved in root fractures, but when they are, the prognosis is good.^{72,74}
3. Quality of treatment: prognosis increases with early treatment, close reduction of the root segments, and semi-rigid splinting for 2 to 4 weeks.⁶⁸

Complications are as follows: (1) pulp necrosis that can be treated successfully^{67,70} by treating the coronal segment with adequate disinfection and long-term calcium hydroxide or MTA and filling when a hard tissue barrier has formed; (2) root canal obliteration

Figure 10 Examples of root canal obliteration in root-fractured teeth. It is common for the segments that maintain vitality to obliterate.

is not uncommon if the root segment (coronal or apical) remains vital (Figure 10).

ENDODONTIC ESSENTIALS

If the coronal segment is reduced quickly and a functional splint is placed for 2 to 4 weeks, pulp necrosis is remarkably low. It will occur only 25% of the time, and in the vast majority of cases, the necrosis will occur only in the coronal segment. Root canal obliteration of both segments is very common. When necrosis does occur, disinfection of the coronal segment only should be initiated, followed by initiation of a physiologic barrier with long-term calcium hydroxide or a physical barrier with MTA. Root canal obliteration is usually not treated endodontically.

Luxation Injuries

DEFINITIONS

1. **Concussion** implies no displacement, normal mobility, sensitivity to percussion.
2. **Subluxation** implies sensitivity to percussion, increased mobility, no displacement.
3. **Lateral luxation** implies displacement labially, lingually, distally, or incisally.

4. **Extrusive** luxation implies displacement in a coronal direction.
5. **Intrusive** luxation implies displacement apically into the alveolus.

Definitions 1 through 5 describe injuries of increasing magnitude in terms of the intensity of the injury and subsequent sequelae.

Luxation injuries result in damage to the attachment apparatus (periodontal ligament and cemental layer), the severity of which is dependent on the type of injury sustained (concussion least, intrusion most). The apical neurovascular supply to the pulp is also affected to varying degrees, resulting in altered or total loss of pulp vitality in the tooth. If the luxation injury is mild, the inflammatory response to the external root surface will be small and the pulp will maintain vitality. Inflammation owing to the trauma will thus be self-limiting, and cemental (favorable) healing will result.

If, on the other hand, the luxation injury is severe, the damage to the external root surface may be so diffuse that healing with new cementum alone may not be possible. If bone attaches directly to the root (ankylosis), the root will eventually be replaced by bone through physiologic resorption and apposition of the bone (osseous replacement). In addition and of special interest to the endodontist, with a severe luxation injury, the neurovasculature tissues of the pulp may be severed,

resulting in a necrotic pulp. If this necrotic pulp becomes infected, the microbial toxins will pass through the tubules and the damaged cemental covering of the root, resulting in potentially catastrophic periradicular inflammation with bone and root resorption.

There are two types of trauma-related resorption in which the pulp plays an essential role:

1. In **external** inflammatory root resorption, the **necrotic, infected pulp** provides the stimulus for periodontal inflammation. If the cementum has been damaged and the intermediate cementum penetrated, as when the tooth undergoes a severe traumatic injury, the inflammatory stimulators in the pulp space are able to diffuse through the dentinal tubules and stimulate an inflammatory response over large areas of the periodontal ligament. Owing to the lack of cemental protection, periodontal inflammation will include root resorption and the expected bone resorption.
2. In **internal** inflammatory root resorption, the inflamed pulp is the tissue involved in resorbing the root structure. The pathogenesis of internal root resorption is not completely understood. It is believed that coronal necrotic infected pulp provides a stimulus for pulpal inflammation in the more apical parts of the pulp. If in "rare" cases, the inflamed pulp is adjacent to a root surface that has lost its predentin protection, internal root resorption will result. Thus, both the necrotic infected pulp and the inflamed pulp contribute to this type of root resorption.

Consequences of Apical Neurovascular Damage

PULP CANAL OBLITERATION

Pulp canal obliteration is common after luxation injuries, if not severe enough to sever the neurovascular supply apically. The frequency of pulp canal obliteration appears inversely proportional to that of pulp necrosis. The exact mechanism of pulp canal obliteration is not known. It is theorized that the sympathetic or parasympathetic control of blood flow to odontoblasts is altered, resulting in uncontrolled reparative dentin formation.^{66,75} Another theory is that hemorrhage and blood clot formation in the pulp after injury are a nidus for subsequent calcification if the pulp remains vital.^{66,75} Pulp canal obliteration can usually be diagnosed within the first year after injury⁷⁶ and was found to be more frequent in teeth with open

apices (>0.7 mm radiographically), in teeth with extrusive and lateral luxation injuries, and in teeth that have been rigidly splinted.⁷⁶

PULP NECROSIS

The factors most important for the development of pulp necrosis are the type of injury (concussion least, intrusion most) and the stage of root development (mature apex > immature apex).⁷⁷ Pulp necrosis can lead to infection of the root canal system, with external inflammatory root resorption as the consequence. To develop pulp space infection, the pulp must first become necrotic. In trauma, necrosis is usually due to displacement of the tooth, resulting in severing of the apical blood vessels. In mature teeth, pulp regeneration cannot occur, and usually by 3 weeks, the necrotic pulp will become infected. For details of the typical bacterial contents of a traumatized necrotic pulp, see Chapter 7, "Microbiology of Endodontic Disease." Because serious injury is required for pulp necrosis, it is usual that areas of cemental covering of the root are also affected, resulting in the loss of its protective (insulating) quality. Now microbial toxins can pass through the dentinal tubules and stimulate an inflammatory response in the corresponding periodontal ligament. The result is resorption of the root and bone. The periodontal infiltrate consists of granulation tissue with lymphocytes, plasma cells, and polymorphonuclear leukocytes. Multinucleated giant cells resorb the denuded root surface, and this continues until the stimulus (pulp space bacteria) is removed (Figure 11).⁷⁸ Radiographically, the resorption is

Figure 11 Histologic appearance of multinucleated osteoclasts (denticloasts) resorbing the dentin of the root.

Figure 12 Inflammatory root resorption owing to pulp space infection. Note the radiolucencies in the root **and** surrounding bone. Courtesy of Dr. Fred Barnett.

observed as progressive radiolucent areas of the root and adjacent bone (Figure 12).

TREATMENT

The attachment damage owing to the traumatic injury is often the focus of an emergency visit that, unfortunately, rarely involves the endodontist. The clinician's attention to pulp space infection should ideally be within 7 to 10 days after the injury.^{79,80} Root canal therapy either removes the necrotic pulp as a nidus for microbes or removes the stimulus (microbes already present) to the periapical inflammation. Without microbial stimulation, resorption will not occur or will heal.³³⁻³⁵ In most cases, a new cemental attachment will form, but if a large area of root is affected,

osseous replacement (ankylosis) can result by the mechanism already described. Treatment principles include prevention of pulp space infection or elimination of the bacteria if they are present in the pulp space.

1. Prevention of pulp space infection

- a) **Reestablish the vitality of the pulp.** If the pulp stays vital, the canal will be free of bacteria, and external inflammatory root resorption will not occur. In severe injuries in which vitality has been lost, it is possible under some circumstances to promote revascularization of the pulp. Revascularization is possible in young teeth with incompletely formed apices if the teeth are replaced in their original position within 60 minutes of the injury.^{81,82} However, even under the best conditions, revascularization will fail to occur on many occasions. Thus, a diagnostic dilemma results. If the pulp revascularizes, external root resorption will not occur and the root will continue to develop and strengthen. However, if the pulp becomes necrotic and infected, the subsequent external inflammatory root resorption that develops could result in the loss of the tooth in a very short time. At present, the diagnostic tools available cannot detect a vital pulp in this situation before approximately 6 months after successful revascularization. This period of time is obviously unacceptable since by that time, the teeth not revascularized could be lost to the resorption process. Recently, the laser Doppler flowmeter has been shown to be an excellent diagnostic tool for the detection of revascularization in immature teeth (see Chapter 14C, "Laser Doppler Flowmetry"). These devices appear to accurately detect the presence of vital tissue in the pulp space by 4 weeks after the traumatic injury.⁸³
- b) **Prevent root canal infection by root canal treatment at 7 to 10 days.** In teeth with closed apices, revascularization cannot occur. These teeth should be endodontically treated within 7 to 10 days of the injury before the ischemically necrosed pulp becomes infected.^{79,80} This is also a convenient time because this is the time period in which the functional splint is removed and chemotherapeutic medicaments to limit the initial inflammatory response are stopped.⁷⁹ From a theoretical point of view, the teeth treated at this time can be considered equivalent to the treatment of a tooth with a vital pulp. Therefore, the endodontic treatment could be completed in one visit. However, efficient

treatment is extremely difficult so soon after a serious traumatic injury, and it is beneficial to start the endodontic treatment with pulpectomy and canal preparation followed by an intracanal dressing with a creamy mix of calcium hydroxide.^{79,80} The practitioner can now fill the canal at his or her convenience, after periodontal healing of the injury is complete, approximately 1 month after the instrumentation visit. There appears to be no necessity for long-term calcium hydroxide treatment in cases in which the endodontic treatment is started within 10 days of the injury. Notwithstanding, in a compliant patient, the calcium hydroxide can be applied for a long term (up to 6 months) to ensure periodontal health prior to final root canal filling.⁸⁰

2. Elimination of pulp space infection

When root canal treatment is initiated later than 10 days after the accident, or if active external inflammatory resorption is observed, the preferred antibacterial protocol consists of microbial control followed by a long-term dressing with densely packed calcium hydroxide.⁸⁰ Calcium hydroxide can affect an alkaline pH in the surrounding dentinal tubules, kill bacteria, and neutralize endotoxin, a potent inflammatory stimulator.

The first visit consists of the microbial control phase with instrumentation of the canal and placement with a lentulo-spiral of a creamy mix of calcium hydroxide as an intracanal antibacterial agent. The patient is seen in approximately 1 month, at which time, the canal is filled with a dense mix of calcium hydroxide. Once filled, the canal should appear radiographically to be calcified since the radiodensity of calcium hydroxide in the canal is usually similar to that of the surrounding dentin (Figure 13). A radiograph is then taken at 3-month intervals. At each visit, the tooth is tested for symptoms of periodontitis. In addition, healing of the resorptive process and the presence or absence of the calcium hydroxide (ie, calcium hydroxide washout) are assessed. Since the root surface is so radiodense as to make the assessment of healing difficult, the adjacent bone healing is assessed. If the adjacent bone has healed, it is assumed that the resorptive process has stopped in the root as well, and the canal can be permanently root-filled (Figure 14). If it is felt that additional healing would be beneficial before root filling, the need for replacing the calcium hydroxide in the canal is assessed. If the canal

Figure 13 Root canal that “disappears” after placement of a thick mix of pure calcium hydroxide. Courtesy of Dr. Fred Barnett.

still appears calcified radiographically, there is no need to replace the calcium hydroxide. If, on the other hand, the canal has regained its lucent appearance, the calcium hydroxide should be repacked and reassessed in another 3 months.

Treatment of Established External Root Resorption in a Young Patient

Arresting external inflammatory root resorption owing to pulp space infection is achieved by disinfecting the pulp space. This is particularly difficult after a luxation injury since the cemental covering is also damaged. This results in the microbes and their by-products moving deep into the dentinal tubules to stimulate and maintain the inflammation in the surrounding periapical tissues.

Recently, a triantibiotic paste introduced by Hos-hino et al.⁸⁴ has been used in the revascularization

Figure 14 The root canal is filled when the adjacent bone has healed, indicating that root resorption has stopped. **Left**, Active root resorption with lucencies in the root and bone. **Middle**, After long-term calcium hydroxide treatment, the adjacent bone has healed. **Right**, The canal is now filled.

process of necrotic teeth with open apices and apical periodontitis.⁸⁵ The antibiotic paste comprising metronidazole, ciprofloxacin, and minocycline has been shown to have an excellent antimicrobial spectrum for pulp space microbes and an excellent ability to penetrate the dentinal tubules. Since many cases of external inflammatory resorption owing to pulp space

infection occur in immature teeth or teeth with apical resorption, the same procedure for the healing of external resorption and revascularization should work in these cases also. With this antibacterial medicament, the potential exists to arrest the external inflammatory root resorption and revascularize the root canal (Figure 15).

Figure 15 Immature tooth with a necrotic infected pulp, apical periodontitis, and external inflammatory root resorption. Treatment is as described in Figure 7. Note the healing of the external root resorption and the continued root development. Courtesy of Dr. Linda Levin.

The canal is disinfected without mechanical instrumentation but with copious irrigation with 5.25% sodium hypochlorite and the use of a mixture of antibiotics for at least 4 weeks.^{64,85} A blood clot is produced by mechanically irritating the periradicular tissues to the level of the cemento-enamel junction to provide a matrix for the ingrowth of new tissue followed by a deep coronal restoration to provide a bacteria-tight seal. The patient is followed every 3 months until evidence of healing of the external root resorption and thickening of the dentinal walls are seen (see Figures 7 and 15).

Recent studies have confirmed the potent antibacterial properties of the triantibiotic paste used in this case,⁶⁴ and studies are under way to find a synthetic matrix that will act as a more predictable scaffold for new ingrowth of tissue than the blood clot that was used in these previous cases. The procedure described here can be attempted in most cases, and if after 3 months no signs of resorption repair and regeneration are present, the more traditional treatment methods can be initiated.

Endodontic Essentials

CONCUSSION AND SUBLUXATION

Since both of these injuries imply no noticeable displacement of the tooth in its socket, pulp consequences should not be expected. However, baseline and follow-up diagnostic tests are essential to pick up late complications such as pulp canal obliteration (most likely) or pulp necrosis.

Teeth that give a positive pulp test response at the initial examination cannot be assumed to be healthy and continue to give a positive response over time. Teeth that yield a negative response or no response, however, cannot be assumed to have necrotic pulps because they may give a positive response at later follow-up visits. It has been demonstrated that it may take as long as 9 months for normal blood flow to return to the coronal pulp of a traumatized fully formed tooth. As circulation is restored, the responsiveness to pulp testing returns.⁸⁵

The transition from a negative to a positive response at a subsequent test may be considered a sign of a healthy pulp. The repetitious finding of positive responses may also be taken as a sign of a healthy pulp. The transition from a positive to a negative response may be taken as an indication that the pulp is probably undergoing degeneration. The persistence of a negative response would suggest that the pulp has been irreversibly damaged, but even

this is not absolute.⁸⁶ Thermal and electric pulp tests of all anterior teeth (canine to canine) of the maxillary and mandibular jaws should be performed at the time of the initial examination and carefully recorded to establish a baseline for comparison with subsequent repeated tests in later months. These tests should be repeated at 3 weeks; 3, 6, and 12 months; and yearly intervals following the accident. The purpose of the tests is to establish a trend as to the physiologic status of the pulps of these teeth. Particularly in traumatized teeth, carbon dioxide snow (-78°C) or dichlorodifluoromethane (-40°C) placed on the incisal third of the facial surface gives more accurate responses than does a water ice pencil.^{87,88} The intense cold seems to penetrate the tooth and splints or restorations and reach the deeper areas of the tooth. In addition, dry ice does not form ice water, which could disperse over adjacent teeth or gingiva to give a false-positive response. The electric pulp test relies on electric impulses directly stimulating the nerves of the pulp. These tests have limited value in young teeth but are useful in cases in which the dentinal tubules are closed and do not allow dentinal fluid to flow in them. This situation is typical of teeth in elderly patients or in traumatized teeth that are undergoing premature sclerosis. In these situations, the thermal tests that rely on fluid flow in the tubules cannot be used and the electric pulp test becomes important.

LATERAL LUXATION, EXTRUSIVE LUXATION

The tooth should be repositioned as soon as possible and a functional splint placed. The endodontic focus takes place at 7 to 10 days after the emergency visit. The endodontist must evaluate the potential for revascularization of the pulp and therefore not initiate root canal treatment, or if revascularization is not likely, root canal treatment should be initiated at this 7- to 10-day time period.

The potential for revascularization depends primarily on the width of the apical constriction at the time of repositioning. If the width is 1.0 mm or more, revascularization is considered a possibility. The wider the apical opening is, the higher the likelihood of revascularization.⁸⁹ If revascularization is considered possible, a regular follow-up regimen must be scheduled. Since pulp testing is so erratic in these types of teeth, radiographic follow-up at short intervals with similar angulations is undertaken. A small amount of

radiographically appearing root resorption should be expected owing to the initial inflammation. This should be self-limiting and not increase in size after 3 weeks. If the radiographic resorption increases or any other signs of pulp infection are present, root canal therapy should be quickly initiated. If the apical opening is < 1 mm, root canal treatment should be started immediately. If the patient does not present to the clinician within 7 to 10 days postinjury, or if radiographic evidence of active external resorption is present, long-term calcium hydroxide treatment or a triantibiotic regimen should be initiated.

INTRUSIVE LUXATION

Intrusive luxation is the most destructive traumatic injury. Attachment damage is diffuse, and pulp survival is considered impossible. It is possible that in immature roots, spontaneous re-erupt and revascularization may occur, but in mature teeth, pulp necrosis is a certainty.⁴ Thus, at the first chance of accessing the pulp space, root treatment should be initiated.

The Avulsed Tooth

The conditions at the emergency visit will have an important effect on the steps taken at the second visit. Ideally, the tooth should be replanted as soon as possible after the avulsion and functionally splinted. If unable to replant the tooth, it should be placed in a physiologic storage solution to allow for an extended extraoral time with fewer resorption complications after reimplantation. At the emergency visit, the root is prepared depending on the maturity of the tooth (open versus closed) and the extraoral **dry time**. A dry time of 60 minutes is considered the point at which survival is unlikely for periodontal ligament cells.

Extraoral Dry Time < 60 Minutes

CLOSED APEX

The root should be rinsed of debris with water or saline and replanted in as gentle a fashion as possible. If the tooth has a closed apex, revascularization is not possible,⁸⁹ but because the tooth was dry for less than 60 minutes (replanted or placed in appropriate medium), the chance for periodontal healing exists. Most importantly, the chance of a severe inflammatory response at the time of replantation is lessened. A dry time of less than 15 to 20 minutes is considered

optimal where periodontal healing would be expected.⁹⁰⁻⁹²

A continuing challenge is the treatment of the tooth that has been dry for more than 20 minutes (periodontal cell survival is ensured) but less than 60 minutes (periodontal survival unlikely). In these cases, logic suggests that the root surface consist of some cells with the potential to regenerate and some that will act as inflammatory stimulators. Exciting new strategies are under investigation that may be extremely valuable in these cases. The use of Ledermix placed in the canal space at the emergency visit has been found to be valuable in cases that were considered hopeless in the past⁹³ (see below), and this medicament may prove extremely valuable in the 20- to 60-minute dry time period. Studies are ongoing to evaluate its potential.

OPEN APEX

Soak in doxycycline or cover with minocycline for 5 minutes, gently rinse off debris, and replant. In an open-apex tooth, revascularization of the pulp and continued root development are possible (Figure 16). Cvek et al.⁹⁴ found in monkeys that soaking the tooth in doxycycline (1 mg in approximately 20 mL of physiologic saline) for 5 minutes before replantation significantly enhanced revascularization. This result was confirmed in dogs by Yanpiset et al.⁹⁵ A recent study found that covering the root with minocycline that attaches to the root for approximately 15 days further increased the revascularization rate in dogs.⁹⁶ Although these animal studies do not provide us with a prediction of the rate of revascularization in humans, it is reasonable to expect that the same enhancement of revascularization that occurred in two animal species will occur in humans as well. As with the tooth with the closed apex, the open-apex tooth is then gently rinsed and replanted.

Extraoral Dry Time > 60 Minutes

CLOSED APEX

Remove the periodontal ligament by placing it in etching acid for 5 minutes, soak it in fluoride, and replant. When the root has been dry for 60 minutes or more, survival of the periodontal ligament cells is not expected.^{90,97} In these cases, the root should be prepared to be as resistant to resorption as possible (attempting to slow the ankylotic osseous replacement process). These teeth should be soaked in an acid for 5 minutes to remove all remaining periodontal ligament

Figure 16 Revascularization of an immature root. A tooth with an open apex was replanted soon after the avulsion. The follow-up radiograph 1 year later confirmed that revascularization had taken place. In this case, it appears that new periodontal tissue has formed with a lamina dura within the pulp canal. Courtesy of Dr. Russell Stock.

and thus remove the tissue that will initiate the inflammatory response on replantation. The tooth should then be soaked in 2% stannous fluoride for 5 minutes and replanted.^{98,99} Alendronate was found to have resorption slowing effects similar to those of fluoride when used topically,¹⁰⁰ but further studies need to be carried out to evaluate whether its effectiveness is superior to fluoride and if this justifies its added cost. Some studies have found that Emdogain (enamel matrix protein) may be beneficial in teeth with extended extraoral dry times, not only to make the root more resistant to resorption but also possibly to stimulate the formation of new periodontal ligament from the socket.^{101,102} More recent studies have not confirmed the beneficial effect of Emdogain.¹⁰³

If the tooth has been dry for more than 60 minutes and no consideration is given to preserving the periodontal ligament, the endodontics may be performed extraorally. In the case of a tooth with a closed apex, no advantage exists to this additional step at the

emergency visit. However, in a tooth with an open apex, the endodontic treatment, if performed after replantation, involves a long-term apexification procedure. In these cases, completing the root canal treatment extraorally, where a seal in the “blunderbuss” apex is easier to achieve, may be advantageous. When endodontic treatment is performed extraorally, it must be performed aseptically with the utmost care to achieve a root canal system free of bacteria.

OPEN APEX

Replant? If yes, treat as described with a closed-apex tooth. Endodontic treatment may be performed out of the mouth. Since these teeth are in young patients in whom facial development is usually incomplete, many pediatric dentists consider the prognosis to be so poor and the potential complications of an ankylosed tooth so severe as to recommend that these teeth not be replanted. However, considerable debate exists

as to whether it would be beneficial to replant the root even though it will inevitably be lost owing to osseous replacement. If the patients are followed carefully and the root is submerged at the appropriate time,^{104,105} the height and, more importantly, the width of the alveolar bone will be maintained. This allows for easier permanent restoration, when the facial development of the child is complete. Studies are ongoing to evaluate whether the present recommendations should be changed.

Adjunctive Therapy

Systemic antibiotics given at the time of replantation and prior to endodontic treatment are effective in preventing bacterial invasion of the necrotic pulp and therefore subsequent inflammatory resorption.¹⁰⁶ Tetracycline has the additional benefit of decreasing root resorption by affecting the motility of the osteoclasts and reducing the effectiveness of collagenase.¹⁰⁷ The administration of system antibiotics is recommended beginning at the emergency visit and continuing until the splint is removed.¹⁰⁸ For patients not susceptible to tetracycline dentin staining, doxycycline twice daily for 7 days at an appropriate dose for patient age and weight^{107,108} is the antibiotic of choice. Penicillin V 1,000 mg and 500 mg every 6 hours for 7 days has also been shown to be beneficial. The bacterial content of the sulcus also should be controlled during the healing phase. In addition to stressing to the patient the need for adequate oral hygiene, chlorhexidine rinses for 7 to 10 days are useful.

In a recent study by our group, great benefit was seen in removal of the pulp contents at the emergency visit and placing Ledermix (not available in the United States) into the root canal.⁹³ This product contains a tetracycline corticosteroid combination that has been shown to move through the dentinal tubules. Based on the results of the study, the use of the medicament was able to shut down the inflammatory response after replantation to allow for more favorable healing compared with those teeth that did not have the medicament.

The need for analgesics should be assessed on an individual case basis. Mild analgesics are usually adequate, or a nonsteroidal anti-inflammatory drug may be recommended. The patient should be sent to a physician for consultation regarding a tetanus booster within 48 hours of the initial visit.

SECOND VISIT

This visit should take place 7 to 10 days after the emergency visit. At the emergency visit, emphasis is

placed on the preservation and healing of the attachment apparatus. The focus of this visit is the prevention or elimination of potential irritants from the root canal space. These irritants, if present, provide the stimulus for the progression of the inflammatory response and bone and root resorption. Also at this visit, the course of systemic antibiotics is completed, the chlorhexidine rinses can be stopped, and the splint is removed.

Endodontic Treatment

EXTRAORAL TIME < 60 MINUTES

Closed Apex.

Initiate endodontic treatment at 7 to 10 days. In cases in which endodontic treatment is delayed or signs of resorption are present, treat with calcium hydroxide until evidence of healing is present, such as redevelopment of the periodontal ligament space. The root canal can then be filled and the crown restored.

Open Apex

Avoid endodontic treatment and look for evidence of revascularization. At the first indication of an infected pulp, initiate the apexification procedure.

EXTRAORAL TIME > 60 MINUTES

Closed Apex

These teeth are treated endodontically in the same way as those teeth that had an extraoral time of < 60 minutes.

Open Apex

If endodontic treatment was not performed out of the mouth, initiate the apexification procedure. In these teeth, the chance of revascularization is extremely poor.^{80,109} Therefore, no attempt is made to revitalize these teeth. An apexification procedure is initiated at the second visit if root canal treatment was not performed at the emergency visit. If a root canal filling was placed at the emergency visit, the second visit is a recall visit to assess initial healing only.

Temporary Restoration

Effectively sealing the coronal access is essential to prevent infection of the canal between visits. Recommended temporary restorations are reinforced zinc oxide-eugenol cement, acid-etch composite resin, or

glass ionomer cement. The depth of the temporary restoration is critical to its sealing ability. A depth of at least 4 mm is recommended and a cotton pellet need not be placed; the temporary restoration is placed directly onto the calcium hydroxide in the access cavity. Calcium hydroxide should first be removed from the walls of the access cavity because it is soluble and will wash out when it comes in contact with saliva, leaving a defective temporary restoration. After initiation of the root canal treatment, the splint is removed. If time does not permit complete removal of the splint at this visit, the resin tacks are smoothed so as not to irritate the soft tissues and the residual resin is removed at a later appointment. At this appointment, healing is usually sufficient to perform a detailed clinical examination on the teeth surrounding the avulsed tooth. The sensitivity tests, reaction to percussion and palpation, and periodontal probing measurements should be carefully recorded for reference at follow-up visits.

Root Filling Visit

The root canal can be filled at the practitioner's convenience or, in the case of long-term calcium hydroxide therapy, when an intact lamina dura can be traced. If the endodontic treatment was initiated 7 to 10 days after the avulsion and clinical and radiographic examinations do not indicate pathosis, filling of the root canal at this visit is acceptable, although the use of long-term calcium hydroxide is a proven option for these cases. On the other hand, if endodontic treatment was initiated more than 7 to 10 days after the avulsion or if active resorption is visible, the pulp space must first be disinfected before root filling. Traditionally, the reestablishment of a lamina dura (see Figure 14) is a radiographic sign that the canal bacteria have been controlled. When an intact lamina dura can be traced, root filling can take place. The canal is cleaned, shaped, and irrigated under strict asepsis. After completion of the instrumentation, the canal can be filled by any acceptable technique, with special attention to an aseptic technique and the best possible seal of the filling material.

PERMANENT RESTORATION

Much evidence exists that coronal leakage caused by defective temporary and permanent restorations results in a clinically relevant amount of bacterial contamination in the root canal after root filling.¹¹⁰ Therefore, the tooth should receive a permanent restoration at or soon after the time of filling of the root canal. As with the temporary restoration, the

depth of restoration is important for its seal; therefore, the deepest restoration possible should be made. A post should be avoided if possible. Because most avulsions occur in the anterior region of the mouth, where esthetics is important, composite resins with the addition of dentin bonding agents are usually recommended in these cases. They have the additional advantage of internally strengthening the tooth against fracture if another traumatic event should occur.

FOLLOW-UP CARE

Follow-up evaluations should take place at 3 months, at 6 months, and yearly for at least 5 years. If osseous replacement (ankylosis) is identified (Figure 17),

Figure 17 Radiographic appearance of osseous replacement. The root acquires the radiographic appearance of the surrounding bone (without a lamina dura). Note that radiolucencies typical of active inflammation are **not** present.

timely revision of the long-term treatment plan is indicated. In the case of inflammatory root resorption (see Figure 12), a new attempt at disinfection of the root canal space by standard retreatment can reverse the process. Teeth adjacent to and surrounding the avulsed tooth or teeth may show pathologic changes long after the initial accident. Therefore, these teeth should be tested at recall and the results compared with those collected soon after the accident.

Internal Root Resorption

Internal root resorption is **rare** in permanent teeth. Internal resorption is characterized by an oval-shaped enlargement of the root canal space.⁴ External resorption, which is much more common, is often misdiagnosed as internal resorption. Internal root resorption is characterized by resorption of the internal aspect of the root by multinucleated giant cells adjacent to granulation tissue in the pulp. Chronic inflammatory tissue is common in the pulp but only rarely does it result in resorption. There are different theories on the origin of the pulpal granulation tissue involved in internal resorption. The most logical explanation is that it is pulp tissue that is inflamed owing to an infected coronal pulp space. Communication between the coronal necrotic tissue and the vital pulp is through appropriately oriented dentinal tubules.⁷⁸ In addition to the requirement of granulation tissue, root resorption takes place only if the odontoblastic layer and predentin are lost or altered.⁷⁸

Reasons for the loss of predentin adjacent to the granulation tissue are not obvious. Trauma frequently has been suggested as a cause.^{111,112} Some report that trauma may be recognized as an initiating factor in internal resorption.¹¹³ They are divided into a transient type and a progressive type, the latter requiring continuous stimulation by infection. Another reason for the loss of predentin might be extreme heat produced when cutting on dentin without an adequate water spray. The heat presumably would destroy the predentin layer, and if later the coronal aspect of the pulp became infected, the bacterial products could initiate the typical inflammation in conjunction with resorbing giant cells in the vital pulp adjacent to the denuded root surface. Internal root resorption has been produced experimentally by the application of diathermy.¹¹³

Internal root resorption is usually asymptomatic and is first recognized clinically through routine

Figure 18 Pink spot associated with internal root resorption.

radiographs. Pain may be a presenting symptom if perforation of the crown occurs and the metaplastic tissue is exposed to the oral fluids. For internal resorption to be active, at least part of the pulp must be vital, so a positive response to pulp sensitivity testing is possible. The coronal portion of the pulp is often necrotic, whereas the apical pulp that includes the internal resorptive defect remains vital. Therefore, a negative sensitivity test result does not rule out active internal resorption. It is also possible that the pulp becomes nonvital after a period of active resorption, giving a negative sensitivity test, radiographic signs of internal resorption, and radiographic signs of apical inflammation. Traditionally, the pink tooth has been thought pathognomonic of internal root resorption. The pink color is due to the granulation tissue in the coronal dentin undermining the crown enamel (Figure 18). The pink tooth can also be a feature of cervical subepithelial external inflammatory root resorption that must be ruled out before a diagnosis of internal root resorption is made.

RADIOGRAPHIC APPEARANCE

The usual radiographic presentation of internal root resorption is a fairly uniform radiolucent enlargement

of the pulp canal (Figure 19). Because the resorption is initiated in the root canal, the resorptive defect includes some part of the root canal space. Therefore, the original outline of the root canal is distorted. Only on rare occasions, when the internal resorptive defect penetrates the root and impacts the periodontal ligament, does the adjacent bone show radiographic changes.

HISTOLOGIC APPEARANCE

Similar to other inflammatory resorptive defects, the histologic picture of internal resorption is granulation tissue with multinucleated giant cells. An area of necrotic pulp is found coronal to the granulation tissue. Dentinal tubules containing microorganisms and communicating between the necrotic zone and the granulation tissue can sometimes be seen.^{78,80,113,114}

Figure 19 Uniform radiolucency observed in teeth with internal root resorption.

Unlike external root resorption, the adjacent bone is not affected with internal root resorption.

ENDODONTIC TREATMENT

Treatment of internal root resorption is conceptually very easy. Since the resorptive defect is the result of the inflamed pulp and the blood supply to the tissue is through the apical foramina, endodontic treatment that effectively removes the blood supply to the resorbing cells is the treatment approach. After adequate anesthesia is obtained, the canal apical to the internal defect is explored and a working length short of the radiographic apex is used. The apical canal is thoroughly instrumented to ensure that the blood supply to the tissue resorbing the root is cut off. **By completion of the root canal instrumentation, it should be possible to obtain a blood-free and dry canal with paper points.** Calcium hydroxide is spun into the canal to facilitate the removal of the tissue in the irregular defect at the next visit. At the second visit, the tooth and defect are filled with a soft root filling technique (Figure 20). With modern dental techniques, this treatment alternative should be weighed against the advantages of implant dentistry.

Figure 20 An internal root resorption defect is filled with a softened gutta-percha filling technique.

CHAPTER 37

PATHOLOGIC TOOTH RESORPTION

JENS OVE ANDREASEN, LEIF K. BAKLAND

The resorption of permanent teeth has been considered an unfortunate and unpredictable phenomenon. During the past 30 years, a wealth of new knowledge about the nature of osteoclasts, and more specifically how they behave in the oral environment, has provided more information about the previously mysterious osteoclastic attacks on roots.¹ This chapter describes the sequence of traumatic and pathologic events that may lead to root resorption; however, it may be of interest to consider why permanent teeth normally survive without succumbing to root resorption.

Homeostasis Phenomenon of Pulp and Periodontal Ligament Preventing Osteoclastic Attacks

It is a surprising fact that a permanent tooth throughout life is placed in an environment of alveolar bone surrounded by very active osteoblasts and osteoclasts without being approached by any of these two cell lines under normal conditions (Figure 1).² Several experimental studies indicate that this immunity possibly relates to the presence of intact cementoblast and odontoblast cell layers, and perhaps also adjacent cell layers.² In various animal experiments, it has been shown that physical and chemical insults to these cell layers can result in loss of protection, leading to active root resorption, both on the external root surface and in the root canal.^{3,4}

To understand the full scope of tooth resorption, it is necessary to understand the nature of osteoclasts, a cell with multipotential behavior that plays at least five significant roles during adolescence and adult life.

Figure 1 Antisorptive and antiosteogenesis signals released from cementoblasts, periodontal ligament cells, and Malassez epithelial islands, creating a periodontal ligament space homeostasis. Reproduced with permission from Lindskog SF et al.¹

Physiology of Osteoclasts

The osteoclasts represent a syncytium of stimulated macrophage progenitor cells. This stimulation is under the control of the RANK-RANKL-OPG system (RANK = receptor activator of nuclear factor; RANKL = receptor activator of nuclear factor ligand; OPG = osteoprotegerin).¹ It serves as an on-off system for osteoclast activity, where downregulating of the OPG system and upregulating of the RANKL system may favor differentiation of new osteoclasts and the opposite regulation may downregulate osteoclastic activity (Figures 2 and 3).

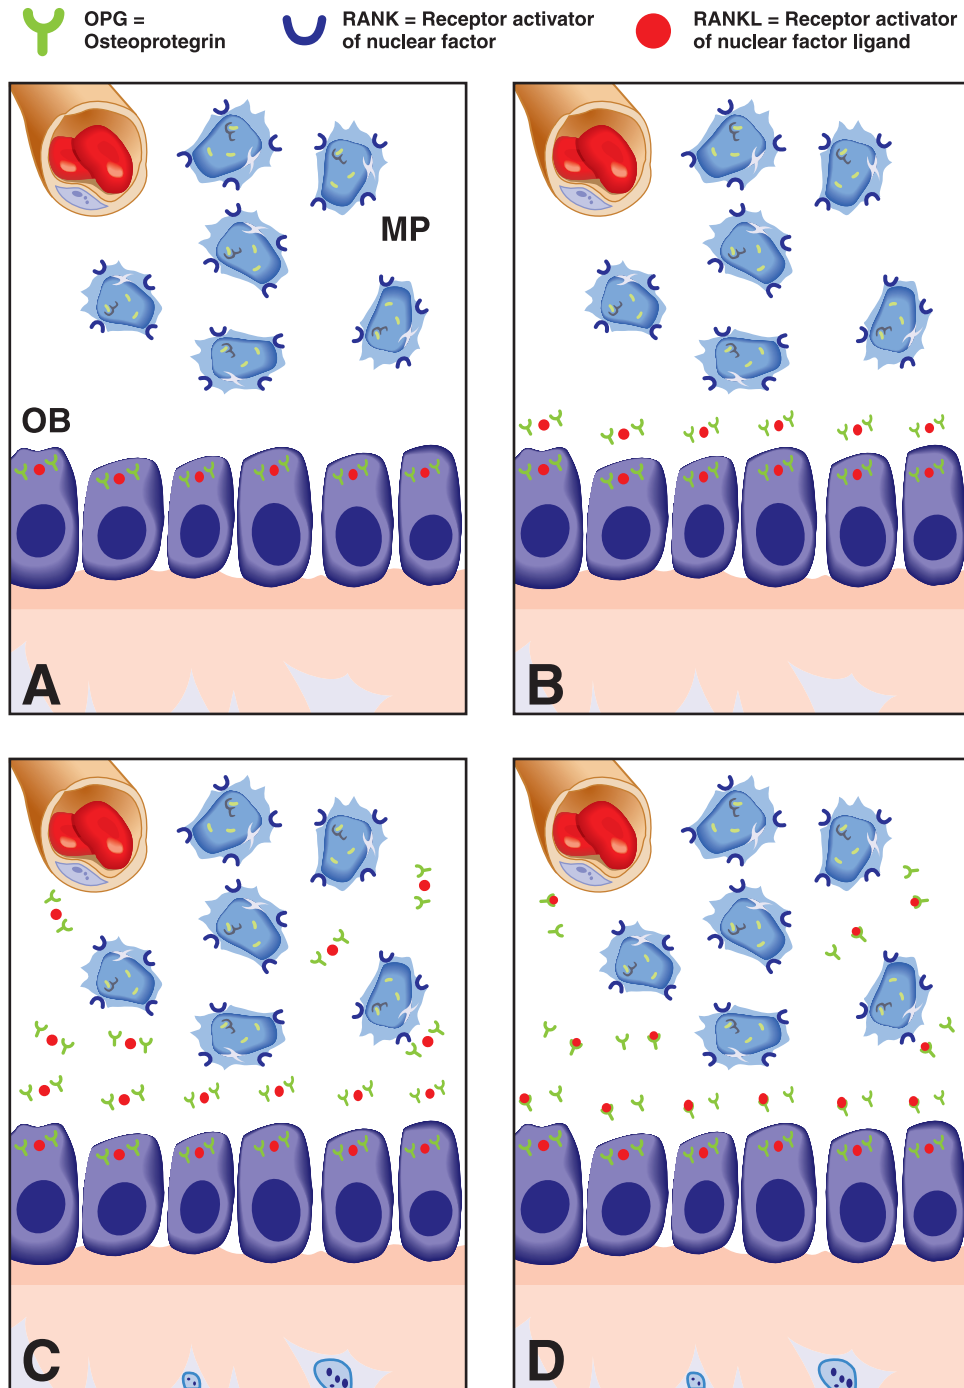

Figure 2 **A** and **B**, Activation of the RANK-RANKL-OPG system. Osteoclastogenesis is the result of differentiation of mononuclear/macrophage progenitor cells (MP) and fusion of these cells to become osteoclasts. The commitment of these cells to become osteoclasts depends on the activation of the RANK receptors on the surface of RANKL, which is produced by stroma cells and osteoblast (OB). **C**, RANKL is liberated into the tissue and attaches to the receptors of the mononuclear/macrophage progenitor cells. **D**, Mononuclear/macrophage cells aggregate, fuse, and form osteoclasts. Proresorptive factors are hormones and cytokines such as parathyroid hormone, 1,25dihydroxyvitamin D₃, interleukin-1, interleukin-6, tumor necrosis factor, leukemia inhibitory factor (LIF), and corticosteroids, which activate osteoblasts and stroma cells to produce RANKL and depress OPG. Reproduced with permission from Lindskog SF et al.¹

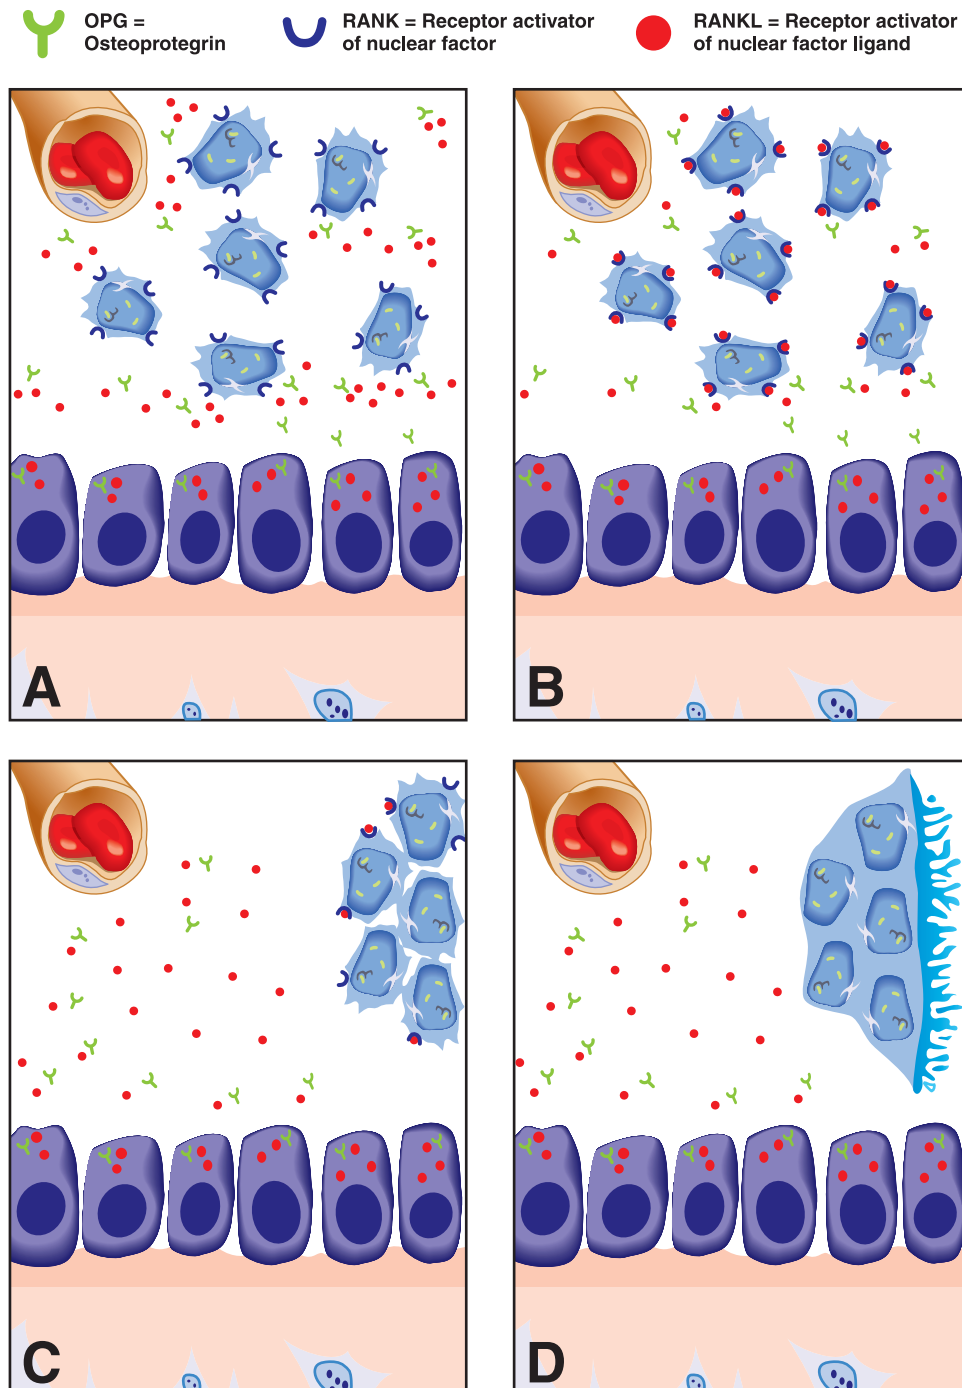

Figure 3 A–C, Inactivation of the RANK-RANKL-OPG system. Antiresorptive factors such as estrogens, calcitonin, bone morphogenetic protein, transforming growth factor {158}, interleukin-17, platelet-derived growth factor, and calcium depress RANKL production by osteoblasts and stroma cells and activate their OPG production. **D**, OPG binds and neutralizes RANKL, leading to a block in osteoclastogenesis and decreased survival of osteoclast. Reproduced with permission from Lindskog SF et al.¹

Figure 4 Physiology of an osteoclast: removal of inorganic material by acids (proton pump) and organic material by matrix metalloproteinases, serine, cysteine, and aspartic proteases.

Mechanism of Hard Tissue Deconstruction

After an osteoclast has been formed, it will start to resorb hard tissue (ie, cementum, dentin, enamel, or bone). The mechanism of hard tissue deconstruction is dissolution of inorganic material by acids associated with a breakdown of the organic structures (Figure 4).¹

Osteoclast as a Cell Responsible for Tooth Eruption

The osteoclast plays a key role in the shedding of primary teeth (**physiologic resorption**). At a certain stage in the development of a permanent successor and the eruption process, the coronal part of the follicle induces a rim of osteoclasts that over a couple of years resorb the roots of the primary predecessor and the adjacent bone.⁵⁻⁷ In the case of the ectopic position of a permanent tooth germ, **nonphysiologic root resorption** may affect adjacent permanent teeth.

ENDODONTIC IMPLICATIONS

In regard to physiologic resorption of primary teeth, it should be noted that chronic periapical inflammation from pulp necrosis in primary teeth accelerates shedding.^{6,7} For example, with the ectopic eruption of a canine, resorption of the permanent lateral incisor may take place (Figure 5). If the lateral incisor has an intact pulp and if the ectopic eruption path

Figure 5 An example of lateral root resorption on a maxillary lateral incisor from the ectopic eruption of the adjacent canine.

changes to a normal path, or if the canine is removed, the resorption process of the lateral incisor will be arrested and the pulp should survive. Consequently, root canal treatment of such teeth is definitely not indicated.

Osteoclast as a Cell Involved in Alveolar Bone Growth and Maintenance

The alveolar bone structure is entirely dependent on a controlled symbiosis between osteoblastic and osteoclastic activity whereby a continuous turnover of bone takes place throughout life (Table 1). If there is a lack of equilibrium in the activity of these two cell types, either osteoporosis or osteosclerosis will occur.^{1,6}

ENDODONTIC IMPLICATIONS

In case of a replacement resorption (ankylosis) of a tooth (external root surface or internal root canal), the tooth becomes part of the general bone remodeling system and continuous replacement of the root with bone takes place. Internal (root canal) replacement resorption leading to infraocclusion can be arrested by pulp extirpation and root filling. In case of external (root surface) replacement resorption, the condition

can, as a rule, not be successfully treated today, at least if the ankylosis has reached a certain extent. Endodontic interventions and placement of calcium hydroxide may slow, but not arrest, the ankylosis process. It also carries the risk of accelerating the process.⁸

Osteoclast as a Member of the Repair Team after Injury

In revascularization situations in bone and teeth, the osteoclast and ingrowing vessels work jointly together

as part of the wound healing module,² the osteoclast having the role of creating space for the new vascular tissue to grow into narrow spaces (root canal). This is later reversed by apposition of new hard tissue (cementum or bone). This phenomenon has been termed **transient apical breakdown, transient marginal breakdown, transient ankylosis, and transient internal surface resorption** according to the location of the process (Figure 6).^{2,9} These events are rather frequently seen after luxation injuries and root fractures with displacement, where avascular but sterile pulp tissue is replaced in conjunction with the revascularization process.

ENDODONTIC IMPLICATIONS

It is very important to consider that the radiographic signs of osteoclastic activity are not always signs of ongoing infection but may represent an actual healing process and therefore only require observation.

Osteoclast as a Defense Cell against Microbial Invasion

In the periodontal ligament (PDL) area, a constant fight takes place between microbial invasion in the cervical area owing to plaque accumulation and periodontal pocket formation and in the apical area owing to bacterial accumulation in the root canal. In both cases, a series of osteoclast-promoting signals are released by bacteria and inflammatory cells, stimulating osteoclast generation and accelerating osteoclast activities (Figure 7).^{1,10} This typically results after some time in marginal or periapical bone loss. Likewise, if a combined injury has happened to the root surface and the pulp canal has become infected, the osteoclast may get a dual stimulation to resorb the root surface. In fact, the first tissue damage to the root surface initiates resorption, and after penetration of the cementum, the osteoclasts are triggered by bacterial toxins from the root canal through the dentinal tubules to continue to resorb dentin (see later).

ENDODONTIC IMPLICATIONS

When radiographic signs of apical or marginal breakdown or external root resorption become evident, an infection-related root resorption caused by necrotic and infected pulp tissue should be suspected (see

Figure 6 Examples of various transient pathologic events. **A**, Transient apical breakdown. **B**, Transient internal surface resorption. **C**, Transient marginal breakdown.

Figure 7 Osteoclast activators related to bacteria in the root canal and dentinal tubules.

Chapter 36, “Endodontic Considerations in Dental Trauma”). Endodontic intervention in such cases is indicated and most beneficial.

Methods for Controlling Osteoclast Activity

During the past century, a series of osteoclast activators have been identified, all being capable of initiating and activating osteoclast activity.¹¹ In Figure 8, some of the agents that have been tried to interfere with or inactivate these triggers of root resorption are shown.^{2,11}(Figure 8). These approaches, whether

Figure 8 Example of various medicaments used to influence osteoclast activity.

Effect of Ledermix®, Triamcinolone and Tetracycline

Method of action: Anti-inflammatory
Model: Dogs
Design: 60 min. Drying. Endo. Obs. 4 weeks.
Administration: Immediate placement in root canal

Results:

Figure 9 Effect of Ledermix (triamcinolone and tetracycline) on periodontal ligament (PDL) healing after replantation. Reproduced with permission from Chen H et al.¹²

administered systemically or topically (in the root canal or on the root surface), have had either no or a very limited effect on the osteoclastic activity on resorption-prone replanted teeth.¹¹ The most promising medication appears to be a combination of tetracycline and cortisone (e.g., Ledermix) topically applied in the root canal. In a detailed experimental study in dogs, it was found that the cortisone part of this combination (Ledermix®) had the most significant influence on reducing the extent of the osteoclastic attack on the root (Figure 9).¹²

An alternative chemical way of arresting or preventing osteoclastic attack on the root surface is to change the dentin environment from a neutral pH to a basic pH that may interfere with the osteoclast's mineral dissolution.¹ Such a change has been shown in several in vitro and in vivo experiments to be possible by an intracanal dressing of calcium hydroxide.⁸ In these cases, the pH of the external portion of the dentin approached a level of 9 to 10 pH.^{13,14} In one clinical study, there was a tendency for an elevated pH to result in a slightly higher likelihood of healing external root resorption.⁸

ELIMINATION OF BACTERIA RESPONSIBLE FOR INFECTION-RELATED RESORPTION

Only one clinical study has investigated the use of antibiotics for infection-related resorption, and it appears that short-term use of antibiotics (a mixture

Periodontal ligament healing related to four types of endodontic treatment of 354 avulsed and replanted teeth. After Andreasen 2007

Figure 10 Efficacy of various endodontic procedures to reduce progressive root resorption after replantation in a clinical study of 334 replanted human teeth. Reproduced with permission from Andreasen JO et al.⁸

of neomycin and bacitracin) has almost the same capacity as short-term use of calcium hydroxide in reducing the extent of infection-related resorption in replanted human teeth (Figure 10).⁸ Owing to the possible side effects of antibiotics (allergy), it seems inappropriate today to use antibiotics for these purposes. In the future, there might be an indication for disinfection of the root canal and dentin with antibiotics in cases in which pulp revascularization is the intent (see Chapter 36). Calcium hydroxide, however, is not able in all cases to eliminate bacteria in the root canal, which seems to be necessary for successful revascularization.

Types of Root Resorption

The following short, systematic synopsis presents the various root resorption types and how they relate to endodontic practice. The reader is also referred to a series of survey articles dealing with diagnosis and treatment of root resorption.^{4,15–22}

External Surface Resorption (Repair-Related Resorption)

ETIOLOGY

This resorption entity represents the healing response to chronic and/or acute injury in the PDL, affecting the cells adjacent to the root surface. The typical situation in which **acute** repair-related resorption occurs appears to be after luxation injuries such as concussion, subluxation, and lateral luxation. It can also occur following intrusion and replantation of avulsed teeth, where it may affect all parts of a root, and in root fractures, where it is observed adjacent to the fracture line. This type of resorption also frequently occurs after **chronic** injury affecting the PDL and associated with orthodontic treatment, traumatic occlusion, and pressure from developing cysts or apical granulomas and ectopically erupting teeth. When the trauma and/or pressure has been discontinued, spontaneous healing

Figure 11 **A**, Pathogenesis of surface resorption (repair-related resorption): healing with minor injury to the periodontal ligament. **B**, The injury site is resorbed by macrophages and osteoclasts. The osteoclasts have exposed factors and other soluble molecules in dentin, such as insulin-like growth factor 1, transforming growth factor {158}, platelet-derived growth factor, bone morphogenetic proteins, fibroblast growth factor 2, and A4 (amelogenin gene splice products). These molecules may serve as stimulators for cementoblasts. **C**, Subsequent repair takes place by the formation of new cementum and insertion of Sharpey fibers. Reproduced with permission from Andreasen JO and Löwischall H.²

takes place, which is a typical feature of repair-related resorption.²

Pathogenesis

The injured tissue adjacent to the root and surface cementum are removed by macrophages and osteoclasts. These events take 2 to 4 weeks. Repair is by progenitor cells from the adjacent PDL. New cementum is formed with insertion of PDL fibers (Figure 11).²

RADIOGRAPHIC FINDINGS

After 2 to 4 weeks, a localized widening of the PDL space can be seen owing to loss of surface layers of the cementum and the bony alveolar socket. At this time, the radiographic images are similar to infection-related root surface resorption. Subsequently, however, healing takes place with reformation of the PDL and deposition of hard tissues. Radiographically, slight cavitations may be seen on the root surface.^{16,23,24} However, most repair-related root surface resorptions have such a limited size that they cannot be recognized radiographically.^{25,26}

ENDODONTIC IMPLICATIONS

Owing to their nature, being primarily related to a periodontal injury, endodontic intervention is not indicated for teeth with this type of root resorption. However, a diagnostic problem may exist since a progressing infection-related resorptive process may have an identical debut.

TREATMENT

If trauma and/or pressure are eliminated, there is almost 100% repair. If the root apex has been resorbed, excessive mobility becomes a problem if the root is shorter than 12 mm.²⁷

External Infection-Related Resorption (Inflammatory Root Resorption)

ETIOLOGY

This resorption entity was described in a clinical and histologic study in 1965 of avulsed and replanted teeth.^{23,24} Infection-related resorption represents a combined injury to the pulp and PDL and where bacteria, primarily located in the pulp space and in dentinal tubules, trigger osteoclastic activity on the root surface. This type of resorption can affect all parts of the root. Infection-related resorption is typically diagnosed 2 to 4 weeks after injury. The resorption is a rapidly progressing process that may result in total resorption of the root within a few months. It is almost exclusively related to acute trauma and is especially common after intrusion and replantation of avulsed teeth.¹⁶

PATHOGENESIS

In the event that the initial resorption has penetrated the cementum and exposed dentinal tubules, toxins from bacteria present in the dentinal tubules and/or the infected root canal can be diffused via the exposed

Figure 12 **A**, Pathogenesis of inflammatory resorption (infection-related resorption): healing with moderate or extensive injury to the periodontal ligament and associated infection in the pulp and/or dentinal tubules. **B**, The initial injury to the root surface triggers a macrophage and osteoclast attack on the root surface. **C**, Osteoclasts are exposed to toxins from bacteria located in the root canal and dentinal tubules, such as lipopolysaccharide, muramyl dipeptide, and lipoteichoic acid. These toxins serve as direct activators of osteoclastic activity. The resorption process is accelerated, and granulation tissue ultimately invades the root canal. Reproduced with permission from Andreasen JO and Løwtschall H.²

tubules to the PDL (Figure 12).^{2,28} This results in continuation of the osteoclastic process and an associated inflammation in the PDL, leading to resorption of adjacent alveolar bone. The process usually progresses, and root dentin is resorbed, until the root canal is exposed. If bacteria are eliminated from the root canal and dentinal tubules by endodontic therapy, the resorptive process will be arrested.^{27–39} The resorption cavity will then be filled in with cementum or bone, according to the type of vital tissue found next to the resorption site (PDL or bone marrow–derived tissue).

CLINICAL FINDINGS

The tooth undergoing infection-related root resorption will have increased mobility and have a dull percussion tone. Sometimes the tooth may be extruded. Sensibility testing gives no response, and sometimes a sinus tract develops.

RADIOGRAPHIC FINDINGS

Infection-related resorption is typically diagnosed 2 to 4 weeks after injury and appears as progressive cavitations involving the root and adjacent alveolar bone. The resorption is a rapidly progressing event that may result in total loss of root structure after only a few months, particularly in young children (Figure 13).

ENDODONTIC IMPLICATIONS

This type of resorption represents a combined periodontal and pulpal injury and requires immediate

endodontic treatment to control or remove the osteoclast-promoting factors (bacterial toxins from the root canal system).

TREATMENT

The treatment goal is to remove or destroy bacteria in the root canal and dentinal tubules to allow healing to take place in the entire periradicular space (root surface, PDL, and adjacent alveolar bone). The bacteria are best destroyed by using $\text{Ca}(\text{OH})_2$ as an intracanal medicament. A side effect, however, of using $\text{Ca}(\text{OH})_2$ for a long term (> 30 days) is weakening of the root structure in **immature** teeth; this may lead to cervical root fractures. This is a risk that has been found to be as high as 66 to 72% in two clinical studies.^{31,32} In **mature** teeth, the problem apparently does not exist.³¹ The endodontic technique therefore varies according to the maturity of the tooth (see Chapter 36).

MATURE TEETH

In fully developed teeth with infection-related resorption, endodontic treatment should include prophylactic extirpation of the pulp in replanted avulsed teeth. Biomechanical canal preparation should include the use of sodium hypochlorite and $\text{Ca}(\text{OH})_2$. The latter can be expected to have accomplished its task of disinfection so that the canal can be filled 2 to 3 weeks after treatment.

IMMATURE TEETH

In situations in which the pulp becomes necrotic before the root is fully developed, the apical opening

Figure 13 Progression of infection-related resorption. Reproduced with permission from Andreasen JO et al.⁵⁵ **A**, Replanted avulsed maxillary left central incisor. **B**, Beginning resorption from trauma-related inflammation in the periodontal ligament (arrows). **C**, Infected necrotic pulp tissue stimulates continuing resorption. **D**, Failure to control infection in the necrotic pulp can rapidly lead total tooth loss.

is often too large to create a resistance to retain the root canal filling. Apexification procedures using calcium hydroxide have been performed with good success. The disadvantage of using calcium hydroxide for apexification is that it takes many months to obtain enough of an apical barrier to allow placement of a root canal filling. Additionally, it appears that long-term use of $\text{Ca}(\text{OH})_2$ can weaken dentin, possibly by dissolving its organic component and thereby resulting in cervical root fracture on even slight impacts or normal use.³³ By using mineral trioxide aggregate (MTA) as a physical barrier apically, a root canal filling can be placed immediately without waiting for a biologic response (Figure 14). Minimizing exposure of root dentin to calcium hydroxide results in less damage to the dentin.^{34,35}

PROGNOSIS

It needs to be understood that dentin lost through resorption cannot be replaced by new dentin (at least with today's treatment approaches). Healing occurs by arresting the resorption process and replacement with either a layer of new cementum or bone and establishment of new PDL. The amount of healing has been found to be 88% in two clinical studies.^{36,37}

External Trauma-Related Replacement Resorption (Ankylosis)

This PDL complication represents a sequel to a defect in or injury to the PDL cells, including the

Figure 14 Combined calcium hydroxide and mineral trioxide aggregate (MTA) treatment of a traumatized permanent tooth with immature root formation. **A**, The tooth is isolated with rubber dam, the crown is disinfected, and an access cavity to the root canal is prepared. **B**, Extirpation of necrotic pulp tissue is done to a level apically, where fresh bleeding from healthy tissue is encountered. This can be anywhere from several millimeters from the apex to flush with the apical foramen. **C**, Root canal preparation in developing teeth requires a conservative approach so as to preserve as much root dentin as possible. Hence, minimal canal shaping is appropriate. **D**, Disinfection of the root canal with sodium hypochlorite is followed by short-term (approximately 2 to 4 weeks) interim dressing with calcium hydroxide. The use of calcium hydroxide allows acceptable disinfection of the root canal system and provides a dry root canal, free of seepage of apical exudates. The coronal access opening must be sealed with a dependable temporary restoration. **E**, At the next visit, the calcium hydroxide is removed and the canal is thoroughly irrigated with saline or sodium hypochlorite to obtain a debris-free canal. Small increments of the MTA-water mixture are introduced into the canal and gently condensed. Length can be controlled using a rubber stopper on a plugger. No harm is done, however, with slight overfilling. **F**, When properly condensed, the apical MTA plug should be at least 4 mm thick. The entire canal can be filled with MTA (to the cervical level), or the coronal part of the canal can later be filled with gutta-percha and sealer. **G**, To allow setting, a moistened (water) cotton pellet is placed in the access cavity, which is then sealed with a temporary filling material. Once set (usually within 4 to 6 hours), the canal can be conventionally filled. **H**, The temporary material and cotton pellet are removed, and the apical plug is checked for setting hardness; it should not be vigorously probed as the material can break. The canal is then irrigated, dried, and filled, followed by a bonded coronal composite restoration. Reproduced with permission from Bakland L.³⁵

Figure 15 **A**, Pathogenesis of replacement resorption (ankylosis-related resorption): healing after extensive injury to the periodontal ligament. **B**, The osteoclasts have been exposed to stimulating factors and other soluble molecules in dentin such as insulin-like growth factor 1, transforming growth factor {158}, platelet-derived growth factor, bone morphogenetic proteins, fibroblast growth factor 2, and A4 (amelogenin gene splice products). These molecules may serve as stimulators for cementoblasts and/or osteoblasts.² **C**, Ankylosis is formed because healing occurs almost exclusively by cells from the alveolar wall. Reproduced with permission from Andreasen JO and Løvschall.²

cell layer next to the cementum.² The most frequent cause appears to be acute trauma (severe luxations such as lateral luxations, intrusions, and replantation of avulsed teeth).² In those situations, the homeostasis of the PDL is lacking. This leads to healing events taking place from adjacent healthy PDL, resulting in a normal PDL. Healing events from the bony alveolus result in creation of a bony bridge between the socket wall and the root surface (Figure 15).

In situations of moderately sized injuries (1–4 mm²), an initial ankylosis forms. If the tooth is allowed functional mobility by the use of a nonrigid splint or no splinting, small areas of resorption can later be replaced with new cementum and PDL attachment (transient ankylosis).^{22,38–42} In more extensive injuries (> 4 mm²), a progressive ankylosis takes place. This implies that the tooth becomes an integral part of the bone remodeling system. The entire process includes osteoclastic resorption dependent on bone remodeling processes, parathyroid hormone-induced resorption, remodeling owing to function, and resorption owing to bacteria present

in the gingival area and/or the root canal.² All of these processes are very active in children and lead to gradual infraocclusion and arrested development of the alveolar process.⁴³ As a result, this combination of resorption processes leads to loss of ankylosed teeth within 1 to 5 years. In older individuals, replacement resorption is significantly slower and often allows a tooth to function for much longer periods of time (ie, 5–20 years), and the position of the tooth in the arch remains the same (similar to an implant).⁴⁴

CLINICAL FINDINGS

A tooth undergoing ankylosis-related root resorption appears very firm in its socket, eliciting a high metallic sound on percussion. This can be demonstrated 4 to 6 weeks post-trauma.^{42,45}

RADIOGRAPHIC FINDINGS

The resorption process is in response to extensive damage to the layer of the PDL closest to the root surface. Owing to the predominant healing response from the bony socket wall, ankylosis takes place.

Figure 16 Progression of replacement resorption (ankylosis). Reproduced with permission from Andreasen JO et al.⁵⁵ **A**, Delayed replantation of maxillary left central incisor. **B**, Initial ankylosis-related resorption due to necrosis of the periodontal ligament cells. **C**, The root is gradually being replaced by bone. **D**, Eventually the entire root is replaced by bone.

Because of the normal remodeling characteristic of bone, the root structure is gradually replaced by bone (Figure 16). Ankylosis is a frequent occurrence after intrusion and replantation of avulsed teeth. It can usually be diagnosed radiographically within 2 months after injury and clinically within 1 month by a high percussion sound.^{42,45}

ENDODONTIC IMPLICATIONS

Endodontic therapy cannot arrest the progressive ankylosis-related resorption process. If the pulp is vital, no endodontic procedures should be undertaken. In the case of an associated pulp necrosis, the treatment described for infection-related root resorption is applicable to control the progression of the process of replacement resorption.⁸

TREATMENT

In **adolescents**, the ankylosed tooth will fail to erupt and will gradually go into infraposition. The younger the age, the more pronounced is the infraposition (Figure 17).

Presently, there are five treatment approaches:

1. Decoronation (to maintain and augment the alveolar process)
2. Luxation of the tooth (breaking of ankylosis sites)
3. Vertical distraction
4. Prosthetic elongation
5. Acceptance of the resorbing tooth

Of the above approaches, the decoronation treatment is very suitable in children and adolescence, when significant remaining alveolar growth is

Figure 17 Infra-positioned maxillary central incisor initially intruded at the age of 9. **A**, A clinical photograph shows the position of the tooth at age 13 years. **B**, A radiograph shows the extent of ankylosis-related resorption. The pulp retained vitality, which is not unusual in teeth with ankylosis-related resorption.

expected. The procedure involves removal of the crown of the tooth (leaving what remains of the root), allowing continued vertical growth of the alveolus.⁴⁶⁻⁴⁹ If the crown is surgically removed slightly below the cervical bone level and the root filling or pulp tissue is removed, the remaining root will

maintain the labiolingual content of the alveolar process. The reformation of the interdental fibers, dentoperiosteal fibers, and periosteum will lead to a normalization of the bone level.⁴⁸ Owing to the ankylosis-related resorption of the remaining root with bone replacement, the alveolar structure will

Figure 18 External spontaneous ankylosis resorption. **A**, Graphic illustration of spontaneous ankylotic resorption. **B**, Clinical example of such resorption.

be optimal for implants placed later when growth has been completed.^{46–49}

External Spontaneous Ankylotic Resorption

ETIOLOGY

This type of ankylosis may affect one or a few primary or permanent teeth. The etiology is presently not known but is suspected to be related to the instability of the RANK-RANKL-OPG system (Figure 18).²

PATHOGENESIS

The ankylosis-related resorption process leads to infraposition of the involved teeth in young individuals and in all cases to gradual substitution of the root substance with bone.

CLINICAL FINDINGS

Primary Dentition

This resorption type especially affects the primary molars, and the mandibular second primary molar is most prone to be involved (20%).⁵⁰ Ankylosis leads to gradual infraposition and tilting of neighboring teeth.⁵⁰

Permanent Dentition

The first and second permanent molars are most prone to show this type of resorption. These molars will, in young individuals, show a gradual infraposition, and the percussion tone is high and metallic.^{6,7,51}

RADIOGRAPHIC FINDINGS

Primary Molars

The ankylosis process starts to affect the interdental area and gradually spreads to the remaining part of the root.

Figure 19 Spontaneous ankylosis affecting the interdental area of a first molar. Reproduced with permission from Andreasen JO, Kurol J.⁵¹

Permanent Molars

The first molars will, in most cases, show replacement resorption starting in the intraradicular area. From this location, it will gradually spread to the remaining part of the root (Figure 19). Semi-impacted or impacted third molars will show ankylosis only in rare cases.

ENDODONTIC IMPLICATIONS

This is primarily a PDL problem, and endodontic intervention may actually aggravate the aggressive nature of the ankylosis process.

TREATMENT

Primary Dentition

If diagnosed early, decoronation is a reasonable option. If diagnosed late in adolescence, the crown may be rebuilt to prevent overeruption of the antagonist.

Permanent Dentition

If diagnosed in early adolescence, the ankylosed tooth should be extracted. At later stages, the crown may be

rebuilt with a restoration to achieve a functional occlusal level.

External Multiple Sites of Ankylosis- or Infection-Related Resorption

ETIOLOGY

These are very rare types of root resorptions; only a handful of new cases are reported each year in Denmark (6 million inhabitants). The etiology is suspected to be a defect in the RANK-RANKL-OPG system and a hereditary background is found in some cases.²

PATHOGENESIS

Any permanent tooth may become involved. The process takes place over 10 to 20 years. It usually affects a single group of teeth (premolars, molars) and gradually affects other groups of teeth.

RADIOGRAPHIC FINDINGS

The radiographic images will show cervical invasive resorption cavities that involve multiple teeth. The

Figure 20 A and B, Multiple cervical invasive resorption cavities. This is sometimes referred to as idiopathic external root resorption because of uncertainty about etiology.

resorption process expands over time in all directions, resulting in the eventual breakdown of the involved teeth (Figure 20).

CLINICAL FINDINGS

In case of ankylosis, the tooth involved gives a high percussion tone. In case of inflammatory resorption, granulomatous tissue is found in the cervical region and is often recognized by a pink spot in that area of the crown.

ENDODONTIC IMPLICATIONS

Endodontic treatment may only promote the resorption process and is therefore not indicated.

TREATMENT

There is currently no predictable treatment available, so the gradual replacement of involved teeth with implants appears to be all that can be offered.

Cervical Invasive Resorption

ETIOLOGY

The cause of cervical invasive resorption may possibly be related to a defect in the cementoblast layer in its RANK-RANKL-OPG system.² In a large clinical study of 259 teeth with invasive cervical resorption, Heithersay found that 23% were related to orthodontic treatment, 15% to acute trauma, and 14% to a cervical restoration.⁵²

PATHOGENESIS

The initial cervical resorption cavity gradually spreads and may progress in both an apical and a coronal direction, leading eventually to a tooth fracture.

CLINICAL FINDINGS

Often expansive lesions will show up as a “pink spot” next to the cervical margin (Figure 21C).

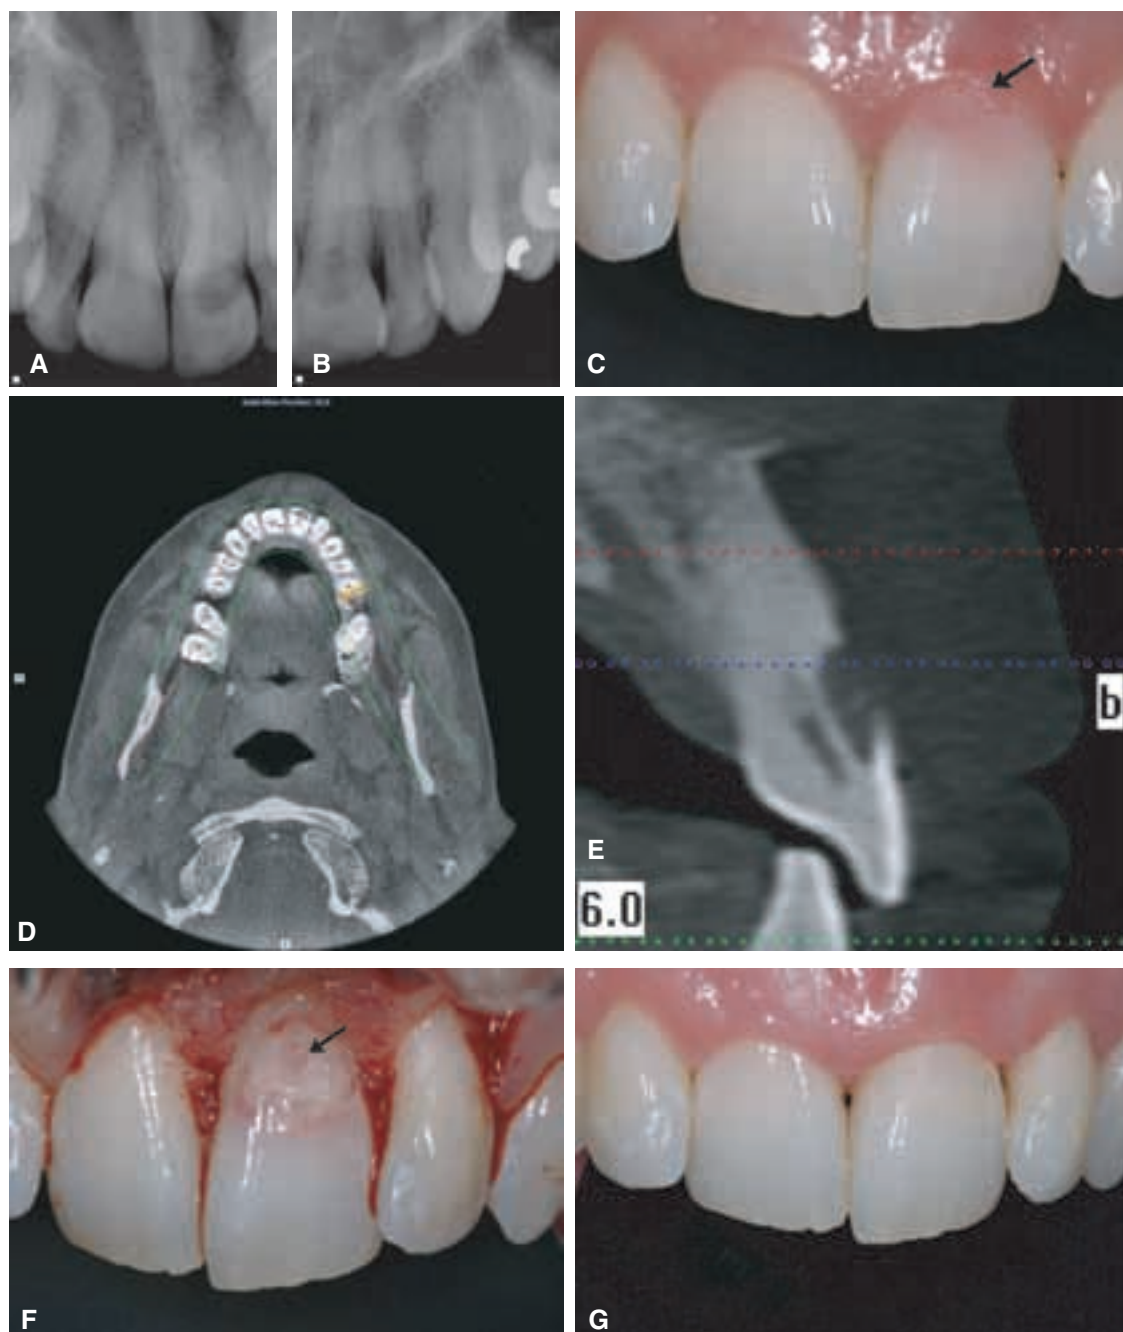

Figure 21 Maxillary central incisor with cervical invasive resorption. The tooth was intact, with no carious lesions. Possible history of trauma many years earlier. **A** and **B**, Periapical radiographs show two views of the well-delineated lesion. **C**, Clinical photograph shows the location of the resorptive lesion (*arrow*), giving the tooth a “pink tooth” appearance. **D** and **E**, Two views obtained with a cone beam three-dimensional imaging system (I-CAT, Imaging Science Int., Inc., Hatfield, PA). Note the ability to clearly determine the location and size of the lesion and relationship to the pulp. Cervical invasive resorptions do not invade the pulps directly, something that can be demonstrated with imaging of this nature. **F**, Removal of the granulation tissue in the resorptive lesion shows a thin layer of dentin covering the pulp (*arrow*). **G**, Appearance after restoration with dentin-bonded restoration. If pulpal symptoms develop, endodontic treatment is indicated. Reproduced with permission from the Endodontic Clinic, Loma Linda University, CA.

RADIOGRAPHIC FINDINGS

A cervical bowl-shaped lesion is the start of an invasive progression of resorption in coronal and apical directions. The pulp canal is not invaded in the initial phases (Figure 21A, B, D, and E).

Endodontic Implications

The pathology is entirely related to a PDL defect and therefore does not primarily imply endodontic considerations. However, the invasive nature of the resorption process will finally encroach on the pulp cavity, necessitating endodontic treatment.⁵³

TREATMENT

A surgical flap can be raised to remove the granulation tissue and to place a dentin-bonded restoration (Figure 21F and G). The prognosis appears to be strongly related to the apical extension of the resorption process (Figure 22).⁵⁴

Internal Surface Resorption

ETIOLOGY

Internal surface resorption can be found in areas where revascularization occurs, such as in fracture lines of root fractures and in the apical part of the root canal of a luxated tooth undergoing revascularization (see Figure 6B and Figure 23).⁵⁵

PATHOGENESIS

Osteoclastic activity is part of the process, along with the formation of granulation tissue.

RADIOGRAPHIC FINDINGS

Radiographically, there appears to be a temporary widening of the root canal.

ENDODONTIC IMPLICATIONS

It is very important to consider that this resorption process is a sign of progressing pulp healing and that any endodontic intervention may arrest this process.

Figure 22 Prognosis of treatment related to the initial extent of cervical invasive resorption. Reproduced with permission from Heithersay GS.⁵³

Figure 23 Internal (root canal) surface resorption.

TREATMENT

No treatment is recommended except periodic observation.

Internal Infection-Related Root Resorption

ETIOLOGY

Coronal to the resorption site in the pulp, necrotic infected tissue (root canal and dentinal tubules or

Figure 24 Internal infection-related root resorption. The resorption site represents resorbing granulation tissue interposed between vital (apically) and diseased (coronally) pulp tissue.

pulp tissue with chronic inflammation) is found. The resorption site represents resorbing granulation tissue interposed between healthy and diseased pulp tissue (Figure 24).⁵⁵ This type of resorption can also be found associated with tooth infractions (see Chapter 19, “Tooth Infractions”).

PATHOGENESIS

The resorptive process will gradually expand, leading to a fracture of the root.

Figure 25 Teeth with internal root resorption can be treated successfully with any of the many endodontic techniques that allow filling material to be compacted into canal irregularities. **A**, Preoperative radiograph of a maxillary central incisor with internal resorption midroot. **B**, Radiograph after completion of the endodontic treatment procedure. Courtesy of Dr. Steve Morrow, Loma Linda University, CA.

TREATMENT

Endodontic treatment is appropriate and requires a technique that allows management of the resorbed area of the root canal (Figure 25).

Internal Replacement Resorption

ETIOLOGY

When damaged pulp tissue is replaced as part of a healing process, tissue metaplasia may take place, leading to formation of bone tissue in the pulp canal. The damage to the pulp tissue is usually related to trauma, and the damaged pulp tissue is replaced with an ingrowth of new tissue, which includes bone-derived cells.⁵⁴

PATHOGENESIS

The root will gradually be replaced with bone. In some cases, the bone replacement will spontaneously arrest.

CLINICAL FINDINGS

The teeth are asymptomatic, but if ankylosis occurs, the teeth will gradually develop infraocclusion.

RADIOGRAPHIC FINDINGS

A dissecting resorptive area may be seen in the root canal; initially, the root canal appears intact. Mesio-distal and orthoradiographic exposures should verify the central location of the ankylosis site.

ENDODONTIC IMPLICATIONS

Since the eventual outcome of allowing this type of condition to continue is the loss of the tooth, it may be advantageous to treat the tooth endodontically, in spite of the fact that it may lead to a poor prognosis owing to the lack of root maturity.

Summary

With few exceptions, pathologic tooth resorptions have endodontic implications that knowledgeable clinicians can address. It is clear that most infection-related resorptions respond well to endodontic treatment. It is hoped that the future will provide avenues for successful management of ankylosis-related resorptions that currently are not available.

CHAPTER 38

TOOTH DISCOLORATION AND BLEACHING

ILAN ROTSTEIN, YIMING LI

Tooth discoloration is a clinical problem in dental practice. Both intracoronal and extracoronal bleaching techniques have been used to correct tooth color.

Etiology of Tooth Discoloration

Tooth discoloration is defined as “any change in the hue, color, or translucency of a tooth due to any cause; restorative filling materials, drugs (both topical and systemic), pulpal necrosis, or hemorrhage may be responsible.”¹ The discoloration may be induced by intrinsic stains incorporated in tooth structures and extrinsic stains deposited on tooth surfaces (Table 1). This can be due to patient- or dentist-related causes^{2,3} as shown in Table 1.

PATIENT-RELATED CAUSES

Pulp Necrosis

Bacterial, mechanical, or chemical irritation to the pulp may result in tissue necrosis. Disintegration by-products penetrate the dentinal tubules and discolor the surrounding dentin. The degree of discoloration is directly related to how long the pulp has been necrotic. The longer the discoloring compounds are present in the pulp chamber, the greater is the discoloration. This type of discoloration can usually be bleached intracoronally (Figure 1).

Intrapulpal Hemorrhage

Intrapulpal hemorrhage and lysis of erythrocytes are common results of traumatic injury to a tooth. Blood disintegration products, mainly iron sulfides, flow into the tubules and discolor the surrounding dentin. If the pulp becomes necrotic, the discoloration persists and usually becomes more severe with time. If the pulp recovers, the discoloration may be reversed, with the tooth regaining its original shade. The severity of such discoloration is again time-dependent;

Table 1 Major Sources of Tooth Stains

Extrinsic Stains	Intrinsic Stains
Foods	Aging
Beverages	Pulpal necrosis
Mouth rinses	Intrapulpal hemorrhage
Tobacco products	Calcific metamorphosis
Restorative materials	Drugs (e.g., tetracycline)
Chromogenic microorganisms	Diseases (e.g., porphyria, erythroblastosis fetalis)

intracoronal bleaching is usually quite effective in this type of discoloration.⁴⁻⁶

Calcific metamorphosis

Calcific metamorphosis is seen most frequently in the anterior teeth, and it is a pulpal response to trauma that is characterized by rapid deposition of hard tissue within the root canal space.⁷ In certain traumatic injuries, a temporary disruption of blood supply occurs, followed by the destruction of odontoblasts. These are replaced by undifferentiated mesenchymal cells that rapidly form reparative dentin. As a result, the translucency of the crowns of such teeth gradually decreases, giving rise to a yellowish or a yellow-brown discoloration. Root canal therapy is often required, followed by intracoronal bleaching.

Age

Tooth color tends to become progressively darker with age, which is a physiological change resulting from dentin apposition and thinning of the enamel, and changes of optical properties of tooth structure. Cumulative extrinsic stains from food and beverages also contribute to this type of tooth discoloration, which becomes more pronounced in the elderly, owing to the inevitable cracking, crazing, and incisal

Figure 1 **A**, Posttraumatic discoloration of a maxillary central incisor caused by pulpal necrosis. **B**, A mixture of sodium perborate and distilled water, placed in the chamber two times for over 3 weeks, achieved lightening of the tooth to its natural color. Reproduced with permission from Claisse-Crinquette A, *Endo Contact*, Paris, France; 1999;2:16.

wear of the enamel and the underlying dentin. When indicated, extracoronary bleaching can be successful for many types of discolorations in elderly patients.

Developmental Defects in Tooth Structure

Discoloration may result from developmental defects during enamel and dentin formation, either hypocalcific or hypoplastic. Enamel *hypocalcification*, a distinct brownish or whitish area, is commonly found on the facial aspect of affected crowns. The enamel is well formed with an intact surface.

Enamel *hypoplasia* differs from hypocalcification in that the enamel is defective and porous. This condition may be hereditary, as in *amelogenesis imperfecta*, or hereditary hypophosphatemia, or a result of environmental factors such as infections, tumors, or trauma. Presumably, during enamel formation, the matrix is altered and does not mineralize properly. The defective enamel is porous and readily discolored by materials in the oral cavity. In such cases, bleaching effect may not be permanent, depending on the severity and extent of hypoplasia and the nature of discoloration.

Dental fluorosis, or mottled tooth, is a type of enamel hypoplasia. It is caused by the excessive exposure to fluoride during tooth formation, resulting in defects in mineralized structures, particularly in the enamel matrix. The severity of subsequent staining generally depends on the degree of hypoplasia that is directly related to the amount of fluoride exposure during odontogenesis.⁸ The affected teeth are not discolored on eruption, but their porous surface

attracts extrinsic stains present in the oral cavity. Discoloration is usually bilaterally symmetric. It presents as various degrees of intermittent white spotting, chalky or opaque areas, yellow or brown discoloration, and, in severe cases, surface pitting of the enamel. Discoloration of mild to moderate dental fluorosis can be bleached externally (Figure 2) however, restorative approaches should be considered for the cases of severe dental fluorosis.

Several systemic conditions may also cause tooth discoloration. *Erythroblastosis fetalis*, for example, may occur in the fetus or in a newborn because of Rh-incompatibility factors, resulting in the lysis of erythrocytes and incorporation of hemosiderin pigment in the forming dentin.⁹ However, such discoloration is now uncommon. High fever during tooth formation may result in chronologic enamel hypoplasia that gives rise to banding-type surface discoloration. Porphyria, a metabolic disease, may also cause reddish or brownish discoloration of deciduous and permanent teeth. Thalassemia and sickle cell anemia may cause intrinsic blue, brown, or green discolorations. *Amelogenesis imperfecta* may result in yellow or brown discolorations. *Dentinogenesis imperfecta* causes brownish violet, yellowish, or gray discoloration. These conditions are usually not amenable to bleaching and correction by restorative means is preferred.

Tetracycline

Administration or ingestion of certain drugs during tooth formation may cause severe discoloration both

Figure 2 Fluorosis of central incisors treated by external bleaching. **A**, Before treatment. **B**, One month following external bleaching treatment. Reproduced with permission from Meyers, DL.

in enamel and dentin.^{10–12} Tetracycline is an antibiotic that was used extensively during the 1950s and 1960s for prophylactic protection and for the treatment of chronic obstructive pulmonary disease, mycoplasma, and rickettsial infections. It was sometimes prescribed for long periods of time, years in some cases, and therefore was a common cause of tooth discoloration in children. While tetracycline is no longer prescribed for prolonged periods, dentists still face the residue of damage to the teeth appearance of the prior two generations.

Tooth shades can be yellow, yellow-brown, brown, dark gray, or blue depending on the type of tetracycline, dosage, duration of intake, and patient's age at the time of administration. Discoloration is usually bilateral, affecting multiple teeth in both arches. Deposition of tetracycline may be continuous or in stripes depending on whether the ingestion was continuous or interrupted (Figure 3).

The mechanism of tetracycline discoloration is not fully understood. Tetracycline bound to calcium is thought to be incorporated into the hydroxyapatite crystal of both enamel and dentin, but mostly found in dentin. The exposure of tetracycline-stained teeth to ultraviolet radiation leads to the formation of a reddish-purple oxidation by-product that discolors the teeth. In children, the anterior teeth often discolor first, whereas the less-exposed posterior teeth are discolored more slowly. In adults, natural photobleaching of the anterior teeth has been observed, particularly in individuals whose teeth are excessively exposed to sunlight owing to maxillary lip insufficiency.

Tetracycline discoloration has been classified into three groups according to severity.¹³ First-degree discoloration is light yellow, light brown, or light gray and occurs uniformly throughout the crown, without banding. Second-degree discoloration is more intense and also without banding. Third-degree discoloration

Figure 3 Fluorescent photomicrograph of tetracycline-discolored tooth. Tetracycline deposition is seen as stripes caused by start and stop ingestion. Reproduced with permission from Meyers, DL.

is very intense, and the clinical crown exhibits horizontal color banding. This type of discoloration usually predominates in the cervical regions.

Correction of tetracycline-stained teeth may pose a clinical challenge. For mild to certain moderate cases, repeated external bleaching for an extended period can be effective^{14,15} (Figure 4); however, severe cases, especially those of dark gray color, should be corrected by restorative means.

DENTIST-RELATED CAUSES

Tooth discolorations caused by certain dental materials or inappropriate operating techniques do occur; such dentist-related discolorations are usually preventable and efforts should be made to avoid them.

Pulp Tissue Remnants

The tissue remaining in the pulp chamber disintegrates gradually and may cause discoloration. Therefore, pulp horns must always be included in the access cavity to ensure removal of pulpal remnants and to prevent retention of sealers at a later stage. Intracoronary bleaching in these cases is usually successful.

Intracanal Medicaments

Several intracanal medicaments can cause internal staining of dentin. Phenolics or iodoform-based medicaments sealed in the root canal and chamber are in direct contact with dentin, sometimes for long periods, allowing penetration and oxidation. These compounds have a tendency to discolor the dentin gradually. Intracoronary bleaching may be used to correct the problem.

Obturing materials

This is a frequent and severe cause of single tooth discoloration. Incomplete removal of obturating materials and sealer remnants from the pulp

Figure 4 Extracoronary bleaching of tetracycline-discolored maxillary incisors. **A**, Before bleaching. **B**, After three sessions of heat-activated bleaching as compared to unbleached discolored mandibular incisors.

chamber, mainly those containing metallic components, often results in dark discoloration.^{16–18} This can be easily prevented by removing all materials to a level just below the gingival margin (Figure 5). Intracoronary bleaching is the treatment of choice in addition to removing the obturating material; prognosis, however, depends on the type of sealer and the duration of discoloration.

Amalgams

Amalgams are frequently used to restore lingual access preparations or a developmental groove in anterior and premolar teeth. In addition to the inherent dark, metallic color of an amalgam restoration, amalgams degrade over time and corrosion products can cause tooth discoloration. Such discolorations are difficult to bleach and tend to redden with time.

Sometimes the dark appearance of the crown is caused by an amalgam restoration that can be seen through the tooth structure. In such cases, replacing the amalgam with an esthetic restoration usually corrects the problem.

Pins and Posts

Metal pins and prefabricated posts have sometimes been used to reinforce a composite restoration in the anterior dentition. Discoloration from inappropriately placed pins and posts is caused by the metal seen through the composite or tooth structure. In such cases, coverage of the pins with a white cement or removal of the metal and replacement of the composite restoration is indicated.

Resin Composites

Microleakage around resin composite restorations attracts extrinsic stains. Open margins allow stains to enter the interface between the restoration and the tooth structure and discolor the underlying dentin. Resin composites may also become discolored with time, affecting the shade of the crown. These conditions are generally corrected by replacing the old composite restoration with a new, well-sealed one.

Tooth Bleaching

Bleaching is a treatment modality involving an oxidative chemical that alters the light-absorbing and/or light-reflecting nature of a material structure, thereby increasing its perception of whiteness. In-office tooth bleaching using peroxide compounds, both intracoronally and extracoronally, has been practiced in dentistry for more than a century.¹⁹ At-home bleaching, however, was not widely available until 1989.²⁰

BLEACHING MATERIALS

The active ingredient in tooth bleaching materials is peroxide compounds. While currently a variety of bleaching materials are available, the most commonly used peroxide compounds are hydrogen peroxide, sodium perborate, and carbamide peroxide. Bleaching materials for extracoronary bleaching mainly contain hydrogen peroxide and carbamide peroxide, whereas sodium perborate is used

Figure 5 Gutta-percha, sealer, and dentin removal prior to bleaching. Green-dotted area represents gutta-percha filling that is removed to a level below the attached gingiva (open arrow) along with the removal of dentin to eliminate heavy stain concentration and pulp horn material (black arrow).

for intracoronal bleaching. Both sodium perborate and carbamide peroxide decompose to release hydrogen peroxide in an aqueous medium.

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) is used in both in-office and at-home bleaching materials. In-office bleaching materials contain high concentrations of H_2O_2 (typically 25% to 38%), while the H_2O_2 concentration in at-home bleaching products usually range from 3% to 7.5%; however, there have been products containing up to 14% H_2O_2 for home use by patients.

H_2O_2 at high concentration, such as those in the in-office bleaching materials, is caustic and burns tissues

on contact. These materials must be handled with care to avoid their contact with tissues during the handling and bleaching treatment.

Sodium Perborate

Sodium perborate ($NaBO_3$) is available in powdered form or as various commercial preparations. When fresh, it contains about 95% perborate, corresponding to 9.9% of the available oxygen. Sodium perborate is stable when dry. In the presence of acid, warm air, or water, however, it decomposes to form sodium metaborate, H_2O_2 , and nascent oxygen.

Three types of sodium perborate preparations are available: monohydrate, trihydrate, and tetrahydrate. They differ in oxygen content that determines their bleaching efficacy.²¹ Commonly used sodium perborate preparations are alkaline, and their pH depends on the amount of H_2O_2 released and the residual sodium metaborate.²²

Sodium perborate is more easily controlled and is safer than concentrated H_2O_2 . Therefore, it is the material of choice in most intracoronal bleaching procedures (Figure 6).

Figure 6 Sodium perborate powder and water are mixed to a thick consistency of wet sand.

Carbamide Peroxide

Carbamide peroxide ($\text{CH}_6\text{N}_2\text{O}_3$), also known as urea hydrogen peroxide, exists in the form of white crystals or as a crystallized powder containing approximately 35% H_2O_2 . It forms H_2O_2 and urea in aqueous solution. It is mostly used in home-use bleaching materials with concentrations ranging from 10 to 30% (equivalent to approximately 3.5% to 8.6% H_2O_2); however, those containing 10% carbamide peroxide appear to be the most common.

Bleaching preparations containing carbamide peroxide usually also include glycerine or propylene glycol, sodium stannate, phosphoric or citric acid, and flavor additives. In some preparations, carbopol, a water-soluble polyacrylic acid polymer, is added as a thickening agent. Carbopol also prolongs the release of active peroxide and improves shelf life.

BLEACHING MECHANISMS

The mechanisms of tooth bleaching remain unclear at present; however, it is generally believed that free radicals produced by H_2O_2 may be responsible for bleaching effects, and they are similar to that in textile and paper bleaching. H_2O_2 diffuses through the enamel and dentin, producing free radicals that react with pigment molecules breaking their double bonds. The change in pigment molecule configuration and/or size may result in changes in their optical properties, and consequently, the perception of a lighter color by human eyes. This assumption also helps to explain the common observation of shade rebounding shortly after the bleaching treatment, probably due to the reformation of double bonds. In addition to the chemical effect, other possible mechanisms include cleansing of tooth surface, temporary dehydration of enamel during the bleaching process, and change of enamel surface.

A number of factors, relating to both the patient (e.g., age, gender, and initial tooth color), the bleaching material used (e.g., type of peroxide compound, peroxide concentration, other ingredients), and application method (e.g., contact time, application frequency, enamel prophylaxis prior to bleaching treatment), may contribute to the bleaching efficacy and the subsequent stability of the bleaching achieved. Among these factors, the contact time of the bleaching material to the enamel surface appears to be more influential than the others.²³

INTRACORONAL BLEACHING OF ENDODONTICALLY TREATED TEETH

Intracoronar bleaching of endodontically treated teeth may be successfully carried out many years after root

Table 2 Indications and Contraindications for Bleaching Endodontically Treated Teeth

Indications	Contraindications
Discolorations of pulp chamber	Superficial enamel discolorations
Dentin discolorations	Defective enamel formation
Discolorations not amenable to extracoronar bleaching	Severe dentin loss
	Presence of caries
	Discolored composites

canal therapy and discoloration. A successful outcome depends mainly on the etiology, correct diagnosis, and proper selection of bleaching technique (Table 2).

The methods most commonly employed to bleach endodontically treated teeth are the “walking bleach” and the thermocatalytic techniques. Walking bleach is preferred since it requires less chair time and is safer and more comfortable for the patient.^{24–27}

Walking Bleach

The term *walking bleach* was first coined by Nutting and Poe²⁸ in 1961 referring to the bleaching action occurring between patients’ visits. Since that time, the technique evolved and underwent few modifications, mainly by eliminating the use of Superoxol (H_2O_2 , 30%) making it a very popular and safe technique.^{27,29} The walking bleach technique should be attempted first in all cases requiring intracoronar bleaching. It involves the following steps:

1. Familiarize the patient with the possible causes of discoloration, the procedure to be followed, the expected outcome, and the possibility of future rediscoloration.
2. Radiographically assess the status of the periapical tissues and the quality of endodontic obturation. Endodontic failure or questionable obturation should always be retreated prior to bleaching.
3. Assess the quality and shade of any restoration present and replace it if defective. Tooth discoloration is frequently the result of leaking or discolored restorations. In such cases, cleaning the pulp chamber and replacing the defective restorations will usually suffice.
4. Evaluate tooth color with a shade guide and, if possible, take clinical photographs at the beginning of and throughout the procedure. These provide a point of reference for future comparison.
5. Isolate the tooth with a rubber dam. The dam must fit tightly at the cervical margin of the tooth

- to prevent possible leakage of the bleaching agent onto the gingival tissue. Interproximal wedges and ligatures may also be used for better isolation.
6. Remove all restorative materials from the access cavity, expose the dentin, and refine the access. Verify that the pulp horns and other areas containing the pulp tissue are clean.
 7. Remove all materials to a level just below the labial–gingival margin. Orange solvent, chloroform, or xylene on a cotton pellet may be used to dissolve sealer remnants. Etching the dentin with phosphoric acid is unnecessary and may not improve the prognosis.³⁰
 8. Apply a sufficiently thick layer, at least 2 mm, of a protective white cement barrier, such as polycarboxylate cement, zinc phosphate cement, glass ionomer, intermediate restorative material (IRM) (Dentsply/Caulk, York, PA), or Cavit (3M ESPE, St. Paul, MN,) to cover the endodontic obturation. The coronal height of the barrier should protect the dentinal tubules and conform to the external epithelial attachment.³¹
 9. Prepare the walking bleach paste by mixing sodium perborate and an inert liquid, such as water, saline, or anesthetic solution, to a thick consistency of wet sand. Although sodium perborate plus 30% H₂O₂ mixture may bleach faster, in most cases, long-term results are similar to those with sodium perborate and water alone and therefore need not be used routinely.^{5,6,29} With a plastic instrument, pack the pulp chamber with the paste. Remove excess liquid by tamping with a cotton pellet. This also compresses and pushes the paste into all areas of the pulp chamber.
 10. Remove the excess bleaching paste from undercuts in the pulp horn and gingival area and apply a thick well-sealed temporary filling (preferably IRM) directly against the paste and into the undercuts. Carefully pack the temporary filling, at least 3 mm thick, to ensure a good seal.
 11. Remove the rubber dam and inform the patient that bleaching agents work slowly and that significant lightening may not be evident for several days.
 12. Evaluate the patient 2 weeks later and, if necessary, repeat the procedure several times.²⁷ Repeat treatments are similar to the first one.
 13. As an optional procedure, if initial bleaching is not satisfactory, strengthen the walking bleach paste by mixing sodium perborate with gradually increasing concentrations of H₂O₂ (3% to 30%) instead of water. The more potent oxidizers may have an enhanced bleaching effect but are not used routinely because of the possibility of permeation into the tubules and damage to the cervical periodontium by these more caustic agents. In such cases, a protective cream, such as Orabase or Vaseline, must be applied to the surrounding gingival tissues prior to dam placement.
 14. In most cases, discoloration will improve after 1 to 2 treatments. If after three attempts there is no significant improvement, reassess the case for correct diagnosis of the etiology of discoloration and treatment plan.

Thermocatalytic

This technique involves placement of the oxidizing chemical, generally 30% to 35% H₂O₂ (Superoxol), into the pulp chamber followed by heat application either by electric heating devices or specially designed lamps.³² Care must be taken when using these heating devices to avoid overheating of the teeth and the surrounding tissues. Intermittent treatment with cooling breaks is preferred over a continuous session. In addition, the surrounding soft tissues should be protected with Vaseline, Orabase, or cocoa butter during treatment to avoid heat damage.

Potential damage by the thermocatalytic approach is external cervical root resorption caused by irritation to the cementum and the periodontal ligament. This is possibly attributable to the oxidizing agent combined with heating.^{33,34} Therefore, application of highly concentrated H₂O₂ and heat during intracoronal bleaching is questionable and should not be carried out routinely.

Ultraviolet Photooxidation

This technique applies ultraviolet light to the labial surface of the tooth to be bleached. A 30% to 35% H₂O₂ solution is placed in the pulp chamber on a cotton

pellet followed by a 2-minute exposure to ultraviolet light. Supposedly, this causes oxygen release, like the thermocatalytic bleaching technique.³⁵

COMPLICATIONS AND ADVERSE EFFECTS FROM INTRACORONAL BLEACHING

External Root Resorption

Clinical reports^{36–46} and histological studies^{33,34,47} have shown that intracoronar bleaching may induce external cervical root resorption (Table 3) and (Figure 7). This is probably caused by the highly concentrated oxidizing agent, particularly 30 to 35% H₂O₂. The mechanism of bleaching-induced damage to the periodontium or the cementum is not completely clear. Presumably, the irritating chemical diffuses via unprotected dentinal tubules and cementum defects^{48,49} and causes necrosis of the cementum, inflammation of the periodontal ligament, and, subsequently, root resorption. The process may be enhanced if heat is applied⁵⁰ or in the presence of bacteria.⁵¹ Previous traumatic injury and age may act as predisposing factors.^{36,52}

Chemical Burns

Superoxol (H₂O₂ at 30%) is highly caustic and causes chemical burns and sloughing of the gingiva. When using such solutions, the soft tissues should always be protected with Vaseline, Orabase, or cocoa butter.

Inhibition on Resin Polymerization and Bonding Strength

Oxygen inhibits resin polymerization; consequently, residual H₂O₂ in tooth structure after bleaching adversely affects the bonding strength of resin composites to enamel and dentin.^{53,54} Scanning electron microscopy (SEM) examination has shown an increase in resin porosity.⁵⁵ This presents a clinical problem when immediate esthetic restoration of the bleached tooth is required. It is therefore recommended that residual H₂O₂ be totally eliminated prior to composite placement. One study reported that 3 minutes of catalase treatment effectively removed all of the residual H₂O₂ from the pulp chamber of human teeth.⁵⁶

SUGGESTIONS FOR SAFE BLEACHING OF ENDODONTICALLY TREATED TEETH

- Isolate the tooth effectively. Intracoronar bleaching should always be carried out under rubber dam isolation. Interproximal wedges and ligatures may also be used for better protection.
- Protect the oral mucosa. Protective creams, such as Orabase or Vaseline, must be applied to the surrounding oral mucosa to prevent chemical burns by caustic oxidizers. Animal studies suggest that catalase applied to oral tissues prior to bleaching treatment totally prevents the associated tissue damage.⁵⁷
- Verify adequate endodontic obturation. The quality of root canal obturation should always be assessed

clinically and radiographically prior to bleaching. Adequate obturation ensures a better overall prognosis of the treated tooth. It also provides an additional barrier against damage by oxidizers to the periodontal ligament and periapical tissues.

- Use protective barriers over the coronal extent of the root canal filling. This is essential to prevent leakage of bleaching agents that may infiltrate between gutta-percha and root canal walls, reaching the periodontal ligament via dentinal tubules, lateral canals, or the root apex. In none of the clinical reports of postbleaching root resorption was a protective barrier used. Various materials can be used for this purpose. Barrier thickness and its relationship to the cemento-enamel junction are most important.^{31,58} The ideal barrier should protect the dentinal tubules and conform to the external epithelial attachment (Figure 8).
- Avoid acid etching. It has been suggested that acid etching of dentin in the chamber to remove the smear layer and open the tubules would allow better penetration of the oxidizer. This procedure has not

proved beneficial.³⁰ The use of caustic chemicals in the pulp chamber is undesirable as they may result in irritation to the periodontal ligament.

- Avoid strong oxidizers. Procedures and techniques applying strong oxidizers should be avoided if they are not essential for bleaching. Solutions of 30% to 35% H₂O₂, either alone or in combination with other agents, should not be used routinely for intracoronal bleaching. Sodium perborate is mild and quite safe, and usually no additional protection of the soft tissues is required. Generally, however, oxidizing agents should not be exposed to more of the pulp space and dentin than absolutely necessary to obtain a satisfactory clinical result.
- Avoid heat. Excessive heat may damage the cementum and the periodontal ligament as well as dentin and enamel, especially when combined with strong oxidizers.^{33,34} Although no direct correlation has been established between heat application and external cervical root resorption, it should be limited during bleaching procedures.

Figure 8 Schematic illustration of the intracoronal protective bleach barrier. The shape of the barrier matches the contour of the external epithelial attachment. Reproduced with permission from Steiner DR and West JD, *J Endod* 1994;20:304.

- Recall periodically. Bleached teeth should be frequently examined both clinically and radiographically. Root resorption may occasionally be detected as early as 6 months after bleaching. Early detection improves the prognosis since corrective therapy may still be applied.

RESTORATION OF INTRACORONALLY BLEACHED TEETH

Proper tooth restoration is essential for long-term successful bleaching results. Microleakage of lingual access restorations is a problem,⁵⁹ and a leaky restoration may again lead to tooth discoloration.

There is no ideal method for filling the chamber after intracoronal bleaching. The pulp chamber and the access cavity should be carefully restored with a light

shade, light-cured, acid-etched composite resin. The composite material should be placed at a depth that seals the cavity and provides some incisal support. Light curing from the labial surface, rather than the lingual surface, is recommended since this results in the shrinkage of the composite resin toward the axial walls, reducing the rate of microleakage.⁶⁰ Placing white cement beneath the composite access restoration is recommended. Filling the chamber completely with composite may cause loss of translucency and difficulty in distinguishing between composite and tooth structure during rebleaching.⁶¹

As stated previously, residual H_2O_2 from bleaching treatment may adversely affect the bonding strength of composites.⁵³ Therefore, waiting for at least 7 days after bleaching, prior to restoring the tooth with resin composites, has been recommended. Catalase treatment at the final visit may enhance the removal of residual peroxides from the access cavity; however, this requires further clinical investigation.⁵⁶ Packing calcium hydroxide paste in the pulp chamber for a few weeks prior to the placement of final restoration, to counteract acidity caused by bleaching agents and to prevent root resorption, has also been suggested; this procedure, however, is unnecessary with walking bleach.²²

EXTRACORONAL BLEACHING

Extracoronary bleaching may be used for whitening vital or nonvital teeth as well as a single tooth or whole arch. It has experienced a dramatic advancement in materials as well as techniques after at-home extracoronary bleaching was first introduced.^{20,62} Research efforts and clinical advancements have also revolutionized the in-office extracoronary bleaching technology.

In-office Extracoronary Bleaching

Various materials and clinical procedures are available for in-office extracoronary bleaching, also called chair-side bleaching or power bleaching. As indicated by the terms, the bleaching procedures are performed in the clinic by a dental professional.

Current commercial in-office bleaching materials are almost exclusively in the form of a gel, with 25% to 38% H_2O_2 . It is not advisable to directly use high concentrations of aqueous H_2O_2 solutions for tooth bleaching as practiced in early years. Besides a higher risk of tissue contact due to its lack of proper viscosity, the high concentrations of aqueous H_2O_2 solutions are thermodynamically unstable and may explode unless properly stored in a dark container and kept refrigerated.

Figure 9 Extracoronary mouthguard bleaching with carbamide peroxide gel. **A**, Before treatment. **B**, Bleaching results of the maxillary teeth after two treatments. Discolored teeth that are not internally stained gel will respond to external bleaching. Subsequently, the patient may maintain the color with an occasional repeat of the procedure with the bleaching gel. Courtesy, Ultradent Products, Inc.

In-office extracoronary bleaching may be performed using a bleaching gel alone or a gel with a *light*. In early years of in-office bleaching, heat, electric current, and other chemicals such as ether were often applied with H_2O_2 solution in an attempt to enhance its bleaching efficacy.¹⁹ While these approaches are rarely seen in current practice, various lights have been used during the in-office bleaching process; the light may be specialized for such procedure, or it can be a regular curing light for resin composites. The light source can be a laser (e.g., argon, CO_2), halogen, plasma arc, or light-emitting diodes (LED). The wavelength may range from high ultraviolet spectra, low visible blue light spectra, to invisible infrared spectra such as the CO_2 laser.^{32,63} Studies have found no significant advantages of using laser lights for bleaching; consequently, laser bleaching has become less popular than other light systems.³²

The light exposure is intended to enhance the bleaching efficacy by activating the bleaching gel, either through a specific catalyst or heat, to promote the decomposition process of H_2O_2 . So far, however, the research on the efficacy of using the light for in-office bleaching has been limited, and the results have been controversial; several studies reported an enhancing effect, while others detected no differences between teeth bleached with and without a light.^{32,63–65} In general, there may be a short-term effect of the light exposure depending on the in-office bleaching and light system. However, currently long-term studies are insufficient regarding the benefits of light-activated bleaching.

At-home Extracoronary Bleaching

A large variety of at-home bleaching products are available. In addition to those offered by dental professionals, various over-the-counter (OTC) tooth bleaching products are available directly to consumers. Most of the at-home bleaching products are gel formulations, although the form of a paste has also been used.

For *professional at-home bleaching*, custom tray technique is most commonly used. The bleaching gel is loaded in the tray, and the patient wears the tray for several hours up to overnight daily usually for 2 weeks or until a satisfactory tooth shade is achieved. Both H_2O_2 and carbamide peroxide are used as active ingredients for professional at-home bleaching products, mostly containing 3% to 7.5% H_2O_2 or 10 to 22% carbamide peroxide, with latter, especially those with 10% carbamide peroxide, being more popular (Figure 9). An H_2O_2 -based professional bleaching strip is also available for at-home bleaching. As the application technique may vary, it is advisable that clinicians follow manufacturers' instructions for using such treatment modality.

While the majority of the *OTC at-home bleaching* materials are also gels, their application may use trays, strips, or brushes. In addition to the bleaching gel, some products offer prebleaching rinses and after-bleaching rubbing-on powders. The range of peroxide content in OTC bleaching products is comparable to that of the professional at-home bleaching materials; however, the quality of the OTC products may vary

greatly. Their peroxide content may not be consistent and stable, and some products, including the pre-bleaching rinses, may come with an excessively low pH.

COMPLICATIONS AND ADVERSE EFFECTS FROM EXTRACORONAL BLEACHING

Extracoronary tooth bleaching can provide lighter tooth shade that is retained up to 10 years after the initial professional tray bleaching treatment.⁶⁶ However, there have been concerns with its safety since the introduction of at-home bleaching materials.^{19,67–72} The safety concerns are mainly associated with potential toxicological effects of free radicals produced by the peroxides used in the bleaching materials. Free radicals are known to be capable of reacting with proteins, lipids, and nucleic acids, consequently causing cellular damage. Consequently, the topic of bleaching safety has been controversial. It appears, however, that no significant long-term oral or systemic health risks are associated with professional extracoronary bleaching with materials containing 10% carbamide peroxide. However, adverse effects may occur depending on the quality of the bleaching material, the techniques used, and the individual's response to the bleaching treatment.

Tooth Sensitivity

Tooth sensitivity to temperature changes is a commonly observed clinical side effect during or after extracoronary bleaching of vital teeth, with an incidence of up to 50%.⁷³ The sensitivity, usually mild to moderate and transient, often occurs during the early stages of treatment and usually persists for 2 to 3 days.^{73–75} The development of tooth sensitivity does not appear to be related to the patient's age or sex, defective restorations, enamel–cementum abrasion, or the dental arch treated; however, the risk increases in patients who change the bleaching gel more than once a day.⁷³ If the patient develops significant sensitivity, shorter bleaching periods are recommended. Topical fluoride application and desensitizing toothpastes may also be used to alleviate the symptoms.

Tooth sensitivity has been suggested as an indication of possible pulpal inflammation.⁷¹ Studies, most of which are used in vitro models, have shown that H₂O₂ in bleaching gel applied on the enamel surface is capable of penetrating through the enamel and dentin and reaching the pulp chamber.^{76–82} Less than 30 μg of H₂O₂ may reach the dental pulp after application of gels with up to 12% H₂O₂ on the enamel surface for up to 7 hours. The amount of H₂O₂ detected in the pulp chamber tends to increase with time and

H₂O₂ concentration in the gel, but not proportionally. It has been suggested that 50,000 μg H₂O₂ is needed to inhibit pulpal enzymes, so that the detected amount of H₂O₂ penetrated into the pulp chamber from the at-home whiteners appears unlikely to cause significant damage to the pulp tissues. However, sufficient in vivo studies on this topic are lacking. Therefore, adequate cautions are advisable, and extracoronary bleaching should not be performed on teeth with caries, exposed dentin, or in close proximity to pulp horns. Defective restorations must be replaced prior to bleaching, and extra caution should be applied to children and adolescents.⁸³

Enamel Damage

The effect of extracoronary bleaching on enamel has been conducted mainly using in vitro systems to examine changes in enamel surface microhardness and morphology.^{84–93} Most SEM studies showed little or no morphological changes in the bleached enamel surface. On the other hand, several investigators reported alteration of enamel surfaces associated with bleaching treatments, including shallow depression, increased porosity, and slight erosion. In most cases, however, the observed alterations of enamel surface morphology varied among different products and were associated with products using acidic prerinse or gels of low pH. A 6-month clinical study reported that long-term use of a bleaching gel containing 10% carbamide peroxide did not adversely affect the surface morphology of human enamel.⁹³

To date, no clinical evidence of adverse effects of the dentist-monitored at-home whiteners on enamel has been reported. However, there have been two clinical cases of significant damage on enamel associated with the use of OTC tooth-whitening products.^{94,95}

Gingival Irritation

Gingival irritation is also a commonly observed clinical side effect in extracoronary bleaching, sometimes also associated with tooth sensitivity.^{57,87,96–99} The gingival irritation is usually mild to moderate, occurring in 2 to 3 days of using the bleaching gel and then dissipating, and for most patients it is tolerable till the completion of treatment. When using the tray systems, an ill-fitted tray can cause irritation, and the gingival irritation usually resolves after proper trimming of the tray. For at-home bleaching, the risk of the gingival irritation appears to be related to the H₂O₂ concentration of the gel and the contact of the gel to the gingiva. Gingival irritation associated with in-office bleaching is mostly caused by a leaky or failed gingival barrier protection. Care must be taken to check the barrier for signs of

leakage, usually indicated by air bubbles, and the patient's complaint of discomfort during the bleaching treatment. When tissue burn is detected, the surface should be extensively rinsed with water until the whiteness is reduced. In more severe cases, a topical anesthetic, limited movements, and a good oral hygiene aid healing. Application of protective creams such as Vaseline or cocoa butter can prevent most of these complications.

Mercury Release from Amalgam Restorations

Mercury release from amalgam restorations during and after extracoronal bleaching has been reported.¹⁰⁰⁻¹⁰³ The amount of mercury release may vary, and the health implications of these mercury amounts require further investigation. It is not advisable to perform extracoronal bleaching for teeth with extensive amalgam restorations.

ROLE OF DENTAL PROFESSIONALS IN EXTRACORONAL BLEACHING TREATMENT

Dental professionals should be involved in tooth bleaching, including at-home bleaching. Initial evaluation and examination of tooth discoloration is necessary for proper diagnosis and treatment. Discoloration, particularly intrinsic stains, may not simply be an esthetic problem,⁷¹ and at-home bleaching may not be the appropriate or the best choice for the treatment. For the tray-based at-home bleaching systems, professionally fabricated, custom-fit trays reduce the amount of gel needed for the whitening efficacy and minimize gel contact with oral soft tissues. In addition, routine monitoring of bleaching by dentists allows early detection of any possible complications and reduces the risk of using inferior bleaching products and inappropriate application procedures as well as any temptation to abuse the product.^{94,95} For further information on extracoronal bleaching, the reader is encouraged to refer to additional publications.¹⁰⁴⁻¹¹¹

CHAPTER 39

ENDODONTIC THERAPY FOR PRIMARY TEETH

J. TODD MILLEDGE

Dedicated to the memory of Dr. Clifton Dummett Jr., 1944–2006, professor and chair of pediatric dentistry, Louisiana State University.

A dentist who provides emergency or restorative care for children will inevitably encounter a situation where a primary tooth has a pulp exposure. This could be from a traumatic injury or as the result of a mechanical or a carious pulp exposure. It is important that the practitioner understands the options available for proper treatment.

Dental treatment of primary teeth must satisfy different goals than treatment for permanent teeth. Primary teeth have a limited life span, and if the choice of dental care is properly matched to the needs of the patient's tooth, it is often possible to treat a primary tooth once. Treating primary teeth more than once in the tooth's life span wastes time and is costly. Primary teeth are very important for the child's smile, for proper chewing, and for maintaining space for the developing permanent dentition. Premature loss of a primary tooth can cause a number of problems including arch perimeter loss, supraeruption of opposing teeth, and changes in the patient's occlusion. There are situations where it is impossible to save a primary tooth and extraction of the tooth is indicated. In these cases a space maintainer needs to be placed and monitored to prevent negative changes in the patient's occlusion.

The main goal of endodontic therapy for primary teeth is to maintain an intact dental arch, a healthy periodontium, and vitality of the dental pulp when possible. In situations where a tooth's pulp becomes necrotic or irreversibly involved, a tooth can still be treated and maintained in a healthy state until exfoliation. In this chapter, there will be a number of references to a document entitled *Guideline on Pulp Therapy for Primary and Young Permanent Teeth* published by the American Academy of Pediatric Dentistry.¹ These guidelines are prepared by a committee of pediatric dentists to sum

up the current recommendations from the Academy for dentists who provide dental care for children. Currently accepted endodontic therapy for primary teeth can be divided into two categories: vital pulp therapy and root canal therapy. Vital pulp therapy includes indirect pulp cap, direct pulp cap, and pulpotomy. Root canal therapy includes pulpectomy. This chapter is intended to provide information on endodontic therapy for primary teeth only. For information on pulp therapy for young permanent teeth, please see Chapter 35, "Vital Pulp Therapy".

A Comparison of Primary and Permanent Tooth Anatomy

The anatomical structure of primary teeth differs from permanent teeth in a number of ways. Compared to permanent teeth, primary teeth have thinner enamel and it is more consistent in thickness. The pulp space of primary teeth is very large in comparison to the overall size of the tooth. The dentin that separates the enamel and the pulp does not provide very much protection to the large pulp (Figure 1). Once a carious lesion begins in a primary tooth, it can quickly progress through the thin enamel, the thin dentin, and infect the pulp more quickly than in a permanent tooth (Figure 2).

In a study of the root canal anatomy of primary incisors and molars, Salama et al.² found that primary central incisor root canals have a fairly consistent length of 16 to 17 mm. Primary lateral incisors root canals are more varied, ranging from 14 to 16 mm. Incisors do not have any significant differentiation between the chamber and the root canal, and roots of incisors frequently curve facially in the apical third to half of the root. The cross-sectional shape of incisor root canals varies from round or oval to triangular. Apical foramina are generally associated with the

Figure 1 Contrasting primary (left) and permanent (right) tooth. Note large pulp space and thin dentin in the primary tooth.

Figure 2 Severely cariously involved primary second molar.

anatomical apex of the root. Mandibular primary molars are found to have three to four root canals. The lengths of root canals in primary molars are more variable than in primary incisors with the mesiobuccal canal usually being the longest in mandibular primary molars. The cross-sectional shape of the canal in mandibular primary molars is usually oval and the mesial canals are wider buccolingually than the distal root canals. Maxillary primary molars were not included in the study.

Puddhikarant³ did a radiographic study of pulp chambers of primary molars. Twenty primary molars were radiographed prior to any preparation of the teeth. The pulp chambers were outlined on the radiographs and the number of pulp horns were counted. The teeth were then sectioned at the cervix and filled with a radiopaque resin. Each of the teeth was sec-

tioned mesiodistally and radiographed from the buccal side of the section. The radiographs were then projected onto a screen and a tracing was made for each specimen. The tracings were superimposed and analyzed.

The radiographs of the presectioned *mandibular second primary molars* demonstrated three to four pulp horns with the mesial pulp horn being the largest. The radiograph of the buccal section demonstrated three pulp horns with the mesiobuccal pulp horn being the largest. The lingual section demonstrated two pulp horns: a mesial and a distal. The mesial pulp horn was the largest.

Mandibular first primary molars demonstrated two pulp horns in the presectioned radiographs. The mesial pulp horn was the largest. The radiographs of the sectioned crowns demonstrated both a mesial and a distal pulp horn for both the buccal and lingual sections. The mesial pulp horns were larger than the distal for both sections.

Maxillary second primary molars showed two to four pulp horns in the presectioned radiographs. The mesial pulp horn was the largest. In the sectioned groups, the radiographs of the buccal and lingual sections showed pulp horns on both the mesial and the distal. The mesial pulp horns were larger than the distal.

The radiographs of the presectioned *maxillary first primary molars* demonstrated mesial and distal pulp horns. The buccal and lingual sections also revealed mesial and distal pulp horns with the mesial being the largest. The authors of this study made the following conclusions: Radiographs of extracted unsectioned primary molars showed two to five overlapped pulp horns. The radiographs of the sectioned buccal and lingual specimens showed that the lingual pulp horns were superimposed by the larger buccal pulp horns.

The clinical significance of this research is that pulp exposures can occur very easily in primary molars. Overextending an amalgam or a composite resin preparation, either axially or buccolingually, or over-reducing the occlusal reduction of a stainless steel crown preparation can very easily cause a pulp exposure in a primary molar tooth.

Another study of primary molars demonstrated that cervical pulp horns exist bilaterally in slightly over one-third of all molars. The average buccal extension of the pulp horns was one-quarter to one-third of a millimeter. It was speculated that pulpal sensitivity can occur when a primary molar with cervical pulp horns is prepared or overprepared in the cervical area.⁴ It is interesting to note that instructions for the preparation of primary molar teeth in pediatric

dental texts as well as crown manufacturers of stainless steel crowns do not routinely recommend reduction of the buccal surface of the tooth. Reduction of the buccal surface is recommended only in situations where there is an excessive buccal cervical bulge. It seems wise to avoid reducing or overreducing the buccal cervical area of primary molars when possible and to avoid causing irritation to the teeth with cervical pulp horns.

Numerous studies have been performed to determine the presence of accessory canals in primary molar furcations. In 1965, Moss⁵ studied histologically the pulpal floor of primary molars. Fifty-six teeth were chosen because they had more than half of the root present and preextraction radiographs demonstrated that furcal radiolucencies were confined to the area directly below the furcation. The study was divided into two parts. First, to determine if pulpally infected primary molar teeth furcations were more porous than noninfected teeth. Second, to study the dental hard tissues of furcations of infected and noninfected molars to determine if there was any change in the infected teeth that allowed the formation of the interradicular radiolucencies noted in radiographs.

Overall findings of this study demonstrated that infected primary molar teeth furcations have an increase in porosity of the dentin and cementum. In addition, accessory canals were not always present in all primary molars and therefore could not be considered as the only pathway for the formation of an interradicular radiolucency. Finally, the dentin and cementum of the infected teeth had structural changes in the dentin and cementum.

Ringelstein⁶ using dye penetration with the aid of vacuum suction, showed that 42.7% of primary molars in the study had foramina in the furcation region. Paras⁷ used scanning electron microscopy (SEM) to ascertain the presence of accessory foramina in the internal and external furcation surfaces of primary molar teeth. Accessory foramina were present on 20% of internal surfaces and 50% of external surfaces. Wrbas⁸ used light microscopy to study the furcation of 40 primary molars that were decalcified and embedded in paraffin, and then sectioned. The sections were studied sequentially. Channels were classified as an accessory canal if patency was evident from the pulp completely through to the periodontal ligament. Accessory foramina with a completely patent canal were present in approximately 30% of the maxillary and mandibular primary second molars.

Kramer⁹ also performed an SEM study of the furcations of primary molar teeth. The teeth were taken from two groups: previously infected teeth and healthy unaf-

ected teeth. He found that in the specimens studied, 53% of the teeth had accessory foramina in the external surface of the tooth and 25% had accessory foramina in the internal surface. There was no difference in the test or control groups in regard to the prevalence or the diameter of accessory foramina. He concluded that external furcation areas had a higher prevalence of accessory foramina than internal furcation areas, the presence or absence of infection of the pulp did not influence the prevalence or anatomical characteristics of foramina, and the presence of accessory foramina is not the only reason for furcation pathological bone resorption following pulpal necrosis.

In 2004, Dammaschke et al.¹⁰ performed an SEM study on permanent and primary molar teeth to determine the presence of accessory foramina. Ninety-four percent of the primary molars were found to have accessory foramina with maxillary and mandibular molars having equal numbers. Primary molars had significantly more accessory foramina and foramina of larger diameter than the permanent molars studied. There was no attempt to determine if there was a patent canal connected to the foramina. The authors concluded that accessory canals might contribute to furcation bone resorption when molars have pulpal inflammation.

In conclusion, furcal bone resorption associated with primary molars with pulpal necrosis should not be considered to be the result only of the presence of accessory canals in the furcation. Alterations in the structure of the dental tissues in the furcation of the tooth could also allow communication from a necrotic pulp to the furcation.

Medical Factors in Determining if a Primary Tooth Should be Saved

A thorough medical history is an essential part of the patient's initial examination and can play an important part in the treatment planning process. Listed below are certain medical conditions that contraindicate endodontic therapy in the primary dentition.¹¹

CONTRAINDICATIONS

- Patients with congenital cardiac defects
- Immunosuppressed patients
- Patients who do not heal well, that is, those with uncontrolled diabetes or patients being treated for cancer
- Patients with severe medical conditions who must be treated with general anesthesia in an operating room where the risk of treatment failure and the

need for a second general anesthetic must be minimized

There are also some medical conditions where it would be advisable to perform endodontic therapy in order to avoid extraction of a tooth.¹¹

- Bleeding and coagulation disorders such as hemophilia
- Hypodontia in the permanent dentition, where a primary tooth is expected to remain as long as possible or for the life of the patient.

Diagnosis of Pulpal Pathosis in Children

The first question to ask in regard to a primary tooth with pulp exposure is: Should the tooth be retained or extracted? Other important questions include:¹¹

- Is the tooth close to exfoliation?
- Does the tooth have excessive mobility?
- Is the extent of the infection severe enough to warrant extraction?
- Is the crown of the tooth restorable?
- Is there a permanent successor to the primary tooth? If not, the primary tooth may take on additional importance and may need to be treated similar to a permanent tooth with a conventional root canal treatment to extend the life of the tooth as long as possible (Figure 3).
- Is this tooth critical to the eruption of other teeth? It may be important to save a primary second molar prior to the eruption of a first permanent molar in

Figure 3 Primary second molar with no permanent successor has received root canal treatment with gutta-percha. Such teeth may last for many years.

order to prevent its mesial tipping or drifting. This could interfere with the patient's occlusion and prevent the second premolars from erupting correctly.

Aside from specific medical and dental indications and contraindications for endodontic therapy for primary teeth, there are some other real-life challenges that may influence the choice of care for a child's tooth. A dentist may technically be able to perform endodontic therapy for a child, but if the child cannot cooperate for the treatment or sit still for a long enough period of time, extraction may be the treatment of choice.

Once the dentist and the patient have decided to keep the tooth, a correct pulpal diagnosis must be made. The type of endodontic therapy chosen for a primary tooth must be based on the clinical diagnosis of normal pulp, reversible pulpitis, irreversible pulpitis, or necrotic pulp. The choice of treatment must also include evaluation of the following criteria:

1. Consideration of the patient's dental history, including any signs or symptoms the patient may have experienced.
2. A thorough clinical examination including any tests. Percussion and mobility are helpful but electric pulp testing is not reliable in children.
3. Periapical and bitewing radiographs

It is very important to discuss with the parent and the patient the types of signs or symptoms the patient has been experiencing. Provoked pain or pain that occurs only when the patient eats sweet, hot or cold foods or liquids, but resolves when the stimulus is removed, is usually indicative of reversible pulpitis. In these situations, vital pulp therapy is usually the appropriate treatment. Spontaneous or nocturnal pain usually indicates irreversible pulpitis or pulpal necrosis. Teeth that exhibit irreversible pulpitis or necrosis will usually have associated signs such as pathologic mobility, sinus tract, internal and/or external resorption, and furcal or periapical radiolucency.¹

Treatment of Deep Caries: Indirect Pulp Therapy

Indirect pulp therapy can be performed when a tooth has a deep carious lesion that is very close to the pulp and it is anticipated that the pulp would be exposed when the caries is excavated. The tooth should not have any signs or symptoms of irreversible pulpitis. This treatment relies on the natural ability of teeth to

form reparative dentin. In this treatment the caries is removed in all areas of the lesion except where there would be an exposure. The most infected portion of the caries is removed leaving less infected demineralized dentin. The remaining demineralized dentin is usually covered with a calcium hydroxide liner. The tooth is then restored to completely seal the tooth from the oral environment. When bacteria are excluded from the caries, the tooth can remineralize the dentin directly over the site where the exposure would have occurred. The patient should not experience any pain with this procedure.¹

The literature concerning indirect pulp therapy contains some very interesting studies and results. In a study in 1966, Aponte et al.¹² studied 30 primary molars that received calcium hydroxide indirect pulp therapy, zinc phosphate bases, and amalgam restorations. These teeth were evaluated post operatively by removing the amalgam restoration and cement base with sterile burs and rubber dam isolation. The hardness of the dentin was checked and a culture of the remaining dentin was taken. The cultures were incubated and evaluated for bacterial growth. The cultures of 93% of the teeth were sterile. Two teeth were positive for lactobacilli and streptococci. The dentin was hard and shiny in appearance. They concluded that in 93% of the molars studied, the residual carious dentin was free of microorganisms 6 to 46 months after treatment. In addition there was radiographic evidence of reparative dentin formation in many of the postoperative radiographs. Some of the earlier studies, regarding indirect pulp therapy, were concerned about calcium hydroxide formulation. In a 1982 study, Sawusch¹³ tested Dycal (Dentsply International, York, PA) and a newer formulation of Dycal. He demonstrated that both formulations of Dycal were acceptable for use in indirect pulp therapy, and the teeth that failed generally were associated with a faulty restoration. In similar studies, success rates have been about 94%.^{14,15}

Coll et al.¹⁶ performed a study comparing pulpotomy, indirect pulp therapy, and pulpectomy on primary incisors. In this study of 45 patients, 28 received pulpotomy, 26 were treated with indirect pulp therapy, and 27 received pulpectomy. These were compared with a control group of 58 teeth receiving no treatment. The teeth receiving the pulpotomy treatment met the following criteria: no medical contraindication, radiographic visible caries approximating the pulp with no contraindicating pathosis, no pathologic mobility, no history of traumatic dental injuries, presence of a carious pulp exposure after caries excavation, and appropriate hemorrhage in the

pulp chamber after pulp amputation. Teeth treated with indirect pulp therapy had deep caries approximating the pulp, with no signs of irreversible pulpitis. Criteria for pulpectomy were based on clinical signs of pulp necrosis, total lack of hemorrhage in the canal, and 90% of the teeth had a sinus tract. The teeth were followed clinically and radiographically. The overall success rate for pulpotomy was 85.7% for teeth followed for a mean of 43.8 months. Teeth treated with indirect pulp therapy had a success rate of 92.3% at 42 months. The teeth treated with pulpectomy had a success rate of 77.7% at 45.5 months. They found, however, that when endodontically treated incisors exfoliated, in 73% of the cases, zinc oxide–eugenol (ZOE) cement remained in site. The researchers concluded that in a clinical situation where there was deep caries but no pulp exposure, indirect pulp therapy would be indicated. When there was a direct pulp exposure of an otherwise healthy pulp, pulpotomy should be the treatment of choice. They also concluded that because of the high incidence of retained ZOE, pulpectomy treatment should be chosen only if there is evidence of pulp necrosis.

Farooq et al.¹⁷ performed a retrospective study comparing the success rates of formocresol pulpotomy and indirect pulp therapy for primary teeth. In this study, 133 primary molars with deep caries were treated with either indirect pulp therapy or formocresol pulpotomy. All of the indirect pulp therapy teeth were restored with stainless steel crowns. Sixty-one of the pulpotomized teeth received a stainless steel crown, 13 received a reinforced ZOE base, and 4 received an amalgam. The overall success for *indirect pulp therapy* was 93% compared to 74% for the *formocresol pulpotomized* teeth. Of the teeth treated with formocresol pulpotomy, 38% exfoliated prematurely while the teeth treated with indirect pulp therapy exfoliated normally. The pulpotomized teeth that had immediate stainless steel crowns had the best success rate of 82%, while the ZOE base-restored teeth had a success rate of only 39%. The conclusion was that indirect pulp therapy had a success rate that was much higher than formocresol pulpotomy. They also concluded that indirect pulp therapy can be performed as a one-step procedure, and restoring a pulpally treated tooth with a stainless steel crown immediately after the pulp therapy increases the chances of success.

In 2002, a study by Al-Zayer et al.¹⁸ demonstrated that 187 posterior primary teeth treated with *indirect pulp treatment* had a success rate of 95%. All the teeth received a Dycal calcium hydroxide liner to cover the remaining carious dentin. Ninety-one of

the teeth that received stainless steel crowns had cement bases and the crowns were cemented with ZOE cement. Eighteen additional teeth received a resin-modified glass ionomer material for base and for cementing the crowns. Sixty-eight teeth were restored with amalgam and 13 were restored with a composite resin. There are a number of interesting conclusions to this study. First primary molars were more likely to fail than second primary molars. Teeth restored with amalgam, after an indirect pulp treatment, are 7.7 times more likely to fail than teeth restored with a stainless steel crown. Teeth that had a base placed over the calcium hydroxide liner had a higher success rate than teeth that received no base.

Dentists today are more likely to restore teeth with adhesive restorations. Amalgam and stainless steel crowns are becoming less desirable to patients and their parents. A 2002 study by Falster et al.¹⁹ compared indirect pulp treatment using an adhesive resin system and the traditional calcium hydroxide base. Forty-eight primary molar teeth, treatment planned for an occlusal resin restoration for deep caries, were divided into two groups and followed for 2 years depending on the type of pulpal protection used: calcium hydroxide (Dycal) and Scotchbond MultiPurpose (3M, St. Paul, MN). The researchers found that 83% of the teeth treated with calcium hydroxide and 96% of the teeth treated with Scotchbond MultiPurpose were found to be successful. They concluded that protection of the pulp, with indirect pulp treatment with an adhesive resin, is as effective as the use of a traditional calcium hydroxide liner when placed under a single surface resin restoration. In addition, they stated that after removing deep caries in a primary tooth and establishing a good seal, the tooth's innate healing abilities are more important to success than the use of calcium hydroxide.

In a recent study, Vij et al.²⁰ compared caries control procedures on the success rate of indirect pulp treatment and formocresol pulpotomy. Teeth with deep caries were treated with either formocresol pulpotomy or indirect pulp treatment. Seventy-eight of the teeth were treated with caries control 1 to 3 months prior to the actual procedure. Caries control is a procedure similar to alternative restorative treatment where a large part of the caries is removed and a reinforced ZOE or a glass ionomer base is placed. This is done to slow the progression of the caries and allow the tooth to heal itself by forming reparative dentin. The success rate of indirect pulp treatment after 3 years follow-up was 94%, whereas formocresol treatment attained a success rate of only 70%. Pulpotomized teeth that had only a reinforced ZOE base as the

final restoration had a success rate of 39%. When these teeth were excluded from the total number of pulpotomized teeth, the success rate of the pulpotomies increased to 74%, still much lower than the 94% of the indirect pulp treatments. Thirty-six percent of the pulpotomized teeth but only 2% of the indirect pulp-treated teeth exfoliated early. Conclusions from this study include the following: long-term success rates of indirect pulp therapy was much better than the success rate for formocresol pulpotomy; glass ionomer caries control 1 to 3 months prior to the actual treatment increased the chances of success; vital pulp therapy in primary first molars was lower than primary second molars; and teeth with formocresol pulpotomy exfoliated earlier than teeth treated with indirect pulp therapy.

It seems that success with indirect pulp treatment depends on a number of important criteria: no symptoms or symptoms consistent with reversible pulpitis, absence of clinical or radiographic lesions such as internal or external resorption or furcation radiolucency, complete removal of caries on all of the walls of the preparation leaving only a small amount of caries in the area where there would be an exposure, and placement of a restoration that provides an excellent seal to prevent recontamination from bacteria. All these improve the tooth's innate capabilities to remineralize the dentin and heal the pulp.

Vital Pulp Therapy for Children: Direct Pulp Cap

Direct pulp cap is a treatment option for teeth with traumatic or mechanical pulp exposures. It should be attempted only when the pulp is vital and has not had any signs or symptoms of irreversible pulpitis. The exposed pulp and the adjacent dentin are covered with a base such as calcium hydroxide or Mineral Trioxide Aggregate (MTA) and the tooth receives a permanent restoration. The patient should not experience any pain and reparative dentin is expected to form. The tooth pulp should remain vital and free of any signs or symptoms of irreversible pulpitis.¹ In spite of the recommendation from the American Academy of Pediatric Dentistry, direct pulp capping is not a common procedure for most pediatric dentists. In the current editions of both of the most accepted pediatric dental textbooks,^{21,22} the sections are very small and contain relatively few journal references. Both of these textbooks make the following recommendations regarding direct pulp cap

for primary teeth. Direct pulp cap is indicated for pinpoint-sized mechanical or traumatic pulp exposures. Direct pulp capping of a carious pulp exposure is not recommended. There should be an absence of pain and no bleeding or only a small amount of bleeding consistent with a healthy pulp. The cap should be performed with the use of a rubber dam to prevent any contamination of the pulp. Calcium hydroxide remains the pulp capping agent of choice at this time.^{21,22} Direct pulp capping should be performed in older children where the pulp capped tooth is not expected to last for more than a couple of years until normal exfoliation.

Pulpotomy

Pulpotomy is a procedure for teeth with healthy pulps or teeth with symptoms of reversible pulpitis and deep caries where carious pulp exposure is encountered. Radiographically, the tooth should not show signs of pathological resorption or radiolucency.¹

Pulpotomy is also an alternative for a tooth with traumatic pulp exposure. The coronal pulp is amputated leaving an intact vital radicular pulp. The remaining radicular pulp is treated with an appropriate medicament, the chamber filled with a suitable base and the tooth is restored with a suitable restorative material.¹ Under ideal circumstances it may be preferable to do pulpectomy and root canal treatment for such teeth, but as described earlier, primary teeth have very unpredictable and tortuous root canal systems. It can be very difficult or impossible to clean and shape and properly obturate the root canals (Figure 4). In addition, primary teeth have thin enamel and large pulp chambers and caries can progress very quickly. Cooperation can be difficult for some children and behavior management can be difficult for the dentist who has to provide extensive restorative treatment. Pulpotomy seems to be a reasonable treatment option to meet these situations. By removing only the coronal pulp, the difficult root canal systems are avoided. A pulpotomy certainly requires less time than complete root canal treatment, solving the problem of keeping a child patient in the dental chair too long. It is recommended that all pulp therapies be performed

Figure 4 Root canal system of a primary molar (resin impression).

with a rubber dam to protect the patient from accidental swallowing or aspiration and to prevent contamination of the tooth during treatment.¹ Clinical signs and symptoms should resolve within about 2 weeks. After this, the pulpotomized tooth should remain asymptomatic exhibiting no pathologic mobility, sensitivity, or pain.

Formocresol

Formocresol is the most common pulpotomy medicament used in pediatric dentistry today. It is the standard to which all other pulpotomy procedures are compared. For these two reasons, it is important to understand the history of formocresol in pediatric dentistry.

The use of formocresol as pulp medicament is attributed to Buckley from 1904 to 1906.^{23,24} Buckley outlined the use of a mixture of formalin and cresol to treat necrotic or “putrescent” pulps. In the 1930s, Sweet^{25–27} developed a multiappointment pulpotomy procedure that became very popular and is the predecessor for our current single-appointment pulpotomy. In his articles, he recommended a five-appointment procedure that he later modified to three appointments. Since then, formocresol has been the subject of a great deal of research. A modern formocresol pulpotomy generally involves removal

Figure 5 Caries removal.

Figure 6 Removal of the roof of the pulp chamber.

Figure 7 Removal of the coronal pulp with a spoon excavator.

of the carious tooth structure with a slow-speed round bur (Figure 5) followed by removal of the roof of the pulp chamber with a high-speed bur with water spray (Figure 6). The coronal pulp is then removed with a slow-speed round bur or an excavator (Figure 7). Hemostasis is obtained with sterile cotton pellets. After hemostasis, a medicated pellet with either full-strength or diluted formocresol is placed with slight pressure for 5 minutes (Figure 8), after which the medicated pellet is removed and the pulp is assessed for continued bleeding. When bleeding has been completely controlled, a ZOE base is placed (Figure 9), followed by a final restoration (Figure 10). Research reports are usually based on modifications of the above procedure. The following review of the literature follows a historical sequence. It is difficult to directly compare the studies since each one contains some variables that are different from the other studies. Therefore each study, and its conclusions, must be evaluated individually.

The first area considered will be overall success rates of formocresol pulpotomies. In 1975 to 1978, Rolling²⁸ studied formocresol pulpotomies for a period of up to

Figure 8 Formocresol used for pulpotomy in primary teeth.

Figure 10 Primary molar with a stainless steel crown.

36 months. She used full-strength formocresol and also added formocresol to her ZOE base. The results of her study found that there was a success rate of 90% after 3 months and an overall success rate of 70% after 3 years. In a follow-up study, Rolling et al.²⁹ continued evaluation of the same group of teeth. They found that the pulp conditions, as evidenced by enzyme histochemical methods, varied from normal to total necrosis. They concluded that the formocresol procedure should be regarded only as a way to keep primary teeth with exposed pulps functioning for a short time. In a third study from 1978, Rolling et al.³⁰ examined histolo-

Figure 9 Placement of a zinc oxide–eugenol (ZOE) base.

gically the pulps of primary molars treated with formocresol pulpotomy which were considered to be both clinically and radiographically successful for a period of up to 24 months after treatment. They found that the condition of the pulp varied from total necrosis to varying states of fixation and inflammation. They once again concluded that formocresol pulpotomy should be considered a temporary procedure for primary teeth.

In 1975, Ranly³¹ performed a study to determine if formocresol added to the ZOE base was adequate to treat the pulp, allowing the clinician to skip the step of placing the formocresol pellet. His study showed that formocresol leached out of the ZOE in adequate amounts and concluded that the use of a medicated pellet prior to the placement of the base was unnecessary. In 1978, Magnusson³² performed a study comparing a two-appointment to a 5-minute formocresol pulpotomy. He found that there was no advantage in a two-appointment procedure, since the success rates were similar.

Cox et al.³³ studied the bactericidal potential of materials used in primary tooth pulpotomies. They found that plain zinc oxide did not have any inhibitory effect on the bacteria tested. When eugenol was added, the growth of gram-positive organisms was retarded. Addition of zinc acetate as an accelerator to the cement inhibited both the gram-positive and the gram-negative bacteria. When formocresol or paraformaldehyde was added to the zinc oxide–eugenol–zinc acetate cement, there was an even greater inhibitory

effect. They concluded that zinc oxide–eugenol–zinc acetate cement, with or without formocresol, was probably effective in eliminating bacteria from pulpotomized primary teeth. Adding highly cytotoxic materials to cement bases that remain active for long periods of time may not be necessary for successful treatment.

Mejare³⁴ studied mandibular primary molar pulpotomies on teeth with diagnosis either of clinically healthy or clinically inflamed root pulp, using full-strength formocresol ZOE base. She had a success rate of 63% and concluded that there was no statistical difference in the two groups. In 1982, Garcia-Godoy³⁵ published two studies. In the first, he compared the pulpal response of various application times to formocresol in dogs. He found that an application time of 1 minute produced less inflammation than 3 and 5 minutes. He also found that when formocresol was incorporated into the ZOE base, it produced a more intense inflammatory response. He concluded that the longer formocresol is in contact with the pulp tissue, the worse the tissue response. In addition, he stated that additional studies should compare 1- and 5-minute pulpotomy application times. In his second dog study, Garcia-Godoy³⁶ compared formocresol pulpotomy with two different bases, ZOE and polycarboxylate. He had two pulpotomy treatment groups, one without formocresol treatment and either a ZOE or polycarboxylate cement base, and the other group was treated with formocresol followed with either a ZOE or polycarboxylate cement. The polycarboxylate groups had similar amounts of inflammation. The ZOE-treated teeth that had not been treated previously with formocresol had more intense inflammatory responses than the teeth treated with formocresol. He concluded that formocresol seems to reduce the pulpal response to ZOE; probably the eugenol in the ZOE base is an irritant. He concluded that dentists should rethink the use of ZOE as a base in pulpotomies.

In 1986, van Amerongen et al.³⁷ compared formocresol pulpotomy treated teeth with their untreated contralateral teeth. They found that there was no significant difference in the life span between the formocresol-treated teeth and the control teeth concluding that formocresol pulpotomy is a reasonable treatment for primary teeth with pulp exposure. In 1986, Hicks et al.³⁸ performed a study in a pediatric dentist's practice and evaluated formocresol pulpotomized teeth radiographically. In this office, the dentists did not use a formocresol-treated cotton pellet after obtaining hemostasis, but instead they immediately placed a ZOE base that also contained formocresol. When they evaluated the radiographs, they found furcation

radiolucency in 3.7% of the cases. When they classified the results as successful, questionable, or failure, the success rate was 89%. When they combined the successful with the radiographically questionable but clinically successful cases, the success rate jumped to 93.8%. Clinically, this is how most pediatric dentists deal with their patients.

There are certain clinical outcomes that would be definite failures and others that are questionable but tolerable. Most practitioners play a waiting game, hoping that these questionable teeth will exfoliate before they have a problem that requires extraction. Thompson et al.³⁹ studied the formocresol pulpotomy opting to delete the step that obtains hemostasis with dry sterile cotton pellets and instead they obtained hemostasis with the formocresol pellet that was placed over the amputated pulp. They studied 194 teeth for up to 38 months. The radiographic success rate was 87% with the most frequent radiographic problems being pulp canal obliteration and internal resorption. Overall clinical success rate was 98%. They concluded that skipping the step of obtaining hemostasis with a dry cotton pellet was an acceptable variation of the formocresol pulpotomy when hemostasis was obtained with the formocresol-treated pellet. Strange et al.,⁴⁰ using modified radiographic success and failure criteria, studied formocresol pulpotomies with a ZOE base incorporating formocresol instead of a formocresol-medicated cotton pellet. Traditionally, internal resorption has been considered a sign of failure. More recently, researchers have joined clinical dentists in excluding internal resorption as a sign of failure. A small area of internal resorption that does not perforate the root can be tolerated and probably indicates the pulp is still vital. In this study, Strange et al. studied 196 primary molars for up to 49 months. Using the traditional radiographic failure criteria, a success rate of 79% was obtained. When internal resorption was excluded, the radiographic success rate jumped to 99%. Overall clinical success rate was 99%. They concluded that incorporating formocresol into the ZOE base was a successful form of formocresol pulpotomy.

Holan et al.⁴¹ compared the success rate of formocresol pulpotomy when restored with amalgam and stainless steel crowns. They concluded that formocresol pulpotomized teeth that were restored with two or more surface amalgams had a higher failure rate than formocresol pulpotomized teeth restored with a one-surface amalgam or a stainless steel crown. They concluded that pulpotomized primary molars can be successfully restored with a one-surface

amalgam if the tooth is expected to naturally exfoliate in less than 2 years.

Guelmann et al.⁴² evaluated the success of emergency pulpotomies on primary molars. They studied the records of 216 formocresol pulpotomies that were temporarily restored with a reinforced ZOE material. The outcome was determined at the time of placement of the permanent restoration. Sixty-four teeth were available for the study. A 53% success rate was obtained if the tooth was restored in the first 3 months after the pulpotomy and 31% success if the tooth was restored after 1 year. They concluded that the low success rate in the first 90 days was probably attributed to an undiagnosed pulpitis at the time of treatment and later failures were probably associated with microleakage of the ZOE material. Their second follow-up study revealed that when a stainless steel crown was placed immediately or very soon after the emergency pulpotomy, the success rate increased significantly.⁴³ Guelmann et al.⁴⁴ also studied the success of formocresol pulpotomized teeth that were restored with a resin. Fifty-nine teeth were included in the study with an average follow-up time of 21 months. Overall, pulpotomized teeth with a resin restoration had success rates that were inferior to the previously published success rates of stainless steel crowns. When the occlusal surface was the only surface restored, however, the success rate was 100%. Overall, formocresol pulpotomies have success rates that range from a low in the 50% range up into the mid 90% range. As one can see, there are many variables and techniques used, and it depends on whether clinical or radiographic or combined success rates are being considered.

A number of studies have questioned the post-operative effect of formocresol pulpotomy on the primary teeth, and also on the succedaneous premolars. It has been demonstrated in studies, and it is obvious to clinicians, that teeth treated with formocresol pulpotomy routinely demonstrate pulp canal calcification.^{45,46} Conflicting information has been published regarding the effect of pulpotomized primary molars on their permanent successors. Some studies show that premolars, successors to pulpotomized primary molars, demonstrate no correlation.⁴⁷⁻⁵⁰

Early on, clinicians and researchers began to question Buckley's original formulation strength and wondered if a more dilute concentration would be just as effective as full strength. A number of *in vitro* and *in vivo* studies tested formocresol to determine the minimum effective concentration that would give the same or very similar benefit while reducing the negative

effects.⁵¹⁻⁶⁰ From these studies, it is generally agreed that 20% dilution of the original Buckley's formulation is an effective concentration for clinical practice. Unfortunately, in spite of the science, pediatric dentists persist in using full-strength formocresol. In 2002, a survey of 422 pediatric dentists revealed that 84% of those who responded use formocresol for pulpotomies. Of that group, 69% use full-strength formocresol. Many unknowingly use full-strength formocresol and think they are using a diluted product. These latter dentists stated that they buy diluted formocresol even though it is not available commercially. It is unfortunate that a technique that is so widely used has so much confusion in practice.⁶¹

Formocresol has been found to be cytotoxic to pulp tissues. In studies, formocresol, formaldehyde, and cresol have been placed in contact with pulp cells. Formocresol and formaldehyde have been found to be more cytotoxic than cresol. The response of the pulp tissue appears to be time- and concentration-dependent. The more dilute the concentration of formocresol, the less intense the inflammatory response. In addition, the longer formocresol is in contact with the pulp tissue, the more intense the inflammatory response. The formocresol-treated pulp responds by forming a number of "zones" depending on the proximity of the tissue to the medicament. At the amputation site, and where the formocresol concentration is the highest, the tissue is fixed and eosinophilic. Below this fixed zone there is a pale zone with poor cellular definition that some have described as necrotic. Close to the apex, the tissue is chronically inflamed.⁶²⁻⁶⁹

Several researchers have performed studies that measured the systemic distribution of formocresol that is applied to the pulp in the pulpotomy technique. Meyers et al.⁷⁰ studied pulpotomies on monkey teeth and found that in a 5-minute pulpotomy with ¹⁴C-formaldehyde, there was systemic absorption into the plasma of approximately 1% of the dose of the medicament placed in the tooth. A 2-hour exposure did not increase the absorption. Multiple pulpotomies performed sequentially caused a higher systemic absorption of the medicament. When ¹³¹I was applied to a pulpotomy not previously treated with formocresol, it was absorbed systemically in large amounts. When ¹³¹I was applied to a formocresol-treated pulp, it was absorbed only in moderate amounts. This indicates that formocresol compromises the circulation of the pulp and probably limits its systemic uptake. Timed urinalysis after treating the teeth with formocresol showed that formocresol was excreted and not protein-bound. In a follow-up study, researchers in

the previous study wanted to determine where the absorbed formocresol was going. In a dog study, they confirmed their previous findings that formocresol was systemically absorbed. In addition, formocresol was found in the liver, lung, muscle, heart, spleen, kidney, and even in the cerebral spinal fluid. They found that formocresol could be metabolized and excreted through the lung, but the reaction was not very fast and certainly not quick enough to account for the total amount of the medicament. Tissue binding seems to account for most of the systemic absorption. The researchers concluded that formocresol is absorbed in small quantities and they did not think that the use of formocresol should be discontinued.⁷¹ Block et al.⁷² performed another dog study and found that ¹⁴C-labeled paraformaldehyde incorporated within formocresol was systemically distributed in the blood, regional lymph nodes, kidney, and liver. They measured the radioactivity over time and found that it decreased. They concluded that formocresol should not be brought into contact with vital tissues.

Ranly⁷³ studied pulpotomies in rats, in response to the previous two studies, because he saw a possible clinical correlation for children receiving multiple pulpotomies during full mouth dental care under general anesthesia. They were concerned with the possible transient systemic morbidity associated with a larger than normal amount of systemically absorbed formocresol. In this rat model, Ranly determined that approximately 30% of the formaldehyde that was placed into the pulp chamber was absorbed systemically in 5 minutes. He concluded that with larger doses, comparable to multiple pulpotomies, the metabolic systems that break down the medicament were not overloaded or damaged. In part two of his study, Ranly⁷⁴ questioned the findings of two previous studies.^{68,71} He found that the formaldehyde used in his study required higher levels than the formocresol used in the other studies to produce biochemical changes and seemed to infer that it would require a higher quantity of formaldehyde than had been suggested to cause morbidity.

All of these studies demonstrated that formocresol is distributed systemically. There is disagreement, however, about whether this distribution can be tolerated or whether there is some lasting damage.

Other researchers sought to determine the allergenic potential of formocresol. A human study on children who had received pulpotomy treatment 2 months to 8 years prior to a skin patch allergy test showed no positive test results for formaldehyde, eugenol, or cresol.⁷⁵ Another study presensitized guinea pigs with formaldehyde or cresol. The presensitized animals

received an endodontic procedure using formocresol and subsequently skin tested. In the test, the researchers demonstrated a weak allergenic potential.⁷⁶ One study documents the embryotoxicity and teratogenicity of formocresol to chick embryos.⁷⁷ Additional journals articles thoroughly document the mutagenic and carcinogenic potential of formaldehyde and formocresol.^{78–80}

In 2004, the International Agency for Research on Cancer concluded that formaldehyde is carcinogenic to humans. In addition, they state that there is strong but insufficient evidence that formaldehyde is a causative agent for leukemia.⁸¹ It would seem that with such a strong statement by the World Health Organization, and the weight of the evidence from the dental and medical literature, formocresol would have been banned for use in humans. However, the debate still goes on regarding its safety and use in dentistry. In 2005 and 2006, two articles^{82,83} present opposite sides of the formocresol debate demonstrating that the debate is not over. In conclusion, two excellent articles by Srinivasan et al.^{84,85} did a great job of summarizing the use of formocresol for pulpotomies and discussing medicaments that may take its place.

Glutaraldehyde

In 1975 to 1976, 's-Gravenmade⁸⁶ and Dankert et al.⁸⁷ proposed that glutaraldehyde could be an alternative pulpotomy fixative medicament. They stated that glutaraldehyde would be less likely to diffuse out of the apical foramen and it has effective disinfecting properties. It was also found to have better fixative properties with true crosslinking. The property of glutaraldehyde not diffusing out of the apex of tooth has been confirmed in studies.^{88,89} It has also been demonstrated that glutaraldehyde is absorbed into the systemic circulation after being applied to a pulpotomy site.^{90–92} There was a low amount of tissue binding and the remainder of the glutaraldehyde was excreted in the urine or exhaled as carbon dioxide. It has further been shown that glutaraldehyde does not reach the nucleus of cells and its potential for mutagenicity is low.⁹² Ranly et al.⁹³ demonstrated that buffering glutaraldehyde increased its concentration, and along with applying it for longer periods of time increased fixation. It was only when the concentration was made stronger that the glutaraldehyde penetrated deeper into the tissues.

In 1980, Kopel et al.⁹⁴ used 2% glutaraldehyde to perform pulpotomies on primary teeth. They found it to be a biologically acceptable pulp medicament

capable of maintaining the vitality of the radicular pulp following pulpotomy. The remaining pulpal tissue did not resemble the tissues of teeth subjected to treatment with formocresol. Adjacent to the pulp dressing there is surface fixation where the pulp is amputated and treated. The remaining pulp appears normal.⁹⁵ Glutaraldehyde has been shown to be less cytotoxic than formocresol.⁹⁶

A study by Ranly⁹⁷ demonstrated that glutaraldehyde produced less allergenic response than formocresol. Multiple studies have shown no damage to the erupted permanent teeth adjacent to the glutaraldehyde-treated primary teeth.^{98,99} Numerous clinical studies have documented the clinical success of glutaraldehyde pulpotomies with ZOE base in the range of 74.1 to 100% with times ranging from 6 to 42 months.¹⁰⁰⁻¹⁰⁶ It is important to note that the highest success rates were from studies that had shorter study periods, and that none of the studies had a study time longer than 3.5 years. Glutaraldehyde pulpotomies with calcium hydroxide base have a lower success rate than pulpotomies using a ZOE base.¹⁰⁷

Ranly and Garcia-Godoy¹⁰⁸ found it not advisable to skip the step of applying the glutaraldehyde directly to the pulp stumps with medicated pellets for 5 minutes, instead of incorporating the medicament into the cement subbase. This modification of the pulpotomy procedure produced a failure rate of 48.6%. A potential drawback to using glutaraldehyde is its limited shelf life. Glutaraldehyde has been tested for many years now. It appears that this medicament is not the ideal material to replace formocresol. It has many of the same problems and concerns in regard to safety, and there are conflicting studies about clinical success rates.

Freeze-Dried Bone

Two studies were performed on monkeys using freeze-dried bone as a pulp capping agent.^{109,110} In the first study, 15 primary teeth and 1 permanent tooth were treated with freeze-dried bone as the pulp capping material. The monkeys were sacrificed after 12 weeks and the teeth were evaluated histologically. The results showed that the teeth treated with freeze-dried bone demonstrated a complete or partial calcific barrier next to the pulp with normal odontoblastic cells. The researchers concluded that freeze-dried bone produced favorable results but that the material should be evaluated for longer periods of time and with a larger sample size. The same researchers performed a second study again using 15 primary teeth

on monkeys. These teeth were followed for periods of 6 weeks to 6 months. In the 6-week samples, all of the pulps were vital and a dentin bridge formed in 87.5% of the teeth. In the samples evaluated after 6 months, 83.3% of the teeth had vital pulps and all of the samples had a dentin bridge. The researchers recommended clinical studies with freeze-dried bone on human teeth.

Electrosurgery/Electrofulguration

Numerous researchers have proposed electrosurgery or electrofulguration as an alternative to chemicals or cements for pulpotomies in primary teeth. In 1983, Ruemping et al.¹¹¹ performed electrosurgical pulpotomies on monkey teeth. After making access preparations, the pulps were amputated with sharp spoon excavators and hemostasis was obtained with dry cotton pellets. Then the pulp stumps were treated with the electrosurgical unit. They were careful to limit the amount of contact of the electrosurgery unit with the pulp, and when multiple treatments were needed, a 10-second delay was recommended to prevent overheating of the pulp tissue. A ZOE base was then placed. The teeth were followed for periods from 1 hour up to 2 months and evaluated histologically. In the 1-hour specimens, the electrosurgically treated specimens demonstrated tissue debris and coagulation necrosis on the surface and increased fibrosis in the coronal one-fourth of the pulp. There was no involvement of the furcation or at the tooth apex. The 1-week specimens again demonstrated coagulation necrosis at the electrosurgically treated surface and increased fibroblasts below. The apical four-fifths of the pulp as well as the furcation and the periapical areas was normal. The 2-month specimens demonstrated some chronic inflammation and fibroblasts oriented in the long axis of the tooth with some secondary dentin seen below this area. The remaining apical two-thirds of the pulp was normal to slightly fibrous, with no apical or furcation involvement noted. The researchers concluded that the electrosurgically treated teeth maintained vitality for up to 2 months with no evidence of periapical or furcation involvement.

In 1987, Morton, one of the researchers from the previous primate study, and Sheller¹¹² published a study pilot testing electrosurgical pulpotomies on humans. They tested 11 primary human canine teeth scheduled for extraction for orthodontic reasons. They used an Ellman 90 FFP Dento Surg unit (Ellman International, Inc., Oceanside, NY) at a setting of 3 (139.5V) and were

careful not to overheat the pulp. Warm gutta-percha was gently condensed on top of the pulp and covered with Cavit (3M). Clinically, all patients were asymptomatic at 6 and 48 hours. One patient developed symptoms at 72 hours and the tooth had to be extracted. Histologically, the two teeth extracted 1 hour after treatment were free of acute inflammation. The teeth that were extracted after 6 days showed acute inflammation in the apical third and edema and necrosis in the remaining pulp. The 13-day posttreatment specimens varied in their responses to treatment. One tooth had necrotic pulp. Another tooth had acute and chronic inflammation with some necrosis in the apical two-thirds and pulp calcifications in the coronal third. The one tooth that was considered successful had limited necrosis at the pulp amputation site and the middle and apical thirds of the pulp were vital. The two 17-day posttreatment specimens were similar, with acute and chronic inflammation in the coronal third and secondary dentin on the walls of the coronal and middle thirds of the canal. One of the specimens had a pulp stone. The best results were obtained in the 70-day posttreatment specimens. Some acute and chronic inflammatory cells were visible in the coronal third of the pulp and secondary dentin and pulp stones were also present. In the 100-day posttreatment specimens, one of the teeth was considered successful, but had chronic inflammation and secondary dentin formation. The other tooth had acute inflammation in the remaining pulp and secondary dentin.

The conclusion of this pilot study was that electrosurgical pulpotomy could not be recommended as a pulpotomy technique superior to formocresol. Sheller and Morton from the previous two studies, as well as two other researchers, published another primate study later in 1987. In this study, they used a split-mouth design, performing equal numbers of electrosurgical and formocresol pulpotomies. The formocresol pulpotomy technique was a standard 5-minute pulpotomy and the electrosurgical pulpotomy was the same as described in their previous studies. The teeth were followed for up to 6 months. The teeth were evaluated histologically and revealed that the two techniques produced similar results, which can be summarized as acute and chronic inflammation in the coronal third of the pulp. Some teeth demonstrated reparative dentin, and a few had periapical or furcation pathosis. Most of the teeth had vital pulp tissue in the apical third of the root. They concluded that the next step should be well-designed studies of electrosurgical pulpotomies on humans.¹¹³

Shulman et al.¹¹⁴ compared electrosurgical and formocresol pulpotomies in monkey teeth. They studied 80 primary teeth divided into treatment groups that included electrosurgery, ¹⁴C-labeled full-strength formocresol in a ZOE base, and a combined technique of electrosurgery and formocresol. When performing these electrosurgical pulpotomies, the researchers did not mechanically remove the pulp first and then treat the remaining pulp with the electrosurgical current. Instead they used the electrosurgical unit to completely remove the coronal pulp and treat the radicular pulp. This appears to have been an important finding. They concluded that removing the coronal pulp with the electrosurgical unit probably produces too much lateral heat injuring the remaining pulp irreversibly and causing the treatment to fail. The conclusions of this study were that this particular electrosurgical technique produced periapical and furcation pathosis and root resorption, and using formocresol after the electrosurgical technique produced no better results than the electrosurgery alone.

Mack et al.¹¹⁵ did a retrospective study of patients treated with electrosurgical pulpotomy with the dental tip of electrofulguration. All of the procedures were performed by the same operator on primary molars with carious pulp exposures. They followed 164 pulpotomies on children aged 18 months to 10 years old (mean age, 5 years 11 months), for up to 5 years 10 months (mean postoperative time, 2 years 3 months). Of the 164 teeth studied, 127 were considered normal at the last observation, 32 had exfoliated, 4 had an abnormality that was not considered a failure, and 1 tooth was considered a failure. The overall clinical and radiographic success rate was 99.4%.

Two studies comparing histological results of electrosurgical and formocresol pulpotomies on dog primary teeth were performed by two different groups. In the first study, they found that conventional formocresol pulpotomy was histologically superior to electrosurgical pulpotomy.¹¹⁶ In the second study, they concluded the opposite, that electrosurgical pulpotomy exhibited less histopathological reaction than formocresol pulpotomy.¹¹⁷ The two studies used different electrosurgical units and this may account for the different results.

Two other human studies using the Hyfrecator (ConMed Corporation, Utica, NY) to perform electrofulguration pulpotomies were performed by different research groups. In the first study, Fishman et al.¹¹⁸ tested 47 primary molars for up to 6 months using two different bases, ZOE in one group

and calcium hydroxide in the second group. Clinical and radiographic success rates were 77 and 55%, respectively, for the ZOE group and 81 and 57%, respectively, for the calcium hydroxide group. They concluded that when used with an electrofulguration pulpotomy, there was no statistical difference between ZOE and calcium hydroxide. In the second study,¹¹⁹ formocresol and electro-surgical pulpotomy with the Hyfrecator were again compared. The formocresol-treated teeth received full-strength formocresol and both groups received a ZOE base. The teeth were followed for up to 5 months. Clinical and radiographic success rates for the formocresol were 100 and 92%, respectively, and 96 and 84%, respectively, for the electro-surgically treated teeth. The researchers concluded that there was no statistical difference in the success of the two techniques.

Sasaki et al.¹²⁰ tested calcium hydroxide pulpotomy with and without the use of an electro-surgical unit. Thirty-three primary molars were followed for a period of up to 34 months (mean, 12 months). Caries was removed with an excavator or a slow-speed bur. After carious exposure, a high-speed diamond was used to open the access preparation. The coronal pulp was amputated with a high-speed bur with continuous water spray. Cotton pellets were placed to obtain hemostasis. If hemostasis was achieved, a calcium hydroxide base was placed. If hemostasis was not obtained, the electro-surgical unit was used to stop the bleeding. This was followed by a calcium hydroxide base. The teeth were restored with a crown. Clinical and radiographic success rates were 93.8% and 93.8%, respectively, for the electro-surgical group and 94.1 and 88.2%, respectively, for the nonelectro-surgical group.

Rivera et al.¹²¹ performed a clinical study on 80 primary molars comparing formocresol and electro-surgical pulpotomies on children aged 4 to 7. In order to be included in the study, the child had to have two molars requiring pulpotomy. In each child, one tooth received formocresol pulpotomy and the other tooth received electro-surgical pulpotomy. Both teeth received a ZOE base and were followed for up to 6 months. In both of the groups, 7.5% of the teeth failed. There were no statistically significant differences in the success of the two groups. The authors acknowledged that this was a fairly short observation period, but observed that, when comparing equal success rates of formocresol and electro-surgery, electro-surgery has distinct advantages. It is faster and there are no risks of formocresol side effects.

A common problem with dental research for electro-surgical pulpotomies is that there are different techniques, materials, and electro-surgical units among the various studies. This can produce vastly different results and makes it difficult to compare the studies. Dentists in private practice are left wondering which technique of electro-surgical pulpotomy is right.

Lasers

Lasers have been suggested for a number of procedures in dentistry including pulpotomy. Some of the earlier studies used CO₂, argon, and Nd:YAG lasers to perform pulpotomies on dogs and swine.¹²²⁻¹²⁴ The results of these studies demonstrated that using a laser to perform pulpotomies was a viable option in animal models and should be attempted in humans.

Subsequent to these animal studies, six studies have been published on the use of lasers to perform pulpotomies in primary teeth. Liu et al.¹²⁵ published a case report of 23 teeth that received pulpotomy treatment with an Nd:YAG laser with the following settings, 2 W, 20 Hz, 100 mJ, and followed for 12 to 27 months. The teeth were anesthetized and isolated with a rubber dam. Caries was excavated and the roof of the chamber was removed with a high-speed bur. The coronal pulp was removed with a spoon excavator and hemorrhage control was obtained with dry sterile cotton. The laser was used to treat the pulp after the removal of the cotton, and IRM cement was used to fill the chamber. The teeth were restored with a composite resin or a stainless steel crown. All of the teeth were clinically successful with no signs or symptoms. One tooth showed signs of internal resorption at the 6-month recall visit. At 9 months, approximately half of the teeth show some canal calcification.

Elliott et al.¹²⁶ compared CO₂ laser pulpotomies with formocresol pulpotomies. In this study, the caries- and restoration-free primary canine teeth were anesthetized, isolated with a rubber dam, and cleaned with providine iodine and isopropyl alcohol. An access preparation was made on the lingual surface of each tooth and the coronal pulp was removed with a slow-speed round bur. A damp sterile cotton was placed for 5 minutes to obtain hemostasis. The teeth were treated with the laser or with formocresol, and both groups of teeth received a zinc oxide and eugenol base and an amalgam restoration. The settings on the laser were 6 W, 0.1 second, and a single impulse. The distance from the tip to the canal orifice was 1 to 1.5 mm. The laser was fired until there was a char

layer and no more bleeding. The teeth received a periapical radiograph prior to extraction and were extracted at 28 or 90 days. The teeth were evaluated radiographically and histologically. These researchers concluded that on the basis of symptomatic, clinical, radiographic, and histological findings, the CO₂ laser compares favorably to formocresol pulpotomies.

A study was performed comparing a conventional formocresol-ZOE pulpotomy with a diode laser-MTA pulpotomy. In this study, the teeth were studied clinically and radiographically for a period of up to 15.7 months. The researchers concluded that the laser-MTA pulpotomy showed slightly reduced radiographic success rates compared to the formocresol-ZOE pulpotomy, but the results were not statistically significant. They recommended that a larger sample with a longer follow-up was needed to consider the laser-MTA as an alternative to the formocresol-ZOE pulpotomy.¹²⁷

In a study by Huth et al.,¹²⁸ four pulpotomy techniques were compared: calcium hydroxide, Er:YAG, dilute formocresol, and ferric sulfate on a sample of 200 primary molars treated and followed for up to 24 months. The teeth were anesthetized and isolated with a rubber dam, and the caries was excavated and the roof of each pulp chamber removed with a diamond bur. The coronal pulp was removed with a slow-speed round bur and a spoon excavator. Hemostasis was obtained by placing wet cotton pellets with slight pressure in the chamber for 5 minutes. Formocresol-medicated cotton pellets were applied to the pulp for 5 minutes in the control group. In the laser group, the teeth were treated with an Er:YAG laser set at 2 Hz and 180 mJ per pulses without water cooling. The mean number of laser pulses per tooth was 31.5 ± 5.9 . In the calcium hydroxide group, the teeth were dressed with aqueous calcium hydroxide and covered with calcium hydroxide cement. In the last group, the teeth were treated with cotton pellets wetted with ferric sulfate for 15 seconds. All of the teeth received an IRM base, followed by a glass ionomer cement and a stainless steel crown, or a composite resin. The teeth were followed clinically and radiographically for up to 24 months. After 24 months, the total (combined clinical and radiographic success rates) and clinical success rate percentages (in parenthesis) were as follows: formocresol 85 (96%), laser 78 (93%), calcium hydroxide 53 (87%), and ferric sulfate 86 (100%). The authors concluded that calcium hydroxide was significantly less effective than formocresol. They also pointed out that an increased sample size would be necessary before it could be definitively said that this laser technique or ferric sulfate was equal to, or better, than formocresol.

A study by Liu,¹²⁹ which was conducted similarly to his previously published case report, using an Nd:YAG laser with follow-up for up to 64 months demonstrated a 97% clinical success rate and a 94.1% radiographic success rate for the laser group that was compared to the 85.5% clinical success rate and a 78.3% radiographic success rate for the formocresol control group.

Odabas et al.¹³⁰ performed a clinical, radiographic, and histological study of Nd:YAG laser pulpotomies compared to formocresol pulpotomies on 42 primary teeth studied for a period of up to 12 months. This study was conducted nearly identically to the previous studies. The laser group had a clinical success rate of 85.71%, and a radiographic success rate of 71.42%, at 9 and 12 months. The formocresol group had a clinical success rate of 90.47% and a radiographic success rate of 90.47% at 9 and 12 months. These researchers conclude that the Nd:YAG laser may be considered as an alternative to formocresol for pulpotomies for primary teeth.

As lasers become more commonplace in dentistry, dentists who own a laser now have a body of research literature to justify the use of the laser to perform pulpotomies for children in their practices.

Ferric Sulfate

The use of ferric sulfate as a primary tooth pulpotomy medicament begins to appear in the literature in the late 1980s when Landau and Johnson¹³¹ published an abstract describing the use of ferric sulfate as a pulp medicament in monkey's teeth. The sample size was small and followed for only 60 days. They noted secondary dentin formation and partial dentin bridging. They also described ferric sulfate as a "promising medicament for teeth indicated for pulpotomies." Subsequently, Fei et al.¹³² presented the first clinical study of ferric sulfate as a pulpotomy medicament for primary teeth. In this study, 29 primary molars received ferric sulfate pulpotomies and 27 received 1:5 Buckley's formocresol pulpotomies. Both groups received a ZOE base and were followed over 12 months. Criteria for clinical success included no symptoms of pain, no tenderness to percussion, no swelling or fistula, and no pathological mobility. Criteria for radiographic success included normal periodontal ligament space, no pathological internal or external resorption, and no furcal or apical radiolucency. Results of the study showed that after 1 year, 28 of 29 of the ferric sulfate-treated teeth were considered successful while only 21 of 27 of the formocresol-treated teeth were

considered successful. Combined overall success rates were 96.6% for the ferric sulfate group and 77.8% for the formocresol group. They raised some interesting points in their discussion. The use of ZOE as a base for formocresol pulpotomies is standard for this procedure. A ZOE base is also paired with ferric sulfate in order to standardize the two pulpotomy treatments. The authors suggested that ZOE is appropriate for formocresol because the pulp tissue is somewhat fixed from formocresol and would not react with the slightly irritating eugenol. Because ferric sulfate is not a tissue fixative, and probably leaves the tissue in a more vital state, using ZOE as a base introduces an irritant that may contribute to failure. They suggested that it would be advisable to continue to study ferric sulfate as a primary tooth pulp medicament for longer periods of time and with more inert base materials.

Additional animal studies on rat and baboon teeth have been performed to assess histologically the pulpal healing response after pulpotomy with ferric sulfate and dilute formocresol. In her study using rats, Cotes¹³³ had four test groups pairing ferric sulfate and dilute formocresol each with ZOE and polycarboxylate cements. She demonstrated that in the coronal third of the teeth tested, there was necrosis for all groups tested. In the middle third, there was a lesser degree of inflammation for the dilute formocresol-ZOE and ferric sulfate-polycarboxylate groups. In the apical third, the dilute formocresol-ZOE group showed the least inflammation. In addition, reparative dentin formation was noted in the apical third of the pulp in the ferric sulfate-ZOE group while it was not found in the other groups. Conclusions from this study include the following: dilute

formocresol-ZOE produced the least inflammation, the use of polycarboxylate cement as a substitute for ZOE did not improve the pulpal response, and significant differences were not found regarding the pulpal inflammation between ZOE and polycarboxylate cements.

Fuks et al.¹³⁴ studied ferric sulfate and dilute formocresol pulpotomies in baboon teeth. Both medications produced similar degrees of pulpal inflammation and dentin bridging. Sixty percent of the teeth had normal pulps and the remaining 40% had severe inflammation. They recommended more clinical study of ferric sulfate. A number of clinical studies comparing ferric sulfate and formocresol pulpotomies have been performed. In 1997, Fuks et al.¹³⁵ performed dilute formocresol and ferric sulfate pulpotomies and evaluated the teeth for up to 34 months. They concluded that dilute formocresol and 15.5% ferric sulfate have similar success rates. Smith et al.¹³⁶ performed a retrospective study of clinical and radiographic data from the charts of patients who received ferric sulfate pulpotomies and ZOE base. They followed 242 teeth for 4 to 57 months (mean, 19 months). Their clinical success rate was 99% and the radiographic success rate was 74% to 80%. The longer the teeth were followed, the more failures were noted radiographically. The most common pathological radiographic observations were calcific metamorphosis and internal resorption (Figure 11). Ninety percent of the teeth survived after 3 years. They concluded that ferric sulfate has a success rate similar to dilute formocresol. In addition, if the radiographic changes are separated into dental and osseous categories, and the

Figure 11 **A**, Radiograph showing internal resorption in a primary molar after ferric sulfate pulpotomy. **B**, Resorption resulted in perforation (arrow). **C**, Perforated area resulting from the resorptive process (arrow).

dental changes (internal resorption and calcific metamorphosis) are reclassified as acceptable variations of success, then the radiographic success rate would be 84% to 92%. The only radiographic changes that would be classified as failures were interradicular or periapical bone destruction and external resorption. These investigators also suggest that since the goal is to keep the pulpotomized tooth asymptomatic until exfoliation, some degree of dental changes is acceptable as long as it does not cause pain or any symptoms.

Additional clinical and retrospective studies and one evidence-based assessment conclude that ferric sulfate and dilute formocresol have similar clinical and radiographic rates of success.^{137–139} Vargas¹⁴⁰ demonstrated that both ferric sulfate and formocresol pulpotomies can cause early exfoliation of the pulpotomized teeth with the subsequent need of space maintenance until the premolar erupts.

While most of the published studies on ferric sulfate compare it to formocresol pulpotomy, Casas et al.^{141,142} took a different path, comparing it instead to primary tooth root canal therapy (pulpectomy). Root canal therapy with a plain ZOE obturation and ferric sulfate pulpotomy were found to have similar success rates up to about 2 years, but past 2 years, the root canal treatment had better success. They suggested that complete obturation of the canal rather than the partial treatment of the pulp is the best treatment for pulpally involved primary teeth. They did concede that it will be difficult to get the pediatric dental community to change because of the relatively high success rates of pulpotomy, because this was the treatment they learned as a student or a resident, and because pulpotomy is a simple treatment and some children are not cooperative enough to sit for a pulpectomy treatment (Figure 12).

Mineral Trioxide Aggregate

MTA has only recently been recommended as a pulp capping agent in primary teeth. The first published clinical trials in primary teeth began in 2001 and in animal studies occurred in 2003 to 2004 in rat and dog teeth.

A study involving rat first molars demonstrated that after 2 weeks the treated teeth responded well to MTA and were attempting to form dentinal bridges. In the 4-week samples, dentin bridges were completely formed at the pulp–MTA interface and the pulps appeared normal.¹⁴³ In the dog study, the researchers tested white and gray MTA as well as regular and white Portland cements as pulpotomy medicaments. Seventy-six teeth from mongrel dogs received pulpotomy treatments. The teeth were evaluated after 120 days and all four of the materials were found to have similar results. The pulps healed with dentin bridges that completely closed the pulpotomy access preparations and the pulps appeared normal. The researchers concluded that both MTA and Portland cement were good pulp capping agents, and they further suggested that Portland cement has the potential to be used as a less expensive material in endodontics.¹⁴⁴ They did not address the fact that Portland cement is not approved for human use.

A number of human studies using MTA as a pulp capping material in primary teeth have demonstrated that MTA performs as well or better than formocresol. Teeth in these studies were followed for periods of 6 to 74 months. Pulp canal obliteration was a common finding in teeth treated with MTA. Various authors conclude that MTA is a reasonable replacement for formocresol because of its high success rates and it lacks the undesirable side effects of formocresol.^{145–150} Studies that tested both gray and white MTA concluded that the gray formulation produces better results than the white.^{146,150} While MTA has shown excellent results as a pulp capping agent for primary teeth pulpotomies, the one factor that seems to keep it from becoming the new gold standard replacement for formocresol is the cost of the material. Only time will tell if MTA will replace formocresol as the most commonly used pulp capping material for primary teeth.

Nonvital Pulp Therapy for Children

In children, complete root canal treatment on primary teeth is often referred to as a pulpectomy procedure. While the term pulpectomy only infers removal of the pulp, this term in pediatric dentistry has come to mean removal of the caries and the inflamed or necrotic

Figure 12 Pulpotomy technique. **A**, Primary molar with large carious lesion. **B**, Caries removed and pulp exposed. **C**, Pulp tissue removed from the chamber. **D**, Pulp space being treated with ferric sulfate. **E**, After treatment with ferric sulfate. **F**, ZOE base has been placed.

pulp, cleaning and shaping the root canals, and obturation of the tooth with a resorbable root filling material. Pulpotomy is indicated when a tooth has irreversible pulpitis or a necrotic pulp or when a tooth has been treatment planned for a pulpotomy and excessive hemorrhage (hyperemia) is encountered at the time of treatment.¹ Some pediatric dentists prefer pulpectomy procedure for primary anterior teeth even if the tooth could be a candidate for only a pulpotomy

procedure or if the tooth has only reversible pulpitis symptoms because they believe a complete obturation of the canal is preferable to partial obturation whenever possible. A number of articles recommend pulpectomy as a substitute for all pulpotomies.^{151–153}

Pulpotomy procedures for primary teeth must be done with a consideration for the subjacent succedaneous tooth (Figure 13). It begins with profound pulpal anesthesia followed by placement of a rubber dam.

Figure 13 Illustration shows the proximity of primary molar roots to subjacent succedaneous tooth. Courtesy of Dr. A.C. Goerig.

All caries are removed with a slow-speed round bur or a spoon excavator (Figure 14). From the point of the pulp exposure, an access preparation is made by connecting the pulp horns with the bur. This creates the outline of the access preparation. The roof of the chamber and the coronal pulp are removed. The access preparation is refined to make sure that access to all of the canals is possible. There should be slight flaring of the access to allow for ease of insertion of the files.

In clinical situations where a primary incisor has no caries but has been affected by dental trauma that caused a gray discoloration, the access can be performed from the facial. It is very similar to a lingual access, as it connects the pulp horns and makes a triangular-shaped preparation that is combined with

Figure 14 Removal of the roof of the chamber and coronal pulp. Courtesy of Dr. A.C. Goerig.

a facial veneer preparation. Following pulpectomy, the tooth can be restored with a light composite resin in the pulp chamber to veneer the facial surface of the tooth to mask the discoloration.

To remove the radicular pulp in anterior teeth, a good technique is to insert two very small files (size 10 or 15) on either side of the pulp and twist the files removing the whole pulp in one motion. In posterior teeth, a barbed broach is used. The canals can be irrigated with sodium hypochlorite or sterile saline. It will be necessary to irrigate the canal several times throughout the procedure.

Files are measured 1 mm short of the apex by comparing them to the length of the tooth on a radiograph. This gives a preliminary working length. It is important to avoid extending instruments into the

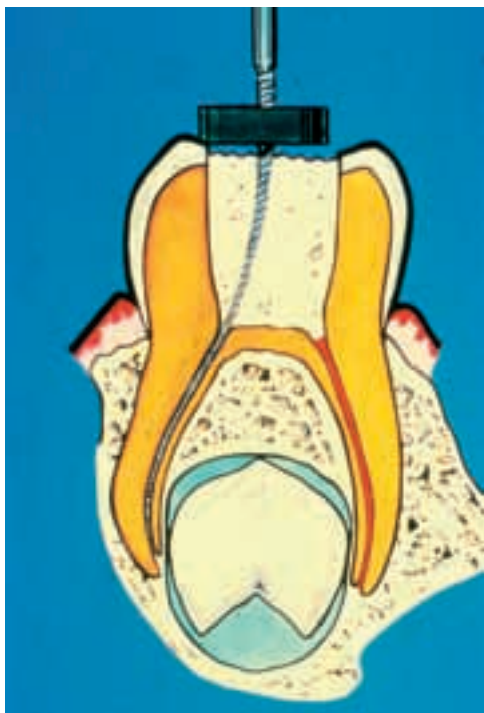

Figure 15 Pulpectomy treatment—file inserted into the canal. Courtesy of Dr. A.C. Goerig.

Figure 16 Pulpectomy treatment—obturation of the canals with zinc oxide–eugenol (ZOE) placed with an instrument. Courtesy of Dr. A.C. Goerig.

apical area. The file is inserted into the canal and with tactile sense felt for an apical stop (Figure 15). An alternative method is to insert a medium or a large-sized file (medium for molars and larger files for anterior teeth) into the canal of the tooth and feel for an apical stop. This measurement is then compared to the radiograph. After the correct length is established, smaller files are set to this length. Studies have shown that electronic apex locators can accurately be used when treating primary teeth.^{154,155} Excessive cleaning and shaping of the canal should be avoided since that can damage the tooth and lead to extraction caused by perforation in the furcation or the lateral wall of a canal. The purpose of filing is to remove the pulp tissue and make room for the root canal filling material. After the canals are cleaned, they should be irrigated again and dried with appropriately sized sterile paper points.

There are a number of choices of root canal filling materials that can be used for primary teeth, and each of these materials has an appropriate obturation technique (Figure 16). Unreinforced zinc oxide and eugenol is a very common material and is easily placed

into the canal with a rotary paste filler (Figure 17). It is very important that commercially prepared zinc oxide cements, with reinforcing fibers, *not* be used, as these reinforced cements are not well resorbed. The unreinforced ZOE is mixed into a thick paste. Large rotary spirals work well for maxillary anterior teeth, and small spirals are suited for molars and mandibular incisors. The rotary spiral is inserted into the canal while it is not turning and is used to search for the apical stop. The paste filler is then slightly removed so that it is short of the apical stop and the handpiece is revolved slowly. The dental assistant places the ZOE on the spatula next to the revolving paste filler that pulls the ZOE off the spatula and introduces the cement into the canal. The speed of the handpiece can be adjusted to cause the ZOE to completely fill the canal. When the dentist believes that the canal is completely filled, the paste filler is removed while still rotating. If the paste filler is removed after it has stopped, it will pull the ZOE from the canal.

A periapical radiograph is then exposed to determine the adequacy of the root canal filling. If the

Figure 17 Examples of rotary paste fillers.

canal is not completely filled, the paste filler is reintroduced into the canal to achieve a better obturation. Small amounts of ZOE overfill can be expected

Figure 18 Pulpectomy treatment—tooth restored with a stainless steel crown. Courtesy of Dr. A.C. Goerig.

to be resorbed uneventfully although it is better to have an underfill than an overfill. The tooth is then restored and monitored until it exfoliates^{21,22,151,156} (Figures 18 and 19).

There have been many articles that quantify the success rate of pulpectomy and root canal treatments in primary teeth. In 1978, Jokinen et al.¹⁵⁷ studied 1,304 pulpectomies and found that only 53% were successful. Success rates in the mandible and maxilla were nearly equal. This study is of historical interest, but it is difficult to use these results in judging today's dental care because the technique was very different than the average pulpectomy that is performed today.

Flaitz et al.¹⁵⁸ followed 87 pulpectomies in primary incisors that were obturated with ZOE, with a drop of formocresol in the cement mixture, for a period of 37.4 months. They found a success rate of 84%. In a follow-up study of 62 patients over a period of 12 to 74 months, these same researchers demonstrated a success rate of 82.3% for primary molar pulpectomies with a ZOE filling material.¹⁵⁹ Yacobi¹⁵³ et al. performed ZOE pulpectomies on both primary incisors and molars on 51 children over a period of 12 months and found a success rate of 76% for the anterior teeth and a success rate of 84% for the posteriors. Payne et al.¹⁶⁰ studied primary 253 anterior and posterior primary teeth for up to 24 months. Their success rate for anterior teeth was

Figure 19 **A**, Primary molar with large caries lesion involving the pulp. **B**, Radiograph taken after pulpectomy and root canal filling. **C**, Evaluation 1 year later.

82.8% and 90.3% for posterior teeth. Coll et al.¹⁶¹ followed 65 ZOE pulpectomies for a period of 90.8 months. The overall success rate was 77.7%. Two additional studies provide success rates of 76% and 78.5% for ZOE pulpectomies.^{162,163}

Rifkin¹⁶⁴ used Kri Paste (a mixture of *p*-chlorophenol, camphor, menthol, and iodoform) to treat 45 primary teeth. The teeth were treated in either 1 or 2 appointments depending on the symptoms. After 1 year, 42 of the 45 teeth were asymptomatic. Garcia-Godoy¹⁶⁵ treated 55 primary teeth with multiple appointment pulpectomies, obturated with Kri Paste, and followed for up to 2 years. There were no clinical or radiographic signs or symptoms in 95.6% of the teeth. Coll et al.¹⁶⁶ compared 41 pulpectomies on primary teeth with pulp necrosis that were obturated with Kri Paste over a period of up to 6 years 10 months. The teeth had a success rate of over 80%. An additional study by Coll¹⁶⁷ confirmed this success rate. Another study by Reyes and Reina¹⁶⁸ with a similar technique documented a 100% success rate. Thomas et al.¹⁶⁹ studied 36 primary teeth for 3 months after pulpectomies and obturated with iodoform paste. They found a success rate of 94.4%. Holan and Fuks¹⁷⁰ compared ZOE- and Kri Paste-filled pulpectomies on primary molars evaluated for periods up to 48 months. They demonstrated a success rate of 84% for Kri Paste and 65% for ZOE. After a number of clinical studies using Kri Paste for pulpectomies, Wright et al.¹⁷¹ performed an *in vitro* antimicrobial and cytotoxic study of Kri Paste and ZOE. In this study, they found that ZOE had better antimicrobial activity and that both materials had similar cytotoxicity.

Hendry¹⁷² and his fellow researchers performed pulpectomies using calcium hydroxide and plain ZOE on mongrel dogs. They exposed the pulps of the dogs to produce inflamed pulps. The teeth were later instrumented and obturated with either calcium hydroxide or ZOE. Clinical, radiographic, and histo-

logical evaluations of both calcium hydroxide and ZOE found that the calcium hydroxide specimens were more successful in all areas. Another study by Mani et al.¹⁷³ compared 60 ZOE and calcium hydroxide pulpectomies. Combined clinical and radiographic success rates were 83.3% for the ZOE group and 86.7% for the calcium hydroxide group. Ozalp et al.¹⁷⁴ found a success rate of 80 to 90% for pulpectomies that were obturated with calcium hydroxide.

Vitapex (NeoDental International, Inc., Federal Way, WA) is a commercially prepared calcium hydroxide and iodoform mixture that is prepackaged in syringes specifically for pulpectomies. It has been tested by a number of researchers. A case report by Nurko et al.¹⁷⁵ recommends it as an excellent material for pulpectomies in spite of some problems with resorption of the material. Three additional studies document the use of Vitapex with follow-up of up to 22 months; the success rates approached 100%.^{162,174,176}

One *in vitro* study by Tchaou et al.¹⁷⁷ compared various dental materials used in pulpectomies for primary teeth for bacterial inhibition. They compared calcium hydroxide mixed with camphorated *p*-chlorophenol ($\text{Ca}(\text{OH})_2 + \text{CPC}$), calcium hydroxide mixed with sterile water ($\text{Ca}(\text{OH})_2 + \text{H}_2\text{O}$), zinc oxide mixed with CPC ($\text{ZnO} + \text{CPC}$), zinc oxide mixed with eugenol (ZOE), ZOE mixed with formocresol (ZOE + FC), zinc oxide mixed with sterile water ($\text{ZnO} + \text{H}_2\text{O}$), ZOE mixed with chlorhexidine dihydrochloride (ZOE + CHX), Kri paste, Vitapex paste, and Vaseline. They found that the materials could be divided into three groups. Category I with the strongest antibacterial effect included $\text{ZnO} + \text{CPC}$, $\text{Ca}(\text{OH})_2 + \text{CPC}$, and ZOE + FC. Category II with a medium bacterial effect included ZOE + CHX, Kri, ZOE, and $\text{ZnO} + \text{H}_2\text{O}$. Category III with no or minimal antibacterial effect included Vitapex, $\text{Ca}(\text{OH})_2 + \text{H}_2\text{O}$, and Vaseline.

There are many articles that describe aspects of the pulpectomy technique and the instruments involved in the procedure. Once a primary molar begins to resorb, from physiological resorption or from pathosis, it can be difficult for the dentist to know if the canals of the tooth can be properly instrumented or even to obtain a correct working length. Rimondini and Baroni¹⁷⁸ studied 80 primary molars in children 4 to 12 years old, 75 of which were extracted because of pulpal involvement. The teeth were measured and the apices and areas of resorption were located. They found that roots that were longer than 10 mm were related to a curved root shape with no external resorption. Roots with length between 4 to 7 mm were associated with advanced root resorption. Roots that were shorter than 4 mm were associated with resorption and perforation of the furcation. They identified 4 mm as the limit of the length of a root that can be treated successfully.

Barr et al.¹⁷⁹ presented the use of rotary nickel–titanium files to prepare primary teeth for pulpectomy treatment. Advantages of this technique include ease of removal of tissue and debris, flexible design allowing access to canals, files prepare the canal in a funnel shape to ease obturation, and the files are available in 21 mm length. Disadvantages of the use of these files include cost of the equipment (handpiece), increased cost of the files, and the time required to learn the technique. An *in vitro* study was performed on three pulpectomy filling devices: Lentulo spiral (Dentsply International), NaviTip (Ultradent Products, Inc., South Jordan, UT), and Vitapex syringe (NeoDental International, Inc.). Seventy extracted primary teeth were prepared and mounted in acrylic blocks. The teeth were divided into three groups and pulpectomies were done followed by obturation with three different methods. The specimens were radiographed and evaluated and the conclusion was that the NaviTip produced the best quality fill.¹⁸⁰ Bawazir and Salama¹⁸¹ studied two methods of obturating root canals with Lentulo spiral paste fillers. One technique was with the Lentulo mounted on a slow-speed handpiece and the other method was with a handheld Lentulo. They concluded that there was no difference in the two methods as far as the quality of the fill or in the success of the obturation.

Johnson et al.¹⁸² performed an *in vitro* study using an apical resorbable collagen barrier to prevent overfill of the canal. The apices of the teeth were coated with wax and the teeth were embedded into acrylic. The canals were filed, rinsed, and dried. A resorbable collagen barrier was packed into some of the canals and the remainder of the teeth served as controls. The

teeth were then obturated with Vitapex. Radiographs were evaluated for the presence of an overfill. In the test group, overfills were present in 16% of teeth. In the control group (no barrier), overfills were present in 42% of teeth. They suggest that resorbable collagen barriers can help prevent overfills. One problem that can be experienced with resorbable cements placed in root canals of primary teeth is overretention of the material in the alveolus after exfoliation of the primary tooth (Figure 20). Studies by Sadrian and Coll¹⁸³ and Coll et al.^{166,167} have shown that ZOE cement was retained in the alveolus in 49.4% to 73.3% of the exfoliated teeth, and this material was still retained in 27.3% of the patients after 40.2 months. Short-filled pulpectomies were significantly less likely to overretain ZOE.¹⁶¹ One of the two studies evaluated over 6,000 charts in a pediatric dentistry private practice.¹⁸³ Jerrell and Ronk¹⁸⁴ presented a case study of the arrest of eruption of a permanent premolar after ZOE material was extruded from the primary molar pulpectomy into the developing tooth bud. Fortunately in the case of this particular patient, premolar extraction was a part of the patient's orthodontic treatment plan, so the tooth was extracted. It is reassuring that studies have shown a low incidence of enamel hypoplasia in succedaneous teeth when the primary teeth have been treated with pulpectomy techniques.^{161,166}

Educational Curricula and Attitudes of Pediatric Dentists

A study by Avran¹⁸⁵ in 1987 surveyed pediatric dentistry residencies in Canada and a number of dental schools worldwide. He found that in Canada among pediatric dental specialists, the preferred pulp medicament for 50% of the respondents was 1:5 formocresol and full-strength formocresol was preferred by 42.2%. In Canadian pediatric dental residency programs, full-strength formocresol was preferred by 40.8% of respondents and 1:5 formocresol was preferred by 36%. Seventy percent of respondents in Scandinavian dental schools preferred calcium hydroxide. This is not unexpected since much of the research on calcium hydroxide as a pulp medicament has been done there. When respondents were asked if they were considering a change to another medicament, many said they would consider glutaraldehyde.

A second study was published by Primosch¹⁸⁶ in 1997 based on a survey of the pediatric dental

Figure 20 *A*, Large caries on primary incisors at the time of diagnosis. *B*, Approximately 3 years after endodontic treatment. *C*, Five and half years after treatment, the primary tooth is retained and deflecting permanent successor. *D*, The primary incisor has been extracted. Radiograph shows retained zinc oxide–eugenol (ZOE) material. The right primary incisor was subsequently extracted.

programs in the United States regarding curricula for pulp therapy in children. Calcium hydroxide was the preferred base for pulp capping. Most schools taught that after the first appointment of an indirect pulp cap, it would be necessary to reenter the tooth only if the patient experienced symptoms. A 1:5 dilution of formocresol was the most commonly (71.7%) recommended medicament for pulpotomy procedure, and it was left in the tooth for 5 minutes (94.3%). ZOE was the most commonly recommended base (92.4%). It is interesting to note that while some practitioners were considering changing from formocresol to glutaraldehyde in Avram's study in the 1980s, no US dental school included glutaraldehyde in the curriculum in the 1997 study. Further, the Primosh's study reported that 2 of 53 dental schools in 1997 were teaching ferric sulfate or 1:5 formocresol to their students. While

interest in glutaraldehyde has decreased, interest and research on ferric sulfate has greatly increased.

In regard to pulpectomy procedure, 98% of US dental schools were teaching hand instrumentation of canals, with the majority of schools not recommending any enlargement of the canal. The most commonly recommended irrigants were sodium hypochlorite, sterile water or saline, and local anesthetic. Ninety percent of schools recommended zinc oxide and eugenol as the preferred filling for root canals. These two studies have now become outdated. So why include this information? These are only two journal articles that quantify what is being taught in dental schools. It is important to realize that formocresol has been advocated as a pulp medicament for a very long time, and it seems to be very entrenched in pediatric dental education. While it may have a number of problems, no substitute has

been overwhelmingly advocated to take its place. It is certain that there is much room for research on new pulp medicaments to replace formocresol.

Conclusion

Endodontic therapy, from pulp capping, pulpotomy or to pulpectomy, is an excellent procedure to prevent the premature loss of primary teeth. When the appropriate treatment is selected for each situation, success and preservation of the tooth can be anticipated. Vital pulp therapy is indicated when the pulp has the potential for healing, and nonvital pulp therapy is indicated when irreversible pulpitis or necrosis exists. Preserving primary teeth keeps young smiles beautiful and dental arches intact preventing space loss and malocclusion.

CHAPTER 40

RESTORATION OF ENDODONTICALLY TREATED
TEETH

CHARLES J. GOODACRE, NADIM Z. BABA

Various methods of restoring pulpless teeth have been reported for more than 200 years. In 1747, Pierre Fauchard¹ described the process by which roots of maxillary anterior teeth were used for the restoration of single teeth and the replacement of multiple teeth (Figure 1). Posts were fabricated of gold or silver and held in the root canal space with a heat-softened adhesive called “mastic.”^{1,2} The longevity of restorations made using this technique was attested to by Fauchard: “Teeth and artificial dentures, fastened with posts and gold wire, hold better than all others. They sometimes last fifteen to twenty years and even more without displacement. Common thread and silk, used ordinarily to attach all kinds of teeth or artificial pieces, do not last long.”¹

The replacement crowns were made from bone, ivory, animal teeth, and sound natural tooth crowns. Gradually the use of these natural substances declined, to be slowly replaced by porcelain. A pivot (what is today termed a post) was used to retain the artificial porcelain crown into a root canal and the crown–post combination was termed a “pivot crown.” Porcelain pivot crowns were described in the early 1800s by a well-known dentist of Paris, Dubois de Chemant.² Pivoting (posting) of artificial crowns to natural roots became the most common method of replacing artificial teeth and was reported as the “best that can be employed” by Chapin Harris in *The Dental Art* in 1839.³

Early pivot crowns in the United States used seasoned wood (white hickory) pivots.⁴ The pivot was adapted to the inside of an all-ceramic crown and also into the root canal space. Moisture would swell the wood and retain the pivot in place.² Surprisingly, Prothero² reported removing two central incisor crowns with wooden pivots that had been successfully

used for 18 years. Subsequently, pivot crowns were fabricated using wood/metal combinations and then more durable all-metal pivots were used. Metal pivot retention was achieved by various means such as threads, pins, surface roughening, and split designs that provided mechanical spring retention.²

Unfortunately, adequate cements were not available to these early practitioners, cements that would have enhanced post retention and decreased abrasion of the root caused by movement of metal posts within the canal. One of the best representations of a pivoted tooth appears in *Dental Physiology and Surgery*, written by Sir John Tomes in 1849 (Figure 2).⁵ Tomes’ post length and diameter conformed closely to today’s principles in fabricating posts.

Endodontic therapy, by these dental pioneers, embraced only minimal efforts to clean, shape, and obturate the canal. Frequent use of the wooden posts in empty canals led to repeated episodes of swelling and pain. Wooden posts, however, did allow the escape of the so-called “morbid humors.” A groove in the post or the root canal provided a pathway for continual suppuration from the periradicular tissues.¹

Although many of the restorative techniques used today had their inception in the 1800s and early 1900s, proper endodontic treatment was neglected until years later. Today, both endodontic and prosthodontic aspects of treatment have advanced significantly, new materials and techniques have been developed, and a substantial body of scientific knowledge is available upon which to base clinical treatment decisions.

The purpose of this chapter is to answer questions frequently encountered when dental treatment involves endodontically treated teeth and to describe the techniques commonly employed when restoring these

Figure 1 Early attempts to restore single or multiple units. **A**, "Pivot tooth" consisting of crown, post, and assembled unit. **B**, Six-unit anterior fixed partial dental prosthesis "pivoted" in lateral incisors with canines cantilevered. Crowns were fashioned from a diversity of materials. Human, hippopotamus, sea horse, and ox teeth were used, as well as ivory and oxen leg bones. Posts were usually made from precious metals and fastened to the crown and root by using a heated sticky "mastic" prepared by gum, lac, turpentine, and white coral powder.

Figure 2 Principles used today in selecting post length and diameter were understood and taught by early practitioners during mid-1800s.

teeth. Whenever possible, the answers and discussion will be supported by scientific evidence. Conflicting results will be presented to provide a comprehensive understanding of the available evidence.

Should Crowns Be Placed on Endodontically Treated Teeth?

A retrospective study⁶ of 1,273 teeth endodontically treated 1 to 25 years previously compared the clinical success of anterior and posterior teeth. Endodontically treated teeth with restorations that encompassed the tooth (onlays, partial or complete coverage metal crowns, and metal ceramic crowns) were compared with endodontically treated teeth with no coronal coverage restorations. It was determined that coronal coverage crowns did not significantly improve the success of endodontically treated anterior teeth. This finding supports the use of a conservative restoration such as an etched resin restoration in the access opening of otherwise intact or minimally restored anterior teeth. Crowns are indicated only on endodontically treated anterior teeth when they are structurally weakened by the presence of large and/or multiple coronal restorations or they require significant form/color changes that cannot be effected by bleaching, resin bonding, or porcelain laminate veneers. Scurria et al.⁷ collected data from 30 insurance carriers in 45 states regarding the procedures 654 general dentists performed on endodontically treated teeth. The data indicated that 67% of endodontically treated anterior teeth were restored without a crown, supporting the concept that many anterior teeth are being satisfactorily restored without the use of a crown.

When endodontically treated *posterior teeth* (with and without coronal coverage restorations) were compared, a significant increase in the clinical success was noted when cuspal coverage crowns were placed on maxillary and mandibular molars and premolars.⁶ In a study of 116 failed and extracted endodontically treated teeth, Vire⁸ reported that teeth restored with crowns had greater longevity than uncrowned teeth. A strong association was found between crown placement and the survival of endodontically treated teeth. If long-term tooth survival is the primary goal, placing

Figure 3 **A**, Occlusal view showing the fracture of the buccal cusp of an endodontically treated mandibular left first molar. **B**, Extracted tooth showing the fracture extending down both roots.

a crown on an endodontically treated posterior tooth enhances survival (Figure 3).⁹ Therefore, restorations that encompass the cusps should be used on posterior teeth that have intercuspation with opposing teeth and thereby receive occlusal forces that push the cusps apart. The previously discussed insurance data⁷ indicated that 37 to 40% of posterior endodontically treated teeth were restored by practitioners without a crown, a method of treatment not supported by the long-term clinical prognosis of posterior endodontically treated teeth that do not have cusp-encompassing crowns. There are, however, certain posterior teeth (not as high as 40%) that do not have substantive occlusal intercuspation or have an occlusal form that precludes intercuspation of a nature that attempts to separate the cusps (such as mandibular first premolars with small, poorly developed lingual cusps). When teeth are intact or minimally restored (small MO or DO restorations), they would be reasonable candidates for restoration of only the access opening without the use of a coronal coverage crown.¹⁰

In contrast to the above recommendations, a 3-year clinical study by Mannocci et al.¹¹ evaluated the clinical success rate of endodontically treated premolars restored with a post and direct composite resin restorations with and without complete crown coverage. They found that both had a similar success rate. Nagasiri et al.,¹² in a retrospective cohort study, indicated that when endodontically treated molars are

completely intact except for a conservative access opening, they could be restored successfully by using composite resin restorations.

Multiple clinical studies of fixed partial dentures, many with long spans and cantilevers, have determined that endodontically treated abutments failed more often than vital teeth due to tooth fracture,^{13–17} supporting the greater fragility of endodontically treated teeth and the need to design restorations that reduce the potential for both crown and root fractures when extensive fixed prosthodontic treatment is required.

Gutmann¹⁸ reviewed the literature and presented an overview of several articles that identify what happens when teeth are endodontically treated. These articles provide background information important to an understanding of why coronal coverage crowns help prevent fractures of posterior teeth. Endodontically treated dog teeth have been found to have 9% less moisture than vital teeth.¹⁹ In addition, it was found that dehydration increases stiffness and decreases the flexibility in teeth. However, dehydration by itself does not account for the physical property changes in dentin.²⁰ Also, with aging, greater amounts of peritubular dentin are formed, which decreases the amount of organic materials that may contain moisture. It has been shown that endodontic procedures reduce tooth stiffness by 5%, attributed primarily to the access opening.²¹ Tidmarsh²² described the structure of an intact tooth that permits deformation when loaded occlusally

and elastic recovery after removal of the load. The direct relationship between tooth structure removed during tooth preparation and tooth deformation under load has been described.²³ Dentin from endodontically treated teeth has been shown to exhibit significantly lower shear strength and toughness when compared with vital dentin.²⁴ Rivera et al.²⁵ stated that the effort required to fracture dentin may be less when teeth are endodontically treated because of more immature (potentially weaker) collagen intermolecular cross-links. In a recent study, it was found that collagen fibrils degraded over time in teeth with zinc phosphate-cemented posts. Acid demineralization can also occur from bacteria and acid etching.²⁶

CONCLUSIONS

Restorations that encompass the cusps of endodontically treated posterior teeth have been found to increase the clinical longevity of these teeth. Therefore, crowns should be placed on endodontically treated posterior teeth that have occlusal intercuspation with opposing teeth of the nature that places expansive forces on the cusps. Since crowns do not enhance the clinical success of anterior endodontically treated teeth, their use on relatively sound teeth should be limited to situations where esthetic and functional requirements cannot be adequately achieved by other more conservative restorations (Figure 4).

Figure 4 Traumatized tooth before endodontic procedure. Placement of a bonded resin restoration in the access opening after root canal treatment and whitening is the only treatment required since crowns do not enhance the longevity of anterior endodontically treated teeth. A crown will be indicated only when esthetic and functional needs cannot be achieved through more conservative treatments.

With Pulpless Teeth, Do Posts Improve Long-Term Clinical Prognosis or Enhance Strength?

Historically, the use of posts was based on the concept that a post reinforces the tooth.

LABORATORY DATA

Virtually all laboratory studies²⁷⁻³⁷ have shown that placement of a post and core either fails to increase the fracture resistance of endodontically treated extracted teeth or decreases the fracture resistance of the tooth when a force is applied via a mechanical testing machine. Lovdahl and Nicholls²⁷ found that endodontically treated maxillary central incisors were stronger when the natural crown was intact except for the access opening than when they were restored with cast posts and cores or pin-retained silver amalgams. Lu²⁸ found that posts placed in intact endodontically treated central incisors did not lead to an increase in the force required to fracture the tooth or in the position and angulation of the fracture line. Pontius²⁹ found that maxillary incisors, without posts, resisted higher failure loads than the other groups with posts and crowns. Gluskin³⁰ found that mandibular incisors with intact natural crowns exhibited greater resistance to transverse loads compared with teeth with posts and cores. McDonald³¹ found no difference in the impact fracture resistance of mandibular incisors with or without posts. Eshelman and Sayegh³² reported similar results when posts were placed in extracted dog lateral incisors. Guzy and Nicholls³³ determined that there was no significant reinforcement achieved by cementing a post into an endodontically treated tooth that was intact except for the access opening. Leary et al.³⁴ measured the root deflection of endodontically treated teeth before and after posts of various lengths were cemented into prepared root canals. They found no significant differences in strength between the teeth with or without a post. Trope et al.³⁵ determined that preparing a post space weakened endodontically treated teeth compared with ones in which only an access opening was made, but no post space.

A potential situation where a post and core could strengthen a tooth was identified by Hunter et al.³⁶ using photoelastic stress analysis. They determined that removal of internal tooth structure during endodontic therapy is accompanied by a proportional increase in stress. They also determined that minimal root canal enlargement for a post does not substantially weaken a tooth but when excessive root

canal enlargement has occurred, a post strengthens the tooth. Therefore, if the walls of a root canal are thin due to the removal of internal root caries or overinstrumentation during post preparation, then a post may potentially strengthen the tooth.

Two-dimensional finite element analysis was used in one study³⁷ to determine the effect of posts on dentin stress in pulpless teeth. When loaded vertically along the long axis, a post reduced maximal dentin stress by as much as 20%. However, only a small (3 to 8%) decrease in dentin stress was found when a tooth with a post was subjected to masticatory and traumatic loadings at 45° to the incisal edge. The authors proposed that the reinforcement effect of posts is doubtful for anterior teeth because they are subjected to angular forces.

CLINICAL DATA

Sorensen and Martinoff³⁸ evaluated endodontically treated teeth with and without posts and cores. Some of the teeth were restored with single crowns while others served as fixed partial denture abutments or removable partial denture abutments. Posts and cores significantly decreased the clinical success rate of teeth with single crowns, improved the clinical success of removable partial denture abutment teeth, and had little influence on the clinical success of fixed partial denture abutments. Eckerbom et al.³⁹ examined the radiographs of 200 consecutive patients and reexamined the patients radiographically 5 to 7 years later to determine the prevalence of apical periodontitis. Of the 636 endodontically treated teeth evaluated, 378 had posts and 258 did not have posts. At both examinations, apical periodontitis was significantly more common in teeth with posts than in endodontically treated teeth without posts. Morfis⁴⁰ evaluated the incidence of vertical root fracture in 460 endodontically treated teeth, 266 of which had posts. There were 17 teeth with root fracture after a time period of at least 3 years. Nine of the 17 fractured teeth had posts and 8 root fractures occurred in teeth without posts. Morfis⁴⁰ concluded that the endodontic technique can cause vertical root fracture. In an analysis of data from multiple clinical studies, Goodacre⁴¹ found that 3% of teeth with posts fractured. None of these clinical data provide definitive support for the concept that posts and cores strengthen endodontically treated teeth or improve their long-term prognosis.

THE PURPOSE OF POSTS

Since clinical and laboratory data indicate that teeth are not strengthened by posts, their purpose is for

retention of a core that will provide appropriate support for the definitive crown or prosthesis. Unfortunately, this primary purpose has not been completely recognized. Hussey⁴² noted that 24% of general dental practitioners felt that a post strengthens teeth. A 1994 survey (with responses from 1066 practitioners and educators) revealed some interesting facts. Ten percent of the dentist respondents felt that every endodontically treated tooth should receive a post. It was determined that 62% of dentists over age 50 believed a post reinforces the tooth whereas only 41% of the dentists under age 41 believed in that concept. Thirty-nine percent of part-time faculty, 41% of full-time faculty, and 56% of nonfaculty practitioners felt that posts reinforce teeth.⁴³

CONCLUSIONS

Both laboratory and clinical data fail to provide definitive support for the concept that posts strengthen endodontically treated teeth. Therefore, the purpose of a post is to provide retention for a core.

What Is the Clinical Failure Rate of Posts and Cores?

Several studies provide clinical data regarding the number of posts and cores that failed over certain time periods⁴⁴⁻⁵⁵ (Table 1). When this number is divided by the total number of posts and cores placed, a failure

Table 1 Clinical Failure Rate of Posts and Cores

Lead Author	Study Length	Percentage of Clinical Failure
Turner (1982)*	5 years	9 (6 of 66)
Sorensen (1984)	1–25 years	9 (36 of 420)
Bergman (1989)*	6 years	9 (9 of 96)
Weine (1991)*	10 years or more	7 (9 of 138)
Hatzikyriakos (1992)*	3 years	11 (17 of 154)
Mentink (1993)*	1–10 years (mean 4.8)	8 (39 of 516)
Wallerstedt (1984)*	4–10 years (mean 7.8)	14 (8 of 56)

Valderhaug (1997)	1–25 years (mean 2.1)	10 (40 of 397)
Mean values [§]	8 years	9 (292 of 3433)

*Studies used to calculate mean study length.

§Calculation made by averaging numerical data from all studies.

percentage is determined. A 9% overall average for failure was calculated by averaging the failure percentages from 10 studies (an average study length of 6 years). In these studies, the failure percentage ranged from 7% to 14%.

A review of more specific details from the 10 studies provides insight into the length of each study and the number of posts and cores evaluated. The findings of a 5-year retrospective study of 66 posts and cores indicate there were 6 failures and a 9% failure rate.⁴⁴ Another study found that 17 of 154 posts failed after 3 years for an 11% failure rate.⁴⁵ A failure rate of 9% was found in three studies.^{46–48} Two studies reported a 7% post and core failure rate after 9 years or more.^{49,55} An 8% failure rate (39 of 516 posts and cores) was published when 516 posts and cores placed by senior dental students were retrospectively evaluated,⁵⁰ whereas another study recorded a 14% failure rate (8 failures in 56 posts and cores) from posts and cores placed by dental students.⁵¹ A study of 397 posts followed for 25 years reported a 10% post and core failure rate after 25 years (40 of 397 posts failed).⁵⁴

Kaplan-Meier survival statistics (percentage of survival over certain time periods) were presented or could be calculated from the data in nine studies⁵² (Table 2). The survival rates ranged from a high of

99% after 10 years or more of follow-up to a 78% survival rate after a mean time of 5.2 years. The failure percentage per year has also been calculated and ranged from 1.56% per year⁴⁷ to 4.3% per year.⁵³

CONCLUSIONS

Posts and cores had an average clinical failure rate of 9% (7 to 14% range) when the data from 10 studies were combined (average study length of 8 years).

What Are the Most Common Types of Post and Core Failures?

Eight studies indicate that post loosening is the most common cause of post and core failure^{44,45,47,48,50,55–57} (Figure 5). Turner⁴⁴ reported on 100 failures of post-retained crowns and indicated that post loosening was the most common type of failure. Of the 100 failures, 59 were caused by post loosening. The next most common occurrences were 42 apical abscesses followed by 19 carious lesions. There were 10 root fractures and 6 post fractures. In another paper by Turner,⁵⁶ he reported the findings of a 5-year retrospective study of 52 post-retained crowns. Six posts had come loose, which was the most common failure. Lewis and Smith⁵⁷ presented data regarding 67 post and core failures after 4 years. Forty-seven of the failures resulted from post loosening, 8 from root fractures, 7 from caries, and 4 from bent or fractured posts. Bergman et al.⁴⁷ found 8 failures in 96 posts after 5 years. Six posts had loosened and 2 roots had fractured. Hatzikyriakos et al.⁴⁵ reported on 154 posts and cores after 3 years. Five posts had come loose, five crowns had come loose, four roots fractured, and caries caused three failures. Mentink⁵⁰ identified 30 post loosening and 9 tooth fractures when evaluating 516 posts and cores over a 1- to 10-year time period (4.8 years mean study length). Torbjörner et al.⁴⁸ reported on the frequency of three technical failures (loss of retention, root fracture, and post fracture). They did not report biological failures. Loss of retention was the most frequent post failure, accounting for 45 of the 72 post and core failures. Root

fracture (Figure 6) was the second most common failure cause followed by post fracture. Balkenhol et al.⁵⁵ reported on 802 posts and cores over a 10-year period.

Figure 6 Radiograph of a fractured maxillary first premolar with a post with excessive diameter and insufficient length, two problems frequently seen in conjunction with fractured roots.

Thirty-nine posts had loosened, eight had longitudinal root fracture, and six had transverse root fracture.

In two studies, factors other than loss of retention were listed as the most common cause of failure.^{46,49} Sorensen and Martinoff⁴⁶ evaluated 420 posts and cores and recorded 36 failures. Of the 36 failures, 8 were related to restorable tooth fractures, 12 to non-restorable tooth fractures, 13 to loss of retention, and 3 were caused by root perforations. Weine et al.⁴⁹ found 9 failures in 138 cast posts and cores after 10 years or more. Three failures were caused by restorative procedures, two by endodontic treatment, two by periodontal problems, and two by root fractures. No posts failed due to loss of retention.

Four studies have provided data on the incidence of tooth fracture but no information regarding post loosening. Linde⁵⁸ reported that 3 of 42 teeth fractured, Ross⁵⁹ found no fractures with 86 posts, Morfis⁴⁰ found that 10 of 266 teeth fractured, and Wallerstedt⁵¹ identified 2 fractures with 56 posts.

Loss of retention and tooth fracture (in that order of occurrence) are the 2 most common causes of failure when these studies are collectively analyzed by averaging the numerical data from all the studies. Five percent of the posts placed (144 of 2,980 posts)

experienced loss of retention (Table 3). Two percent of the posts placed (82 of 3,827 posts) failed via tooth fracture (Table 4).

CONCLUSIONS

Loss of retention and tooth fracture are the two most common causes of post and core failure.

Which Post Design Produces the Greatest Retention?

LABORATORY DATA

There have been many laboratory studies comparing the retention of various post designs. Threaded posts provide the greatest retention, followed by cemented,

parallel-sided posts. Tapered cemented posts are the least retentive. Cemented, parallel-sided posts with serrations are more retentive than cemented, smooth-sided parallel posts. These laboratory data are discussed below.

CLINICAL DATA

There is clinical support for these laboratory studies. Torbjörner et al.⁴⁸ reported significantly greater loss of retention with tapered posts (7%) compared with parallel posts (4%). Sorensen and Martinoff⁴⁶ determined that 4% of tapered posts failed by loss of retention whereas 1% of parallel posts failed in that manner. Turner⁵⁶ indicated that tapered posts loosened clinically more frequently than parallel-sided posts. Lewis and Smith⁵⁷ also found a higher loss of retention with smooth-walled tapered posts than parallel posts. Bergman et al.⁴⁷ and Mentink et al.⁵⁰ evaluated only tapered posts, and both studies reported that 6% of tapered posts failed via loss of retention, values higher than those recorded by Torbjörner et al.⁴⁸ and Sorensen and Martinoff⁴⁶ for parallel posts.

Contrasting results were reported by Weine et al.⁴⁹ They found no clinical failures from loss of retention with cast tapered posts. Hatzikyriakos et al.⁴⁵ studied tapered threaded posts, parallel cemented posts, and tapered cemented posts. The only posts that loosened from the root were parallel cemented posts.

CONCLUSIONS

Tapered posts are the least retentive and threaded posts the most retentive in laboratory studies. Most of the clinical data support the laboratory findings.

Is There a Relationship Between Post Form and the Potential for Root Fracture?

LABORATORY DATA

Using photoelastic stress analysis, Henry⁶⁰ determined that threaded posts produced undesirable levels of stress. Another study used strain gauges attached to the root and compared four parallel-sided threaded posts with one parallel-sided non-threaded post.⁵⁹ Two of the threaded posts produced the highest strains, whereas two other threaded posts caused strains comparable to the nonthreaded post. Standlee et al.,⁶¹ using photoelastic methods, indi-

Figure 7 Radiograph showing a threaded post that may have caused root fracture in the second premolar.

cated that tapered, threaded posts were the worst stress producers. When three types of threaded posts were compared in extracted teeth, Deutsch et al.⁶² found that tapered threaded posts increased root fracture by 20 times that of the parallel threaded posts (Figure 7).

Laboratory testing of split threaded posts has provided varying results, but more research groups have concluded that they do not reduce the stress associated with threaded posts. Thorsteinsson et al.⁶³ determined that split threaded posts did not reduce stress concentration during loading. In another study, split threaded posts were found to produce installation stresses comparable to other threaded posts.⁶⁴ Greater stress concentrations than those of some other threaded posts were reported under simulated functional loading.^{65–67} Rolf et al.⁶⁸ found that a split threaded post produced comparable stress to one type of threaded post and less stress than a third threaded post design. Ross et al.⁵⁹ determined that a split threaded post produced less root strain than two other threaded posts and comparable strain to a third threaded post and a nonthreaded post. Another research group⁶⁹ concluded that the split threaded design reduced the stresses caused during cementation compared with a rigid threaded post design. Multiple photoelastic stress studies have concluded that posts designed for cementation produced less stress than threaded posts.^{60,61,68}

When parallel-sided cemented posts were compared with tapered cemented posts, photoelastic stress testing results generally favored parallel-sided posts. Using this methodology, Henry⁶⁰ found that parallel-

sided posts distribute stress more evenly to the root. Finite element analysis studies produced similar results.^{70,71} Two additional photoelastic studies^{63,66} concluded that parallel posts concentrate stress apically and tapered posts concentrate stress at the post-core junction. Also using photoelastic testing, Assif et al.⁷² found that tapered posts showed equal stress distribution between the cemento-enamel junction and the apex compared with parallel posts that concentrated the stress apically.

When fracture patterns in extracted teeth were used to compare parallel and tapered posts, the evidence favoring parallel posts was less favorable. Sorensen and Engelman⁷³ determined that tapered posts caused more extensive fractures than parallel-sided posts did, but the load required to create fracture was significantly higher with tapered posts. Lu,²⁸ also using extracted teeth, found no difference in the fracture location between prefabricated parallel posts and cast posts and cores. Assif et al.⁷⁴ tested the resistance of extracted teeth to fracture when the teeth were restored with either parallel or tapered posts and complete crowns. No significant differences were noted, and post design did not influence fracture resistance.

In analyzing the stress distribution of posts, it was noted that tapered posts generate the least cementation stress and should be considered for teeth that have thin root walls, are nearly perforated, or have perforation repairs.⁶⁶

CLINICAL DATA

There are several clinical studies that provide data related to the incidence of root fracture associated with different post forms. Some of these studies provide a comparison of multiple post forms, whereas other studies evaluated only one type of post. Combining all the root fracture data for each post form from both types of studies reveals some interesting trends (Table 5). Five studies present data regarding root fractures and threaded posts,^{40,46,51,58,75} four regarding fractures associated with parallel-sided cemented posts^{40,46,48,75} and nine related to tapered cemented posts.^{40,46-49,50,54,55,75} If the total number of threaded posts evaluated in the five studies is divided into the total number of fractures found with threaded posts, a percent value can be determined that represents the average incidence of tooth fracture associated with threaded posts in the five studies. The same data can be calculated for parallel cemented and tapered cemented posts, permitting a comparison of the root fracture incidences associated with these three post forms.

Table 5 Post Form and Tooth Fracture

Clinical Data (Percentage of Post and Cores Studied that Failed via Tooth Fracture)

Threaded Posts (Lead Author)	Parallel-Sided Posts (Lead Author)	Tapered Posts (Lead Author)
40 (2 of 5) (Sorensen)	0 (0 of 170) (Sorensen)	7 (18 of 245) (Sorensen)
0 (0 of 10) (Ross)	2 (5 of 332) (Torbjörner)	4 (16 of 456) (Torbjörner)
4 (2 of 56) (Wallerstedt)	0 (0 of 39) (Ross)	1 (2 of 138) (Weine)

		2 (14 of 802) (Balkenhol)
		1 (2 of 397) (Valderhaug)
7% Mean* (11 of 169)	1% Mean* (9 of 687)	2% Mean* (66 of 2752)

*Calculation made by averaging numerical data from all studies.

Combining the five studies that reported data relative to threaded posts produced a mean fracture rate of 7% (11 fractures from 169 posts). The four clinical studies that contain fracture data from parallel-sided cemented posts produced a mean fracture incidence of 1% (9 fractures from 687 posts). From the seven studies reporting root fracture with tapered posts, there is a mean fracture rate of 2% (66 root fractures from 2,752 posts). This combined study data support the previously cited photoelastic laboratory stress tests, indicating that the greatest incidence of root fractures occurred with threaded posts and that the lowest incidence of root fracture was associated with parallel cemented posts. In a meta-analysis of selected clinical studies, Creugers et al.⁵² calculated a 91% tooth survival rate for cemented cast posts and cores and an 81% survival rate for threaded posts with resin cores.

While the combined data from all the studies for each type of post revealed certain trends, analysis of individual studies (where multiple post forms were compared in the same study) produced less conclusive results. One study of threaded posts and cemented posts determined that teeth with threaded posts were lost more frequently than teeth with cast posts.³⁹ In three other clinical comparisons of threaded and cemented posts, no tooth fracture differences were noted.^{40,45,75} In addition to the comparisons of threaded and cemented posts, four clinical studies provide data comparing the tooth fracture incidences associated with parallel-sided and tapered posts. In comparing parallel and tapered posts by reviewing dental charting records, a higher failure rate was reported with tapered posts than with parallel posts

in two studies, and the failures were judged to be more severe with tapered posts.^{46,48} Two other clinical studies determined that there were no differences between tapered and parallel-sided posts.^{48,75} Hatzikyriakos et al.⁴⁵ found no significant differences between 47 parallel cemented posts and 44 tapered cemented posts after three years of service. Ross⁷⁵ evaluated 86 teeth with posts and cores that had been restored at least five years previously. No fracture differences were found between 38 tapered cemented posts and 39 parallel cemented posts.

Unfortunately, the total number of clinical studies that compared multiple post forms in the same study is limited. Also, several factors may have affected the findings of available studies. Two of the papers that contained a comparison of multiple post forms covered sufficiently long time periods (10 to 25 years) that the tapered cemented posts may have been in place for much longer time periods than the parallel-sided cemented posts (due to the later introduction of parallel posts into the dental market).^{46,48} The mean time since the placement of each post form was not identified in these studies. Also, both of these studies were based on reviews of patient records (rather than clinical examinations) and depended on the accuracy of dental charts in determining if and when posts failed as well as the cause of the failure. Another factor that affected the results of many of the referenced clinical studies was the length of the posts. For instance, in Sorensen and Martinoff's study,⁴⁶ 44% of the tapered cemented posts had a length that was half (or less than half) the incisocervical/occlusocervical dimension of the crown whereas only 4% of the parallel cemented posts were that short. Since short posts have been associated with higher root stresses in laboratory studies, the difference in post length may have affected their findings where tooth fractures occurred with 18 of 245 tapered posts compared with no fractures with 170 parallel posts.

CONCLUSIONS

When evaluating the relationship between post form and root fracture, laboratory tests generally indicate that all types of threaded posts produce the greatest potential for root fracture. When comparing tapered and parallel cemented posts by using photoelastic stress analysis, the results generally favor the parallel cemented posts. However, the evidence is mixed when the comparison between tapered and parallel posts is based on fracture patterns in extracted teeth created by applying a force via a mechanical testing machine.

When evaluating the combined data from multiple clinical studies, threaded posts generally produced the

highest root fracture incidence (7%) compared with tapered cemented posts (2%) and parallel cemented posts (1%). Analysis of individual clinical studies as opposed to the combined data produces less conclusive results. Additional comparative clinical studies would be beneficial, including designs that have not yet been evaluated in comparative studies.

What Is the Proper Length for a Post?

A wide range of recommendations have been made regarding post length, which includes the following:

1. The post length should equal the incisocervical or occlusocervical dimension of the crown.^{76–83}
2. The post should be longer than the crown.⁸⁴
3. The post should be one-third of the crown length.⁸⁵
4. The post should be half of the root length.^{86,87}
5. The post should be two-thirds of the root length.^{88–92}
6. The post should be four-fifths of the root length.⁹³
7. The post should be terminated halfway between the crestal bone and the root apex.^{94–96}
8. The post should be as long as possible without disturbing the apical seal.⁶⁰

A review of scientific data provides the basis for differentiating between these varied guidelines.

While short posts have never been advocated, they have been frequently observed during radiographic examinations (Figures 8 and 9). Grieve and

Figure 8 Radiograph displaying a very short post in the distal root of a first molar. The prosthesis has loosened.

Figure 9 Radiograph of a second premolar with a very short post; the lack of adequate retention for the core can result in the prosthesis loosening.

McAndrew⁹⁷ found that only 34% of 327 posts were as long as the incisocervical length of the crown. In a clinical study of 200 endodontically treated teeth, Ross⁷⁵ determined that only 14% of posts were two-thirds or more of the root length and 49% of the posts were one-third or less of the root length. A radiographic study of 217 posts determined that only 5% of the posts were two-thirds to three-fourths of the root length.⁹⁸ In a retrospective clinical study of 52 posts, Turner⁴⁴ radiographically compared the length of the post with the maximal length available if 3 mm of gutta-percha was retained. Posts that came loose used only 59% of the ideal length and only 37% of the posts were longer than the proposed maximal length. Nine millimeters was proposed as the ideal length. Short posts have been associated with higher root stresses^{36,64,66,70,71} and a greater tendency for root fracture to occur.

Sorensen and Martinoff⁴⁶ determined that the clinical success was markedly improved when the post was equal to or greater than that of the crown length.

Johnson and Sakumura⁹⁹ determined that posts that were three-fourths or more of the root length were up to 30% more retentive than posts that were half of the root length or equal to the crown length. Leary et al.¹⁰⁰ indicated that posts with a length at least three-fourths of the root offered the greatest rigidity and least root bending.

These data indicate that post length would appropriately be three-fourths that of the root length. However, some interesting results occur when post length guidelines of two-thirds to three-fourths of the root length are applied to teeth with average, long, and short root lengths. It was determined that a post approaching this recommended length range is not possible without compromising the apical seal by retaining less than 5 mm of gutta-percha.¹⁰¹ When post length was half that of the root, the apical seal was rarely compromised on average length roots. However, when posts were two-thirds of the root length, many of the average and short roots would have less than the optimal gutta-percha seal. Shillingburg et al.¹⁰² also indicated that making the post length equal to the clinical crown length can cause the post to encroach on the 4-mm “safety zone” required for an apical seal.

Abou-Rass et al.¹⁰³ proposed a post length guideline for maxillary and mandibular molars based on the incidence of lateral root perforations when post preparations were made in 150 extracted teeth. They determined molar posts should not be extended more than 7 mm apical to the root canal orifice.

When teeth have diminished bone support, stresses increase dramatically and are concentrated in the dentin near the post apex.¹⁰⁴ A recent finite element model study established a relationship between post length and alveolar bone level.¹⁰⁵ To minimize stress in the dentin and in the post, the post should extend more than 4 mm apical to the bone.

CONCLUSIONS

Reasonable clinical guidelines for length include the following:

1. Make the post approximately three-fourths of the length of the root when treating long-rooted teeth.
2. When average root length is encountered, post length is dictated by retaining 5 mm of apical gutta-percha and extending the post to the gutta-percha (Figure 10).

3. Whenever possible, posts should extend at least 4 mm apical to the bone crest to decrease dentin stress.
4. Molar posts should not be extended more than 7 mm into the root canal apical to the base of the pulp chamber (Figure 11).

Figure 10 Five millimeters of gutta-percha was retained in the maxillary premolar and the post extended to that point.

Figure 11 The post in the distal canal of the mandibular molar extends to a maximal length of 7 mm.

How Much Gutta-Percha Should Be Retained to Preserve the Apical Seal?

It has been determined that when 4 mm of gutta-percha was retained, only 1 of 89 specimens showed leakage, whereas 32 of 88 specimens leaked when only 2 mm of gutta-percha was retained.¹⁰⁶ Two studies found no leakage at 4 mm,^{107,108} and two additional studies found little leakage at 4 mm.^{106,109} Portell et al.¹¹⁰ found that most specimens with only 3 mm of apical gutta-percha had some leakage. When the leakage associated with 3, 5, and 7 mm of gutta-percha was compared, Mattison et al.¹¹¹ found significant leakage differences between each of the dimensions. They proposed that at least 5 mm of gutta-percha is required for an adequate apical seal. Nixon et al.¹¹² compared the sealing capabilities of 3, 4, 5, 6, and 7 mm of apical gutta-percha using dye penetration. The greatest leakage occurred when only 3 mm was retained, and it was significantly different from the other groups. They also noted a significant decrease in leakage when 6 mm of gutta-percha remained. Raiden and Gendelman¹¹³ cemented stainless steel posts with zinc phosphate cement in teeth with residual root canal fillings of 1, 2, 3, and 4 mm. They tested apical leakage using a passive dye system. They concluded that 4 mm of apical seal provided a leakage value of zero. Kvist et al.¹¹⁴ examined radiographs from 852 clinical endodontic treatments. Posts were present in 424 of the teeth. Roots with posts in which the remaining root filling material was shorter than 3 mm showed a significantly higher frequency of periapical radiolucencies. Using a pressure-driven tracer assay, Wu et al.¹¹⁵ and Abramovitz et al.¹¹⁶ found that 4 or 5 mm of apical seal was inferior in their ability to prevent leakage, compared with an original full-length root canal filling. Similarly, Metzger et al.¹¹⁷ compared the sealing capabilities of 3, 5, 7, and 9 mm of apical gutta-percha using a pressure-driven radioactive tracer assay. They concluded that the sealing is proportional to the length of the remaining filling and that original full-length root canal fillings have a superior seal compared with 3, 5, and 7 mm of apical gutta-percha.

CONCLUSIONS

Since there is greater leakage when only 2 to 3 mm of gutta-percha is present (Figure 12), 4 to 5 mm should be retained apically to ensure an adequate seal. Although studies indicate that 4 mm produces an adequate seal, stopping precisely at 4 mm is difficult and radiographic angulation errors could lead to retention of less than 4 mm. Therefore, 5 mm of gutta-percha should be retained apically. This seal is complemented by the seal provided by the post and core, and the overlying crown (Figure 11).

Figure 12 Less than 2 mm of gutta-percha remains in the maxillary first premolar apical to the cast post and core, increasing the risk of failure.

Does Post Diameter Affect Retention and the Potential for Tooth Fracture?

Studies relating post diameter to post retention have failed to establish a definitive relationship. Two studies determined that there was an increase in post retention as the diameter increased,^{102,118} whereas three studies found no significant retention changes with diameter variations.^{119,110,120} Krupp et al.¹²¹ indicated that post length was the most important factor affecting retention and post diameter was a secondary factor.

A more definitive relationship has been established between post diameter and stress in the tooth. Mattison¹²² found that as the post diameter increased, stress increased in the tooth. Trabert et al.¹²³ measured the impact resistance of extracted maxillary central incisors as post diameter increased and found that increasing the post diameter decreased the tooth's resistance to fracture. Deutsch et al.⁶² determined that there was a six-fold increase in the potential for root fracture with every millimeter decrease in tooth diameter. However, two finite element studies failed to find higher tooth stresses with larger-diameter posts.^{70,71}

CONCLUSIONS

Laboratory studies relating retention to post diameter have produced mixed results, whereas a more definitive relationship has been established between root fracture and large-diameter posts (Figure 13).

Figure 13 Excessive post diameters. **A**, Large-diameter post placed in the palatal root of the maxillary molar. **B**, Large-diameter threaded post caused fracture of the maxillary second premolar. The radiographic appearance of the bone is typical of a fractured root—a teardrop-shaped lesion with diffuse border.

What Is the Relationship Between Post Diameter and the Potential for Root Perforations?

In a literature review of guidelines associated with post diameter, Lloyd and Palik¹²⁴ indicated that there are three distinct philosophies of post space preparation. One group advocates the narrowest diameter for fabrication of a certain post length (the conservationists). Another group proposes a space with a diameter that does not exceed one-third of the root diameter (the proportionists). The third group advises leaving at least 1 mm of sound dentin surrounding the entire post (the preservationists).

Based on the proportional concept of one-third of the root diameter, three articles measured the root diameters of extracted teeth and proposed post diameters that would not exceed this proportion.^{102,103,125} Tilk et al.¹²⁵ examined 1,500 roots. They measured the narrowest mesiodistal dimension at the apical, middle, and cervical one-thirds of the teeth except the palatal root of the maxillary first molar that was measured faciolingually. Based on the 95% confidence level that post width would not exceed one-third of the apical width of the root, they proposed the following post widths (Table 6): small teeth such as mandibular incisors (0.6 to 0.7 mm); large-diameter roots such as maxillary central incisors and the palatal root of the maxillary first molar (1.0 mm); and for the remaining teeth (0.8 to 0.9 mm).

Shillingburg et al.¹⁰² measured 700 root dimensions to determine the post diameters that would minimize the risk of perforation. Also based on not exceeding one-third of the mesiodistal root width, they recommended the following post diameters (see Table 6): mandibular incisors (0.7 mm); maxillary central incisors or other large roots (1.7 mm—which was the maximal recommended dimension); post tip diameter (at least 1.5 mm less than the root diameter at that point); and post diameter at the middle of the root length (2.0 mm less than the root diameter).

Post spaces were prepared in 150 extracted maxillary and mandibular molars by using different instrument diameters and the resulting incidences of perforations were recorded.¹⁰³ The authors determined that the mesial roots of mandibular molars and the buccal roots of maxillary molars should not be used for posts due to the higher risk of perforation on the furcation side of the root. For the principal

roots (mandibular distal and maxillary palatal), they determined that posts should not be extended more than 7 mm into the root canal (apical to the pulp chamber) due to the risk of perforation. Regarding instrument size, they concluded that post preparations can be safely completed by using a No. 2 Peeso instrument, but perforations are more likely when the larger Nos. 3 and 4 Peeso instruments are used.

Raiden et al.¹²⁶ evaluated several instrument diameters (0.7, 0.9, 1.1, 1.3, 1.5, and 1.7 mm) to determine which one(s) would preserve at least 1 mm of root wall thickness following post preparation in maxillary first premolars. They determined that instrument diameter must be small (0.7 mm or less) for maxillary first premolars with single canals because the mesial and distal developmental root depressions restrict the amount of available tooth structure in the centrally located single root canal. However, when there are dual canals, the instrument can be as large as 1.1 mm because the canals are located buccally and lingually into thicker areas of the roots.

CONCLUSIONS

Instruments used to prepare posts should be related in size to root dimensions to avoid excessive post diameters that lead to root perforation (Figure 14). Safe instrument diameters to use are 0.6 to 0.7 mm for small teeth such as mandibular incisors and 1 to

Figure 14 Excessive post diameter in the maxillary second premolar created a perforation in the mesial root concavity. Note the distinct border and round form of the radiolucent lesion, characteristics indicative of a root perforation.

1.2 mm for large-diameter roots such as the maxillary central incisors. Molar posts longer than 7 mm have an increased chance of perforations and therefore should be avoided even when using instruments of an appropriate diameter.

Can Gutta-Percha Be Removed Immediately after Endodontic Treatment and a Post Space Prepared?

Several studies indicate that there is no difference in the leakage of the root canal filling material when the post space is prepared immediately after completing endodontic therapy.^{107,109,127,128} Bourgeois and Lemon¹²⁷ found no difference between immediate preparation of a post space and preparation 1 week later when 4 mm of gutta-percha were retained. Zmener¹⁰⁹ found no difference in dye penetration between gutta-percha removal after 5 minutes and 48 hours. Two sealers and 4 mm of gutta-percha was retained apically. When lateral condensation of gutta-percha was used, Madison and Zakariasen¹⁰⁷ found no difference in the dye penetration between immediate removal and 48-hour removal. Using the chloropercha filling technique, Schnell¹²⁸ found no difference between immediate

removal of gutta-percha and no removal of gutta-percha. By contrast, Dickey et al.¹²⁹ found significantly greater leakage with immediate gutta-percha removal.

Kwan and Harrington¹³⁰ tested the effect of immediate gutta-percha removal using both warm instruments and rotary instruments. There was no significant difference between the controls and immediate removal using warm pluggers and files. Compared with the controls, there was significantly less leakage with immediate removal of gutta-percha when using Gates Glidden drills.

Karapanou et al.¹³¹ compared immediate and delayed removal of two sealers (a zinc oxide–eugenol-based sealer and a resin-based sealer). No difference between immediate and delayed removal was noted with the resin-based sealer, but delayed removal of the zinc oxide–eugenol-based sealer produced significantly greater leakage. Abramovitz et al.¹¹⁶ compared immediate gutta-percha removal using hot pluggers and delayed gutta-percha removal (after 2 weeks) using Gates Glidden drills. They found no difference between the two methods.

Portell et al.¹³² found that delayed gutta-percha removal (after 2 weeks) caused significantly more leakage than immediate removal when only 3 mm of gutta-percha was retained apically. Fan et al.¹³³ found more leakage from delayed removal of gutta-percha. Solano et al.¹³⁴ found a less significant difference in apical leakage between teeth whose post spaces were prepared at the time of the obturation and 1 week later using warm gutta-percha condensation and AH Plus sealer.

CONCLUSIONS

Adequately condensed gutta-percha can be safely removed immediately after endodontic treatment.

What Instruments Remove Gutta-Percha Without Disturbing the Apical Seal?

Three methods have been advocated for the removal of gutta-percha during preparation of a post space: chemical (oil of eucalyptus, oil of turpentine, and chloroform), thermal (electrical or heated instruments), and mechanical (Gates Glidden drills, Peeso reamers, etc.). The chemical removal of gutta-percha for post space preparation is not utilized for specific reasons (microleakage, inability to control removal).^{111,127} However, thermal and mechanical

techniques or a combination of both are routinely used.

Multiple studies have determined that there is no difference in leakage between removing gutta-percha with hot instruments and removing it with rotary instruments.^{106,111,135} Suchina and Ludington¹³⁵ and Mattison et al.¹¹¹ found no difference between hot instrument removal and removal with Gates Glidden drills. Camp and Todd¹⁰⁶ found no difference between Peeso reamers, Gates Glidden drills, and hot instruments. Hiltner et al.¹³⁶ compared warm plugger removal with two types of rotary instruments (GPX burs and Peeso reamers). There were no significant differences in dye leakage between any of the groups. Contrasting results were found by Haddix et al.¹³⁷ They measured significantly less leakage when gutta-percha was removed with a heated plugger than when either a GPX instrument or Gates Glidden drills were used. DeCleen¹³⁸ found that it is desirable to remove gutta-percha using a heated instrument first, and then using a small Gates Glidden drill. Using a pressure-driven radioactive tracer assay, Abramovitz et al.¹¹⁶ found no difference in apical leakage between hot pluggers and Gates Glidden drills. Balto et al.¹³⁹ compared two methods of gutta-percha removal and their impact on apical leakage. They found that removing gutta-percha with Peeso reamers showed less leakage compared with using a hot plugger.

CONCLUSIONS

Both rotary instruments and hot hand instruments can be safely used to remove adequately condensed gutta-percha when 5 mm is retained apically.

Can a Separated Instrument Be Removed During Post Space Preparation and Still Maintain the Apical Seal?

Following root canal therapy, the endodontically treated tooth could present with a separated instrument (files, rotary instruments, etc.) in any part of the canal. Attempts to remove these fragments prior to post space preparation could lead to loss of apical seal, perforations, ledge formation, and/or over enlargement of the canal. A decision to bypass or remove the fragment will depend on the type and position of the broken instrument and should be determined by an endodontist with the use of an operating microscope.

Bypassing fractured instruments seems to be the best approach. Hülsmann and Schinkel¹⁴⁰ reported an overall success rate of 68% when bypassing broken instruments from canals in vivo. Ward et al.¹⁴¹ reported an overall success rate of 73%. Suter et al.¹⁴² with the use of an dental operating microscope were able to achieve an overall success rate of 87% when removing broken instruments.

CONCLUSIONS

If a separated fragment of any instrument cannot be removed from the canal during post space preparation, it should be bypassed or left in the canal.

Can a Portion of a Silver Point Be Removed and Still Maintain the Apical Seal?

In one study, all the specimens leaked when 1 mm of a 5-mm long silver point was removed by using a round bur.¹⁰⁹ Neagley¹⁰⁸ found that removal of the filling material coronal to the silver point with a Peeso reamer caused no leakage. However, when all the filling materials and 1 mm of the silver point were removed, complete dye penetration occurred in eight of nine specimens.

CONCLUSIONS

The removal of a portion of a silver point during post preparation causes apical leakage.

How Soon should the Definitive Restoration Be Placed After Post Space Preparation?

ONE-PIECE PROVISIONAL RESTORATION

It is well established that a deficient root canal obturation and a poor coronal restoration will potentially allow endotoxins, bacteria, and saliva to penetrate the root canal causing periapical inflammation.¹⁴³⁻¹⁴⁹

Provisional restorations are mainly used to provide the patient with a functional and esthetic restoration. They also protect the hard and soft tissues prior to placement of the definitive restoration. However, provisional restorations are considered restorations with poor coronal seal. Several studies indicate that there is significant coronal leakage when the tooth is restored

with a provisional restoration.^{139,150–153} Demarchi et al.¹⁵⁰ found that a tooth restored with a temporary post–crown combination had significantly greater leakage than definitively cemented prefabricated posts and separate crowns. Similar results were found by Fox et al.¹⁵¹ when they compared cast posts and cores cemented with zinc phosphate cement, prefabricated posts and composite resin cores cemented with resin cement, and provisional post–crowns cemented with zinc oxide–eugenol cement. In a 3-year retrospective clinical study, Lynch et al.¹⁵² evaluated 176 endodontically treated teeth. They found that the loss of endodontically treated teeth occurred more often with those teeth restored with provisional restorations. Following these results, several studies^{139,151} suggested that the definitive post and restoration should be cemented as soon as possible to prevent recontamination of the root canal. However, to minimize leakage and enhance long-term success, the definitive coronal restoration should be of superior quality.^{147,154–157}

TEMPORARY CORONAL ACCESS FILLING

Balto et al.¹³⁹ compared the leakage of different provisional materials used in post-prepared root canals. They found that none of the provisional restorations tested (Cavit, IRM, and Temp Bond) prevented coronal leakage when left for a long period of time (30 days). Safavi et al.¹⁵³ evaluated the prognosis of endodontically treated teeth following delayed placement of the definitive coronal restoration. A total of 464 endodontically treated teeth were followed radiographically. They found a higher success rate when the definitive restorations (silver amalgam, composite resin, or definitive restoration with or without posts and cores) were placed as compared with teeth restored with provisional coronal access restorations (IRM or Cavit).

Torabinejad et al.¹⁴⁷ found that defective restorations could cause root canal system reinfection within 19 days. Ray and Trope¹⁵⁴ found that a combination of a poor coronal restoration and poor endodontic treatment resulted in a high failure rate of endodontically treated teeth. In a retrospective study, Iqbal et al.¹⁵⁵ found that a combination of good quality endodontic treatment and coronal

restoration leads to a high success rate of endodontically treated teeth. Contrasting results were reported by Tronstad et al.¹⁵⁶ who found that the quality of the endodontic treatment was significantly more important than that of the coronal restoration.

CONCLUSIONS

Following endodontic treatment, post space preparation should be performed and a post definitively cemented as soon as possible: the same day for a prefabricated post, and as soon as possible for a custom-fabricated post and core. The prepared tooth should then be restored with a well-fitting provisional restoration (good marginal seal and occlusion) followed by cementation of the definitive crown in as short a time as possible.

Does the Use of a Cervical Ferrule that Engages Tooth Structure Help Prevent Tooth Fracture?

Survey data have been published that indicate the percentage of respondents who felt a ferrule (circumferential band of metal) increased a tooth's resistance to fracture.⁴³ Fifty-six percent of general dentists, 67% of prosthodontists, and 73% of board-certified prosthodontists felt that core ferrules increased a tooth's fracture resistance. To investigate this concept, several research studies have been performed. Some of the articles found ferrules are beneficial whereas others found no increase in fracture resistance.

The results appear indecisive until differences between study designs are analyzed. First, some of the studies tested ferrules that were part of a cast metal core (core ferrules),^{158–162} whereas other studies evaluated the effectiveness of ferrules created by the overlying crown engaging tooth structure.^{163–176} One study evaluated both core ferrules and crown ferrules.¹⁷⁷ Second, there were differences in the form of the ferrule, and therefore, the manner by which the metal engaged tooth structure (beveled sloping surface versus extension over relatively parallel prepared tooth structure). Third, there were variations in the amount of tooth structure encompassed by the

Table 7 Comparison of Studies and Effectiveness of Various Core and Crown Ferrules

Study	Ferrule Form	Was Ferrule Effective?	Materials/Type of Test
Barkhordar (1989)	2 mm parallel extension of core over the tooth	Yes	Extracted teeth/angular lingual force applied to p and c (no overlying crown)
Sorensen (1990)	1 mm wide 60° bevel at the tooth-core junction	No	Extracted teeth/angular lingual force applied to p and c (with overlying crown)
Tjan (1985)	60° bevel at the tooth-core junction	No	Extracted teeth/angular lingual force applied to p and c (no overlying crown)
Loney (1990)	1.5 mm parallel extension of core over the tooth	No	Photoelastic teeth/angular lingual force applied to p and c (no overlying crown)
Hemmings (1991)	45° bevel	Yes	Extracted teeth/torsional force applied to p and c (no overlying crown)
Saupe (1996)	2 mm parallel extension of core over <i>thin</i> dentin wall (0.5–0.75 mm thick)	No	Extracted teeth/angular lingual force applied to p and c (no overlying crown)
Sorensen (1990)	130° sloping finish line 1–2 mm of tooth grasped by crown	No Yes	Extracted teeth/p and c with crown Extracted teeth/p and c with crown
Libman (1995)	0.5–1 mm of prepared tooth grasped by crown	No	Extracted teeth/p and c with crown/cyclic loading
	1.5–2 mm of prepared tooth grasped by crown	Yes	Extracted teeth/p and c with crown/cyclic loading
Milot (1992)	1 mm wide 60° bevel grasped by crown	Yes	Plastic analogues of teeth/p and c with crowns
Isidor (1999)	1.25 mm of prepared tooth grasped by crown	Yes	Bovine teeth/cyclic angular load/p and c with crown
	2.5 mm of prepared tooth grasped by crown	Yes, but more effective than 1.25 mm	Bovine teeth/cyclic angular load/p and c with crown
Hoag (1982)	1–2 mm of prepared tooth grasped by crown	Yes	Extracted teeth/p and c with crown
Gegauff (2000)	2 mm of prepared tooth grasped by crown; 0 mm of prepared tooth grasped by a crown	Yes	Composite teeth/p and c with crown

ferrules. Table 7 permits a comparison of the studies and the effectiveness of the various core and crown ferrules.

The data generally indicate that ferrules formed as part of the core are less effective than ferrules created when the overlying crown engages tooth structure. In four of the six core ferrule studies, they were found to be ineffective.^{159,160,162,177} Also, in one of the two studies where the core ferrule was effective, the ferrule form was a 2-mm parallel extension of the core over tooth structure as opposed to a bevel.¹⁵⁸ In the other study where core ferrules were found to be effective, a torsional force was used as opposed to an angular lingual force.¹⁶¹ In the crown ferrule studies, most of the ferrules effectively increased a tooth's resistance to fracture. Only when the crown ferrule was of minimal dimension or had a sloping form, it was found to be ineffective.^{163,177} In support of these studies, Rosen and Partida-Rivera¹⁷⁸ found that a 2-mm cast gold collar (not part of the post and core) was very effective in preventing root fracture when a tapered screw post was intentionally threaded into roots so as to induce

fracture. Assif et al.¹⁷⁹ found no difference in the tooth fracture patterns of parallel posts, tapered posts, and parallel posts with a tapered end when they were covered by a crown that grasped 2 mm of tooth structure. Akkayan et al.¹⁷⁰ found no significant difference between fiber-reinforced and zirconia dowels when the ferrule length was 2 mm.

The data also support the concept that ferrules that grasp larger amounts of tooth structure are more effective than those engaging only a small amount of tooth structure. In both the core and crown ferrule studies, the tooth's resistance to fracture was increased when a substantive amount of tooth structure was engaged (2 mm in the core ferrule studies and 1 to 2 mm in the crown ferrule studies). Libman and Nicholls¹⁶³ found the 0.5- to 1.0-mm crown ferrule to be ineffective whereas a 1.5- to 2.0-mm crown ferrule to be effective. Isidor et al.¹⁶⁵ determined that increasing the crown ferrule length significantly increased the number of cyclic cycles required to cause specimen failure. They compared no ferrule with 1.25 and 2.55 mm crown ferrules. They concluded that

ferrule length was more important than post length in increasing a tooth's resistance to fracture under cyclic loading. Zhi-Yue and Yu-Xing¹⁶⁹ found that a 2-mm crown ferrule effectively enhanced the fracture strength of endodontically treated teeth when a cast post and core was used. Pereira et al.¹⁷⁶ compared the effect of no crown ferrule with 1, 2, and 3-mm crown ferrules. They found that a 3-mm crown ferrule significantly increased the fracture resistance of endodontically treated teeth compared with a 2-mm crown ferrule.

The form of the prepared ferrule also appears to affect a tooth's fracture resistance in the previously cited studies. Only one beveled/sloping ferrule was effective in enhancing a tooth's fracture resistance and that was when a torsional force was applied to the tooth. Tan et al.¹⁷² compared a 2-mm uniform crown ferrule that extended around the entire crown circumference with a 2-mm nonuniform crown ferrule where the ferrule was only 0.5 mm on the proximal surfaces. The uniform ferrule produced significantly greater fracture resistance than a nonuniform ferrule. In an in vitro study, Naumann et al.¹⁷³ evaluated the effect of chewing simulation on the fracture resistance of maxillary endodontically treated teeth with incomplete crown ferrules. The greatest variation of failure load was associated with the absence of portions (facial, palatal, or interproximal) of the crown ferrule. Ng et al.¹⁷⁴ investigated the effect of limited residual axial tooth structure on the fracture resistance of maxillary anterior endodontically treated teeth. They found that in the absence of 360° of circumferential coronal tooth structure, the location of the remaining coronal tooth structure may be an important factor for determining the fracture resistance of endodontically treated teeth. The palatal axial wall was as effective as a 360° circumference in providing fracture resistance.

CONCLUSIONS

Differences of opinion exist regarding the effectiveness of ferrules in preventing tooth fracture. Ferrules have been tested when they are part of the core and also when the ferrule is created by the overlying crown engaging tooth structure. Most of the data indicate that a ferrule created by the crown encompassing tooth structure is more effective than a ferrule that is part of the post and core (Figure 15). Ferrule effectiveness is enhanced by grasping larger amounts of tooth structure. The amount of tooth structure engaged by the overlying crown appears to be more important than the length of the post in increasing a tooth's resistance

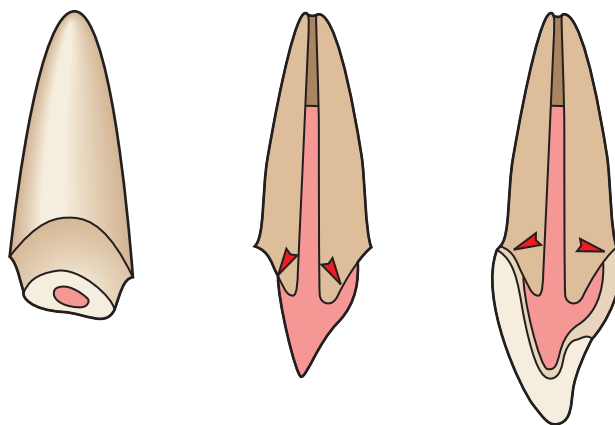

Figure 15 Types of ferrules. **A**, Tooth prepared for a post and core. **B**, Post and core has been cemented into the tooth. The arrows note how the core has created a ferrule around the tooth (note the reduction in the width of remaining coronal tooth structure to develop this core ferrule). **C**, A metal ceramic crown has been cemented over the core. The arrows show how the crown encompasses the tooth cervically, establishing a crown ferrule.

to fracture. Ferrules are more effective when the crown encompasses relatively parallel prepared tooth structure than when it engages beveled/sloping tooth surfaces. Ferrules that encompass 2 mm of tooth structure around the entire circumference of a tooth are more effective than nonuniform ferrules.

Post and Core Placement Techniques

PRETREATMENT DATA REVIEW

When it has been determined that a post and core is required to properly retain a definitive single crown or fixed partial denture, the following characteristics should be determined prior to beginning the clinical procedures associated with the fabrication of a post and core.

POST LENGTH

Since 5 mm of gutta-percha should be retained apically to ensure a favorable seal (as measured radiographically), posts should be extended to that length in all teeth except molars. With molars, posts should be placed in the primary roots (palatal root of maxillary molars and distal roots of mandibular molars) and should not be extended more than 7 mm apical to the origin of the root canal in the base of the pulp chamber (Figure 11). Extension beyond this length can lead to root perforation or only very thin areas of remaining tooth structure.

POST DIAMETER

A frequently used and clinically appropriate guideline for post diameter is not to exceed one-third of the root diameter. It has been determined that when a root canal is prepared for a post and the diameter is increased beyond one-third of the root diameter, the tooth becomes exponentially weaker. Each millimeter increase (beyond one-third of the root diameter) causes a six-fold increase in the potential for root fracture.⁶² Based on measuring the root dimensions of 1,500 teeth (125 for each tooth) and using the guideline that the post should be one-third of the root diameter, optimal post diameter measurements have been determined to be approximately 0.6 mm for mandibular incisors, 1.0 mm for maxillary central incisors, maxillary and mandibular canines, and the palatal root of the maxillary first molar.¹²⁵ The recommended post diameter for the other teeth was 0.8 mm.¹²⁵ Another study of 700 teeth recommended that post diameter should range from 0.7 mm for mandibular incisors to a maximum of 1.7 mm for maxillary central incisors.¹⁰²

ANATOMICAL/STRUCTURAL LIMITATIONS

The practitioner who completed the endodontic treatment is ideally suited to identify characteristics of the pulpal chamber, rooted canal(s) anatomy, and completed endodontic filling that should be reviewed before placing a post and core. These characteristics include the presence and the extent of dentinal craze lines, identification of teeth where further root preparation (beyond that needed to complete endodontic instrumentation) will result in less than 1 mm of remaining dentin or a post diameter greater than one-third of the root diameter area, information regarding areas where the remaining tooth structure is thin, and the point at which significant root curvature begins.

CRAZE LINES

Cracks in dentin are areas of weakness where further propagation may result in root fracture and tooth loss (see Chapter 19). The patient should be informed of their presence with appropriate chart documentation of crack location. It is prudent to avoid post placement, if possible, in favor of a restorative material core. If a post is required, it should passively fit the canal, and the definitive restoration should entirely encompass the cracked area, whenever possible, by forming a ferrule.

DENTIN THICKNESS AFTER ENDODONTIC TREATMENT

Following normal and appropriate endodontic instrumentation, teeth can possess less than 1 mm of dentin, indicating that there should be no further root preparation for the post. When these teeth are encountered, it is best to fabricate a post that fits into the existing morphological form and diameter rather than additionally preparing the root to accept a prefabricated type of post. This characteristic is one of the primary indications for the use of a custom cast post and core. One study determined that canines (maxillary and mandibular), maxillary central and lateral incisors, and the palatal root of maxillary first molars possessed more than 1 mm of dentin after endodontic cleaning and shaping.¹⁸¹ All other teeth had roots with less than 1 mm of remaining dentin following endodontic treatment. With the goal of preserving 1 mm of remaining dentin lateral to posts, it has been determined that single-canal maxillary first premolars should have posts that are 0.7 mm in diameter or less.¹²⁶ Mandibular premolars with oval/ribbon-shaped canals should not be subjected to any preparation of the root canal for a post since it will result in less than 1 mm of dentin.¹⁸¹ Preparation of the mesial root canals in mandibular molars and the facial root canals in maxillary molars can result in perforation or only thin areas of remaining dentin. Based on the measurements of residual dentin thickness, it is recommended that posts not be placed in these roots if possible.

ROOT CURVATURE

When root curvature is present, post length must be limited so as to preserve remaining dentin, thereby helping to prevent root fracture or perforation. Root curvature occurs most frequently in the apical 5 mm of the root. Therefore, if 5 mm of gutta-percha is retained apically, curved portions of the root are usually avoided. As discussed previously under post length, molar posts should not exceed 7 mm in the roots because of the potential for perforation due to root curvature and the presence of developmental root depressions. Molar roots are frequently curved and the post should terminate at the point where substantive curvature begins.

TYPE OF POST AND CORE

Custom Cast Post

For many years, custom cast posts and cores have been considered to be the standard of care when restoring

endodontically treated teeth and have historically been made of metal. Gold, silver–palladium, and base metal alloys are the most commonly used metals. For economic reasons, base metal alloys were introduced as an alternative metal to high-noble alloys. The major disadvantages of base metal alloys are their manipulation (laboratory and clinical), their hardness, and their unstable chemical structure.¹⁸² The degradation of base metal alloys releases substances that could be harmful to the patient.^{182–184} Silver–palladium alloys were introduced as a replacement for gold and base metal alloys. They are relatively easy to manipulate and have many properties similar to those of gold casting alloys.¹⁸⁵ However, the castability of silver–palladium alloys was shown to be inferior to that of gold-based alloys.^{182,186,187}

Cast posts and cores can be fabricated by using either a direct or an indirect technique, and several methods have been described for the intraoral fabrication of an acrylic resin pattern for a direct post and core.^{188–192} Prefabricated plastic patterns are commonly used, and they are relined to fit the post space with an autopolymerizing acrylic resin (Figure 16). The coronal adaptation of the tooth is usually completed by using the same resin, and the core is contoured intraorally to the desired form. The only disadvantage of this direct technique is the amount of chairside time required to perform the procedure.

As an alternative, indirect techniques for the fabrication of cast posts and cores have been proposed.^{193–195} However, this procedure requires meticulous attention to a defined protocol to ensure success. One technique uses a Lentulo spiral instrument to carry an impression material to the apical aspect of the prepared post space. Since a thin projection of a polymerized impression material can be distorted or torn upon removal from the mouth, reinforcement of the impression material is required. This reinforcement can be accomplished by using several materials such as a plastic pin or a metal wire. Care must be taken when using plastic pins to ensure that they are not slightly flexed by placement into a curved canal or through contact with the impression tray, thereby allowing a return to their original form upon impression removal with some resulting distortion. The use of a portion of a safety pin is an excellent material so long as it is made of spring steel, thereby preventing flexion. A bendable metal pin can be distorted upon impression removal. Complete seating of a section from a safety pin until it contacts the gutta-percha is recommended. Upon removal of the impression from the mouth, the presence of the metal pin at the apical extension of the impression

Figure 16 Prefabricated plastic patterns commonly used for the direct technique method for the intraoral fabrication of an acrylic resin pattern for a cast post and core.

material indicates that there was no elongation of the impression material upon removal.

To make the impression technique easier, prefabricated precision plastic dowels were introduced.^{196,197} After the selection of the desired diameter for the dowel, a corresponding drill is used to prepare the post space at the appropriate length. The dowel is then inserted into the prepared canal, picked up in an impression, and transferred to the dental laboratory for fabrication.

A proposed advantage of cast posts and cores is their purported ease of removal in case of an endodontic retreatment.^{198–200} In addition, several long-term clinical studies have reported high success rates with cast post and cores.^{50,201}

Prefabricated Posts

Prefabricated posts have become quite popular and a wide variety of systems are available: parallel-sided or tapered, smooth or serrated, passive (cement/bonded) or active (threaded), or combinations of these.^{202–204} Threaded posts depend primarily on engaging the tooth—either through threads formed in the dentin as

Figure 17 Surface texture of a carbon fiber-reinforced epoxy resin dowel (SEM magnification: $\times 1000$).

the post is screwed into the root or through threads previously “tapped” into the dentin. The majority of these posts are metallic. Recently, in response to a need for tooth-colored posts, several nonmetallic posts such as carbon fiber epoxy resin, zirconia, glass fiber-reinforced (GFR) epoxy resin, and ultrahigh strength polyethylene fiber-reinforced (PFR) posts are available and early data indicates that they can be acceptable alternatives to metallic posts.

The carbon fiber-reinforced (CFR) epoxy resin post system was developed in France in 1988 by Duret and Renaud^{205–207} and first introduced in Europe in the early 1990s.^{208–210} The matrix for this post is an epoxy resin reinforced with unidirectional carbon fibers parallel to the long axis of the post. The fibers are 8 μm in diameter and uniformly embedded in the epoxy resin matrix. By weight, the fibers comprise 64% of the post and are stretched before injection of the resin matrix to maximize the physical properties of the post (Figure 17).^{205,211,212} The post is reported to absorb applied stresses and distribute these stresses along the entire post channel.²¹³ The bulk of the carbon fibers is made from polyacrylonitrile by heating it in air at 200° to 250°C and then in an inert atmosphere at 1200°C. This process removes hydrogen, nitrogen, and oxygen, leaving a chain of carbon atoms and forming carbon fibers.²¹⁴

The CFR post has been reported to exhibit high fatigue strength, high tensile strength, and a modulus of elasticity similar to dentin.^{208,211,215–218} The post was originally radiolucent; however, a radiopaque post is now available. Radiopacity is produced by placing traces of barium sulfate and/or silicate inside the post. Mannocci et al.²¹⁹ examined radiographically five dif-

Figure 18 Available shapes of carbon fiber-reinforced epoxy resin posts.

ferent types of fiber posts. They found that only Cosmopost and Snowpost posts had uniform radiopacity. Finger et al.²²⁰ examined the radiopacity of seven fiber-reinforced resin posts compared with a titanium post. Compared to other posts, they found CFR posts had an acceptable radiopacity.

The posts are available in different shapes: double cylindrical with conical stabilization ledges or conical shapes (Figure 18). The surface texture of the post may be smooth or serrated. Studies have indicated that serrations increased mechanical retention although the smooth post also bonded well to adhesive dental resin.^{217,221} The post has a surface roughness of 5 to 10 μm to enhance mechanical adhesion of the autopolymerizing luting material, and the post appears to be biocompatible based on cytotoxicity tests.^{216,222}

Several studies indicate that CFR posts exhibit adequate physical properties compared to metal posts.^{212,215,223,224} In a retrospective study over 4 years, Ferrari et al.²²³ indicated that the Cosmopost system was superior to the conventional cast post and core system. King and Setchell²¹⁵ and Duret et al.²¹² evaluated the physical properties (fracture resistance and modulus of elasticity) of CFR posts and both

reported that these posts are stronger than prefabricated metal posts.

Contrasting results were reported by Sidoli et al.²²⁵ in an in vitro study. They found that CFR posts exhibited inferior strength when compared with metallic posts. Similar results were also obtained by Purton and Love²²⁶ and Asmussen et al.²²⁷

Martinez-Insua et al.²²⁸ studied the fracture resistance of teeth restored with CFR posts and cast posts. They reported a significantly higher fracture threshold for cast post and cores. A clinical evaluation of CFR posts suggested that these posts did not perform as well as conventional cast post and cores.²²⁹ However, the results of this study must be interpreted with caution because of the relatively small sample size (27 teeth) used in this study.

Multiple studies indicate that there is a decrease in the strength of CFR posts after thermocycling and cyclic loading.^{230–233} In addition, contact of the post with oral fluids reduced their flexural strength values.^{222–234}

In two studies, results indicated no significant difference among a CFR post, cast post and cores, and metal posts when restoring mandibular incisor teeth. No differences were noted in the mode or state of fracture observed.^{235,236}

Multiple in-vitro studies have reported that CFR posts are less likely to cause fracture of the root at failure. The mode of failure of teeth restored with CFR posts in these studies was more favorable to the remaining tooth structure.^{170,215,225,228,237–241}

However, despite all these advantageous properties, in vivo applications of the CFR post should be questioned. When the ferrule is small or absent in an endodontically treated tooth restored with a CFP post, loads may cause the post to flex causing a micromovement of the entire core. The cement seal at the margin of the crown can be compromised, accompanied by microleakage of oral bacteria and fluids. As a result, secondary caries may develop in the space and may not be easily detected.²⁴¹

The short-term clinical studies of CFR posts appear promising but some of the longer-term studies report higher failure rates. Wennström²⁰⁹ restored 173 teeth with CFR posts and reported two failures after a period of 3 to 4 years. A short-term retrospective study of 236 teeth treated 2 to 3 years previously reported no failures of the posts.²⁴² Ferrari et al.²²³ studied 100 CFR posts and reported a failure rate of 3.2% after a mean

time of 3.8 years of clinical service. In a prospective study of 59 CFR posts, Glazer et al.²⁴³ indicated that these posts did not fracture and there was a 7.7% absolute failure rate. Another retrospective study²⁴⁴ of 1,304 CFR posts followed from 1 to 6 years found a 3.2% failure rate that was attributed to debonding during removal of temporary crowns and periapical lesions. Hedlund et al.²⁴⁵ studied the clinical performance of 65 CFR posts for an average of 2.3 years of clinical service and found a 3% failure rate. In a retrospective study of 64 CFR posts, Segerström et al.²⁴⁶ found that nearly 50% of the CFR posts were lost after a mean time of 6.7 years.

Should fracture of a CFR post occur, a potential advantage is the relative ease of removal from the post space compared with metal posts. A removal kit has been suggested for this procedure and the latter is recommended as a single use only item.^{247–251}

Glass fiber-reinforced epoxy resin posts The high demand for esthetic restorations and all-ceramic crowns led to the development of a variety of tooth-colored post systems as an alternative to metal and CFR posts.

The GFR epoxy resin post is made of glass or silica fibers (white or translucent). Glass fiber posts can be made of different types of glasses: electrical glass, high-strength glass, or quartz fibers (Figure 19).^{253,252} The commonly used fibers are silica-based (50% to 70% SiO₂), in addition to other oxides.²⁵³

Figure 19 Surface texture of a glass fiber-reinforced epoxy resin post (SEM magnification: $\times 250$).

Figure 20 Available shapes and designs for glass fiber-reinforced epoxy resin posts.

The GFR post is available in different shapes: cylindrical, cylinthroconical, or conical shape (Figure 20). An *in vitro* assessment of several GFR post systems indicated that parallel-sided GFR posts are more retentive than tapered GFR posts.²⁵⁴

The composition of the glass fibers in the matrix tends to play an important role in the strength of the post. Newman et al.²³² compared the fracture resistance of two GFR posts containing different weight percentages of glass fibers. They found that the higher content of glass fibers in the post contributed to the greater strength displayed by the tested post.

The GFR post has been reported to exhibit high fatigue strength, high tensile strength, and a modulus of elasticity closer to dentin than that of CFR posts.^{218,227,255} The GFR post is as strong as the CFR post and approximately twice as rigid.²⁵⁶

The flexural strength of GFR posts is not related to the type of glass fiber used. Galhano et al.²¹⁸ evaluated the flexural strength of carbon fiber, quartz fiber, and glass fiber posts. They found that the posts behaved similarly because of the same concentration and type of the epoxy resin used to join the fibers together. Pfeiffer et al.²⁵⁷ evaluated, *in vitro*, the yield strength of GFR post, titanium, and zirconia posts. They found that the yield strength was significantly higher for the zirconia and titanium posts when compared with GFR posts.

Several studies have determined that there is a decrease in the strength (about 40%) of GFR posts after thermocycling and cyclic loading. In addition, contact of the post with oral fluids (short- and long-term) reduced their flexural strength.^{230,233,258–260}

Two studies indicated that the tensile bond strength between the composite resin core material and the GFR post is less than that developed with a titanium

post.^{261,262} Other studies indicated that there was a good adhesive bond between the GFR post and composite resin cements.^{261,263,264} The bonding of the core to the post can be improved by treating the post with airborne-particle abrasion.²⁶⁵ Similar results were obtained by treating the surface of the post with hydrogen peroxide and silane or hydrofluoric acid and silane.^{266,267} During fatigue loading, a composite resin core bonded to a GFR post provided significantly stronger crown retention than cast gold posts and cores and titanium posts with composite resin cores.¹⁷¹

Similar to CFR posts, multiple studies have shown that GFR posts are less likely to cause fracture of the root at failure.^{232,268–270} The mode of failure of teeth restored with CFR posts in these studies was more favorable to the remaining tooth structure. However, studies have discussed the importance of the presence of a ferrule effect in achieving a high success rate.^{170,173,174,271} Malferrari et al.²⁷⁰ restored 180 teeth with GFR posts and reported no post, core, or root fracture after 30 months of service. Naumann et al.²⁷² found that the survival rate of parallel-sided and tapered GFR posts was similar.

Polyethylene fiber-reinforced posts (PFR) are made of ultrahigh molecular weight polyethylene-woven fiber ribbon (Ribbond, Ribbond Inc., Seattle, WA). They are not posts and cores in the traditional sense. The post is a polyethylene-woven fiber ribbon that is coated with a dentin bonding agent and packed into the canal, where it is then light polymerized in position.^{273–275} The Ribbond material has a three-dimensional structure due to either a leno weave or a triaxial architectural design. These designs are composed of a great number of nodal intersections that prevent crack propagation and provide a mechanical retention for the composite resin cement. When PFR posts were compared with metal posts in the laboratory, the fiber-reinforced posts reduced the incidence of vertical root fracture. The addition of a small-size prefabricated post to the PFR post increased the strength of the post-and-core complex. However, the strength of the PFR post did not approach that of a cast metal post and core.²⁷³

When compared with other fiber-reinforced composite post systems, the PFR posts were also found to protect the remaining tooth structure.²³² These results may be attributed to the manufacturer's recommendations of not enlarging the root canals, not removing undercuts present in the root canal, and forming a 1.5 to 2mm crown ferrule. The presence of a large volume of core material and a sufficient dentin bonding area coronally seems to greatly affect the mean load-to-failure

value of PFR posts.²³² Eskitascioglu et al.²⁷⁶ evaluated two post and core systems using a fracture strength test and a finite element analysis. They found that stress accumulated along the cervical region of the tooth and along the buccal bone. Minimal stress was recorded within the PFR post system. They suggested that the PFR post could be advantageous for the restoration of teeth with apical resection.

Newman et al.²³² compared the effect of three fiber-reinforced composite post systems on the fracture resistance of endodontically treated teeth. They found that when PFR posts were placed in narrow canals, they performed better than GFR posts. They suggested the PFR post be formed to the shape of the canal.

The use of PFR posts to restore endodontically treated teeth appears to be a promising alternative to the stainless steel and zirconia dowel posts with respect to microleakage.²⁷⁷ Usumez et al.²⁷⁷ compared in vitro the microleakage of three esthetic, adhesively luted post systems with a conventional post system. They found that the PFR posts and the GFR posts exhibited less microleakage compared with zirconia posts.

Zirconia posts The trend toward the use of all-ceramic crowns has encouraged manufacturers to explore the development of all-ceramic posts.^{278–281} A metal-free post avoids discoloration of tooth structure that can occur with metal posts and produces optical properties comparable to all-ceramic crowns.^{282–285} One type of all-ceramic post is the zirconia post, composed of zirconium oxide (ZrO_2), an inert material used for a range of applications. Its high fracture toughness, high flexural strength, and excellent resistance to corrosion encouraged orthopedists to use it at articulation surfaces.²⁸⁶ Studies have suggested that zirconia specimens transplanted in animals were very stable after long-term aging, and there was no apparent degradation of the specimens.^{286,287–290}

Zirconia (tetragonal zirconium polycrystals, TZP) exhibits phase transformation. Low-temperature degradation of TZP is known to occur as a result of spontaneous phase transformation of tetragonal zirconia to monoclinic phase during ageing at 130° to 300°C possibly within a water environment. It has been reported that this degradation leads to a decrease in strength due to the formation of microcracks accompanying the phase transformation. To inhibit this phase transformation, certain oxides (magnesium, yttrium, or calcium oxide) are added to fully or partially stabilize the tetragonal phase of zirconia at

room temperature. This mechanism is known as transformation toughening.^{281,287,291–293}

The type of zirconia used for dental posts is composed of TZP with 3 mol% yttrium oxide (Y_2O_3) and is called YTZP (yttria-stabilized tetragonal polycrystalline zirconia).^{281,294} YTZP is composed of a dense fine-grained structure (0.5 μm average diameter) that provides the post with toughness and a smooth surface.^{292,294,295}

The zirconia post is extremely radiopaque, biocompatible, possesses high flexural strength and fracture toughness, and may act similar to steel.^{287–291,296–304} In addition, the post has a low solubility³⁰¹ and is not affected by thermocycling.²³⁰ The post is available in a cylindroconical shape (Figure 21).

The zirconia post has a smooth surface configuration with no grooves, serrations, or roughness to

Figure 21 Available shapes and designs for zirconia posts.

Figure 22 Surface texture of zirconia post (SEM magnification: $\times 1000$).

enhance mechanical retention (Figure 22). As a result, the zirconia post does not bond well to composite resins and may not provide the best support for a brittle all-ceramic crown.^{261,305–308} Dietschi et al.³⁰⁷ found that these posts also have poor resin-bonding capabilities to dentin after dynamic loading and thermocycling due to the rigidity of the post. In a cyclic loading test performed in a wet environment, Mannocci et al.²³⁹ found that the survival rate of zirconia posts compared with fiber posts was significantly lower.

In vitro studies^{261,264,308,309} indicated that the smooth surface configuration of untreated zirconia posts leads to failure at the cement/post interface. The vast majority of the cement remained in the root and was not attached to the zirconia posts. Wegner and Kern³¹⁰ evaluated the bond strength of composite resin cement to zirconia posts. They found that the long-term bond strength of the resin composite cement to zirconia posts is weak. Several studies found that acid etching and silanization of zirconia posts does not improve the strength of the resin bond to the zirconia-based material because of the lack of or no silica content in the post.^{310–313} However, tribochemical silica coating was found to increase the bond strength of the composite resin to the zirconia post.^{314,315} Oblak et al.³¹⁶ compared the fracture resistance of prefabricated zirconia

posts after different surface treatments. They found that airborne particle-abraded posts exhibited significantly higher resistance to fracture than posts that have been ground with a diamond instrument.

The use of heat-pressed glass to form the core instead of composite resin has been suggested.^{201,299,300} This approach may improve the physical properties of the all-ceramic post and core.

When the mechanical properties of zirconia posts were evaluated, it was reported that these posts are very stiff and strong, with no plastic behavior.^{227,298,299} Pfeiffer et al.²⁵⁷ found that the zirconia post had a significantly higher yield strength compared with titanium and GFR posts.

Several studies indicated that many commonly used posts exhibit higher fracture resistance than zirconia posts.^{238,297,317,318} In addition, once they fracture the, irretrievable posts will leave unrestorable roots.^{170,318}

Nothdurft et al.³¹⁹ evaluated the clinical performance of 30 zirconia posts in a short-term retrospective study. They found no signs of failure of these posts. However, these results should be analyzed with caution because of the small sample size and a short follow-up time.

Root Selection for Multirooted Teeth

PREMOLARS

When posts and cores are needed in premolars, posts are best placed in the palatal root of the maxillary premolar and the straightest root of the mandibular premolar. The buccal root could be prepared to a depth of 1 to 2 mm and to serve as an antirotational lock, if needed.

MOLARS

When posts and cores are needed in molars, posts are best placed in roots that have the greatest dentin thickness and the smallest developmental root depressions. The most appropriate roots (the primary roots) in maxillary molars are the palatal roots and in

Figure 23 Placement of ParaPost and restorative material core in a molar. **A**, Endodontic treatment completed. **B**, Provisional restorative material in the pulpal chamber has been removed and gutta-percha removed from the distal root canal. **C**, Post space formed with a drill. **D**, Trial placement of the post. **E**, The post has been shortened and cemented. A restorative material core has been formed. **F**, The tooth with core has been prepared, an impression made, and the definitive crown cemented. **G**, If there is an extended time delay between placement of the core and preparation of the tooth for a crown, the core can be built to full tooth contour to serve as the interim restoration.

mandibular molars are the distal roots (Figure 23). The facial roots of maxillary molars and the mesial root of mandibular molars should be avoided if at all possible. If these roots must be used in addition to the primary roots, then the post length should be short (3 to 4 mm) and a small-diameter instrument should be used (no larger than a No. 2 Peeso instrument that is 1.0 mm in diameter). When 7-mm long posts were placed in the mesial root of mandibular molars, 20 of the 75 tested teeth had only a thin layer of remaining dentin or were perforated.⁹⁰

Type of Definitive Restoration

It is important to know the type of single crown or retainer (all-metal, all-ceramic, metal ceramic) that will be used as the definitive restoration for each endodontically treated tooth that requires a post and core. This knowledge permits the tooth to be reduced in accordance with the reduction depths and form recommended for each type of crown/retainer.

CORONAL TOOTH PREPARATION

Restoration of endodontically treated teeth must be a team effort between the endodontist and the dentist responsible for the coronal restoration, requiring two-way communication. If it can be co-coordinated, the first step in the fabrication of a post and core should ideally be preparation of the coronal tooth structure (Figure 24) for the type of definitive restoration that will be placed (all-metal crown, metal ceramic crown, all-ceramic crown). This procedure will help in determining the structure of the post–core fabrication. Each type of restoration requires different amounts of tooth reduction, and the form of the tooth preparation varies considerably. By preparing the coronal tooth structure first, the structural integrity of remaining dentin and enamel can be assessed. When the remaining peripheral tooth structure is very thin and would likely not possess sufficient strength to resist occlusal forces transmitted through the crown to the tooth, the thin structure is removed and replaced as part of the core. This order of procedure also establishes morphological borders that can be used to guide core fabrication so that it is confluent with the surrounding tooth structure and possesses the desired tooth preparation form.

PULPAL CHAMBER PREPARATION

Treatment materials present in the pulpal chamber following endodontic treatment (restorative materials

Figure 24 Coronal tooth preparation. The existing crown has been removed on an endodontically treated tooth. Initial reduction of the tooth has been completed to permit assessment of integrity of remaining coronal tooth structure.

Figure 25 Pulp chamber preparation. Rotary instrument being used to remove provisional material.

sealing the coronal access and gutta-percha) are removed by using rotary instruments (Figure 25). If a prefabricated post is cemented into a root canal and a restorative material core built around the post, morphological undercuts present in the pulpal chamber should be retained for core retention. If a custom cast post and core is fabricated, then pulpal chamber undercuts must be either blocked out with a definitive cement or a restorative material that is bonded to the tooth or the undercut eliminated by removing the tooth structure. If removing the undercut through tooth preparation would result in substantive tooth structure removal that weakens the tooth, then blocking out the undercut is the treatment of choice.

ROOT CANAL PREPARATION

The individual who completed the root canal is ideally suited to prepare the root canal, being the one that is most knowledgeable regarding root curvatures and areas where no further root preparation should be performed because it will result in areas of thin

residual dentin. For this reason, it may be prudent to prepare the root canal for a post as a continuation of the endodontic treatment.

If the canal has not been prepared for a post as part of the endodontic treatment process, it is necessary to remove the filling material using either a warm endodontic hand instrument or a slow-speed rotary instrument such as a Gates Glidden drill (Dentsply International, Tulsa, OK) or a Peeso instrument (Dentsply International). If a warm hand instrument is used, it is advisable to place a rubber dam so as to prevent aspiration or swallowing of the hand instrument should it be dropped.

Successful use of rotary instruments is related to initially using a small-diameter instrument (one that removes only the filling material without dentin removal). This small-diameter instrument is used to remove small vertical increments (1 to 2 mm) of the root canal filling material. After each vertical increment is removed, a visual inspection should be made to verify that the endodontic filling material is centered in the post preparation. The incremental root canal filling removal is continued until the appropriate length is established (Figure 26). Post preparation length is determined using a periodontal probe. Remaining gutta-percha length is evaluated by comparing periodontal probing depths with landmarks on the postendodontic radiograph and by making a radiograph of the prepared post space. After the length is established, any required increases to the post diameter are performed using incrementally larger rotary instruments or hand files.

Preparation for Overdentures

“The overdenture is a complete denture supported by retained teeth and the residual alveolar ridge.”³²⁰ Because the “retained teeth” are shortened, contoured,

Figure 26 Root canal preparation. **A**, Rotary instrument being used to prepare post space in the root canal. Note the rubber ring around the instrument to identify the appropriate apical extension of the post preparation. **B**, Periodontal probe being used to measure post space depth. **C**, Post space preparation completed.

and altered to be covered, root canal therapy is almost always required. In 1969, Lord and Teel³²¹ coined the term “overdenture” and described the combined endodontic–periodontic–prosthodontic technique applied thereto. As early as 1916, however, Prothero had referred to the use of root support, stating, “Often-times two or three widely separated roots or teeth can be utilized for supporting a denture.”³²² It should also be noted that much earlier, in 1789, George Washington’s first lower denture, constructed of ivory by John Greenwood, retained a mandibular left premolar.³²³

Retaining roots in the alveolar process is based on the proven observation that so long as the root remains, the bone surrounding it remains (Figure 27). This overcomes the age-old prosthetic problem of ridge resorption. Ideally, then, retaining four teeth, two molars, and two canines, one each at the four divergent points of an arch, should ensure prosthesis balance and long “life” to a complete overdenture (Figure 28). Unfortunately, patients requiring prostheses seldom present just these ideal conditions. Decisions regarding which teeth to retain usually focus on keeping some of the healthiest teeth located in strategic positions such as canines. One situation to be warned against, however, is the diagonal cross-arch arrangements, a molar abutment on one side, for example, and a canine on the opposite side. The rocking and torquing action set up by this arrangement often leads to problems and loss of one or both abutments. The molar abutment alone is preferable to the diagonal cross-arch situation.

If the selected abutment tooth is reduced to a short rounded or bullet-shaped structure and literally “tucking” the abutments inside the denture base, the crown–root ratio of the tooth is vastly improved, especially when periodontally involved teeth have lost some alveolar support. As a shortened tooth, however, it will serve admirably as an abutment for an overdenture.

Figure 27 Dramatic demonstration of alveolar bone remaining around retained canines but badly resorbed under complete maxillary and posterior mandibular removable partial dentures.

Figure 28 Mirror view of four retained abutments providing ideal support for an overdenture. Note the properly contoured and polished copings protecting the abutment teeth.

INDICATIONS AND ADVANTAGES

The indications for overdentures include the psychic support some patients receive from *not* being totally edentulous. Even more important are the preservation of the alveolar ridge and the shielding of the ridge from stress provided by firm abutment teeth. It should also be noted that occlusal vertical dimension is better preserved if ridge height is maintained. A bonus to all these advantages is the support, the stability, and retention derived from abutments. All these advantages are heightened in the young patient who must wear dentures for years to come.

Complete overdentures should be considered for virtually every patient for whom complete mouth extractions are being considered. Sometimes, certain teeth can be periodontally and endodontically treated and retained as abutments to support an overdenture. The overdenture better resists occlusal forces than the totally tissue-supported complete denture. Some attribute this resistance to the proprioceptive sensory mechanism derived from the retained roots under the overdenture. Application of the overdenture to removable partial denture support is also indicated, even if only one abutment is available.

CONTRAINDICATIONS

The overdenture technique is contraindicated when remaining alveolar support is so lacking that no tooth can be retained for very long. This condition often supports the use of endosseous root-form implants to support and retain a prosthesis. Overdentures are also contraindicated if the remaining natural teeth are adequate to restore the mouth with fixed partial

dentures or removable partial dentures. The overdenture technique should be no pathway to expediency.

ABUTMENT TOOTH SELECTION

“A healthy abutment tooth for an overdenture must have minimal mobility, a manageable sulcus depth, and an adequate band of attached gingiva.”³²⁰ If these prerequisites are lacking, the pocket depth can be reduced and attached gingiva developed by using appropriate periodontal procedures.

ABUTMENT TOOTH LOCATION

Ideal teeth to retain are those whose occlusal forces wreak greatest destruction upon the ridges. Opposite a natural dentition, the canine teeth are ideal to retain. In edentulous patients, the anterior portion of the arches is particularly susceptible to resorption, so canines and premolars are again the first choice to be

saved, with incisors the second choice. It is especially important to save mandibular teeth because of difficulties encountered in retaining mandibular dentures. Even saving a single tooth, a molar in particular, may contribute greatly to long-term denture success.

TECHNIQUE

After the selection of the most favorable abutment teeth, the key to successful overdenture fabrication is simplicity of technique (Figure 29). If an immediate denture is to be placed, the endodontic therapy, extractions, and periodontal treatment can sometimes be done at the denture placement appointment. The crowns of these teeth are amputated 3 to 4 mm above the gingival level and the endodontic procedure completed. The coronal 5 to 6 mm of the gutta-percha restoration is removed, the preparation is undercut, and a well-condensed amalgam filling is placed to restore and help seal the canal obturation.

Figure 29 Preparing an overdenture abutment. **A**, The crown is amputated 3 to 4 mm above the gingival level. **B**, The endodontic procedure is started. **C** and **D**, An amalgam restoration is placed in the coronal 5 to 6 mm. **E**, In preparation for fitting the prosthesis, the abutments are shaped and polished.

Figure 30 Improperly contoured overdenture abutments. Square edges invite grip by overdenture and torquing action. Prominent buccal contour and extra height comprise the contour of the overdenture. Courtesy of Dr. David H. Wands.

At this time as well, the abutments should be shaped to rise 2 to 3 mm above the tissue, and be rounded or bullet-shaped with a slope back from the labial to accommodate the denture tooth to be set above it. They should then be highly polished. The abutments must not be too short or the tissue will grow over them as a “lawn grows over a sidewalk”,³²⁰ nor should they be too long, compromising the denture contour and placing greater stress on the supporting teeth (Figure 30).

Figure 31 Soft, autopolymerizing acrylic resin fills the depression prepared in the denture to receive the abutment. This may be replaced whenever necessary.

The denture is relieved over the abutments and adaptation is achieved between the denture base and edentulous ridge tissues without touching the abutment teeth. It is then adapted to the abutment teeth by using a small amount of autopolymerizing acrylic resin (Figure 31). This proper relationship of denture to tissue and tooth is important for denture stability and to keep the stresses on the teeth within physiological limits.

Some overdenture abutment teeth may not need root canal therapy because they are so abraded that the pulp has receded to a level where the tooth only needs shortening, contouring, and polishing (Figure 32). This technique simplifies the treatment and reduces the cost to the patient.

Figure 32 **A**, Teeth with vital, receded pulps but severe abrasion can be ideal overdenture abutments. **B**, Incisor overdenture abutment not requiring therapy owing to pulp recession. The calcified pulpal area should be carefully explored. Courtesy of Dr. David H. Wands.

Figure 33 Rather typical neglect by many denture patients. **A**, Caries and periodontal disease forecast probable lack of future patient cooperation. **B**, Mirror view of lingual gingiva of two possible overdenture abutments. Because it is virtually impossible to develop attached gingiva in the lingual area, the use of these teeth as abutments is contraindicated. Courtesy of Dr. David H. Wands.

If the abutment teeth are periodontally involved or are not surrounded by a good collar of attached gingiva, periodontal therapy will be required to correct these aberrations.

PROBLEMS

A number of problems have arisen with overdentures, most of them related to poor patient selection and lack of patient cooperation. The most serious problems are associated with dental caries and periodontal disease. It must be remembered that throughout their lives, candidates for complete dentures are those who have usually been neglectful of their teeth and supporting structures and have a history of extensive dental disease (Figure 33). In recommending overdentures, there is some risk. The patients' habits must change and they must become motivated and adept at oral hygiene to retain the vestiges of their dentition. That some do not, should come as no surprise (Figure 34). The importance of good home care must be emphasized to the overdenture patient and is a critical factor in long-term success. In a longitudinal study, Ettinger and Qian^{324,325} evaluated the differences in people who experienced postprocedural problems with overdentures and compared them with people who had no problems for the duration of the study. They found that most of the failures could have been prevented by better oral hygiene. The most common problem was the development of periradicular problems around endodontically treated teeth because of recurrent caries causing the loss of the restoration sealing the root

canal. Other challenges related to the use of endodontically treated teeth included wear of the dentin and the need for auxiliary prosthesis retention.

POSSIBLE SOLUTIONS TO THE PROBLEMS

Quite naturally the prime solution to the caries–periodontal problem is better patient cooperation in home care. Fluoride gels should regularly be placed in the “well” of the dentin base where the abutments are located to remineralize the dentin.^{326,327} This, of

Figure 34 Two-year recall reveals advanced caries and periodontal disease of abutments. The patient did not remove the denture for days at a time. Courtesy of Dr. David H. Wands.

Figure 35 Four Locator overdenture attachments (Zest Anchors) ensure adequate retention for a mandibular complete denture.

course, will do nothing for periodontal disease, which can only be controlled by plaque removal and by proper and equal force placed on the abutments. More frequent denture relines may also be required.

Coverage of the dentinal surfaces is recommended for those situations where wear of the contacting dentinal surfaces is noticed. Bruxism is a principal etiological factor in producing wear. Even gold castings placed over the teeth may eventually be worn through, but it takes a much longer time.³²⁸

A possible solution to inadequate denture retention or to the rotational problem centering around a single anterior abutment tooth involves the use of mechanical attachments. There are a number of attachments on the market and they include ball and socket type of attachments, o-rings and magnets, frequently retained in the root through the use of a post (Figure 35).

CHAPTER 41

OPERATIONS MANAGEMENT IN ENDODONTIC PRACTICE

MARTIN D. LEVIN

The establishment of any professional practice should include the development of a vision that promotes excellence in both clinical application and performance. With the advent of new technologies such as in-office cone beam computed tomography, the emergence of molecular dentistry and medicine, new pharmacogenomics, increased dissemination of knowledge on the Internet, and improved electronic communications, we are at the threshold of a new era in patient care. Concurrently, these new technologies, improved relationships, and continual improvements in clinical and experiential performance require good management strategies and, ultimately, financial success to create and maintain an outstanding practice. To accomplish sustainable success, we must not only have mastery of the clinical tools of our profession, but also possess the skills necessary to run a successful business.

To remain successful, this vision must include the possibility that your practice will have to undergo both planned changes to implement new procedures and the need to respond to developments over which the organization will have little or no control. In fact, it has been postulated that today “more than half of the economic value of dental care is derived from procedures that were not available just 20 years ago.”¹

To train practitioners and employees, upgrade technology, and improve client service continually, the practice of dentistry requires entrepreneurial training. Dr. Harold Slavkin, former director of the National Institute of Dental and Craniofacial Research (NIDCR), recognized the need for business training when he proposed increasing “the education and training of our student learners in the field of leadership and management of dental practices.”² Today’s endodontist must be a clinician, infection control expert, entrepreneur,

insurance and financial manager, and human resource (HR) authority.³

Clinical excellence is the hallmark of every true world-class practice. What really matters is adopting an ethical and philosophical level of quality that will enable each practice to do the right thing every time. Basically, we are in the people business, and people naturally align with organizations that value integrity, compassion, quality of care, and high standards of behavior. Only by viewing your organization as a collection of interdependent systems and processes that ultimately depend on each employee to reach his or her full potential will your practice reach the desired result. As outlined by Abraham Maslow⁴ over 50 years ago, successful organizations are the ones that genuinely encourage self-actualization to ensure that people identify and pursue their own unique personal potential.

To this end, this chapter will highlight operational strategies that focus on creating a vision that will fund sustainable success by building a *brand-driven culture* within your organization that is supported by high-performance human systems.

Choosing How You Want to Practice

The healthcare industry is a services profession, and as such has different characteristics than companies producing physical goods.⁵ According to Leonard Berry,⁶ Distinguished Professor of Marketing at the Mays Business School at Texas A&M University, “marketing a performance [e.g., medical services] is not the same as marketing an object... In packaged goods the emphasis is on differentiating tangibles through imagery; in services the emphasis is tangibilizing the intangible.” To truly understand the

medical services world, Berry spent his sabbatical at the Mayo Clinic, immersed in day-to-day hospital procedures and interactions. He came away with a new appreciation for the importance of reliability as the basis of services marketing excellence. What he is saying, essentially, is that you have to do the job right the first time, every time because “who wants to travel on an airline whose pilots are *usually* dependable, [or] be operated on by a surgeon who *usually* remembers where on the body the surgery is to be done?”

As a services profession, the delivery of dental care requires both the provider and the consumer to be present at the same time. This one-on-one relationship gives rise to the potential of real-time customization, one of the most powerful tools available to healthcare providers. When you and the patient are working together to create an agreed-upon result, you can decide how much, or if any, customization will occur, and even whether that customization will occur in the front office, the back office, or both. This consultative function should be managed to create value that satisfies patient and referrer needs. From a customer-centered perspective, it means providing what both the patient and referring doctor want, on their terms, when and how they want it.⁷

Organizations need to establish a strategic framework in order to reach their full potential. This framework consists of (1) a vision for the future, (2) a mission that defines what you are doing now, (3) a step-by-step strategy to clarify your individual situation and develop a program to achieve future objectives, (4) goals and action plans that guide day-to-day decision making,⁸ and (5) feedback to see what really works.

VISION AND MISSION STATEMENTS

A vision statement is a clearly articulated, future-oriented declaration that articulates what your organization wants to become. Vision statements range in length from a couple of words to several pages; shorter vision statements tend to be easier to recall and use.

This statement should resonate with all members of the practice and help them feel proud, excited, and part of something larger than themselves. A vision should stretch the organization’s capabilities and image of itself. It should give clarity, shape, and direction to the organization’s future. Do you want to be the most technologically advanced specialist in your community? Do you want to achieve a high return on your investment? Do you want to be a thought leader, a fee leader, or both? Answers to these and other questions will help you create a vision for your practice.

A mission statement is a succinct proclamation of the practice’s purpose for existence. It should include measurable criteria and address such concepts as image, customer demographics, target market, and expectations for growth and profitability. Mission statements should be broad enough to incorporate every service provided and should include the practice’s moral and ethical position, geographic and demographic domain, and the expectations as well as hopes for growth and profitability.

Once a mission statement is adopted by the organization, everyone must subscribe to its precepts or its usefulness will diminish. It is critical that you align your practice with your mission so that every interaction between employees and patients builds value. Unfortunately, the Workplace 2000 Employee Insight Survey, conducted by Tom Terez, author of “22 Keys to Creating a Meaningful Workplace,”⁹ found that only 23% of US workers say that their company’s mission statement has become a way of doing business.

Visions and missions are usually linked to strategies and goals that are specific, measurable, and short term. Once a vision and mission statement has been adopted and becomes part of the fabric of your practice, you can develop an implementation strategy and a list of annual goals. Finally, adding deadlines and a system of measurement will allow you to continually gauge your progress.

STRATEGIC PLANNING

What is a strategy? The word comes from the Greek word *strategia*, meaning “generalship.” While it is difficult to find agreement on an exact definition of strategy because it includes “thoughts, ideas, insights, experiences, goals, expertise, memories, perceptions and expectations,”¹⁰ almost everyone can agree that it is about the means to reach an end, not what those aims are or how they are established. In most successful practices, the leadership alone is responsible for assuring that the office’s policies are legitimate and ethical. Strategy, on the other hand, is the province of both leadership and management, while tactics are the responsibility of management alone. In other words, determining the goals of an enterprise is mainly a governance issue, while employment of resources is the job of management. Keep in mind that strategy is a changing perspective of what is required to obtain the ends that have been specified in policies, and is dependent on the actual results as measured by business performance. So strategy and tactics actually bridge the gap between resources and policy.

Two useful techniques to evaluate your future practice’s potential for success are the SWOT (Strengths, Weaknesses, Opportunities, and Threats) and PEST

Table 1 SWOT (Strengths, Weaknesses, Opportunities, and Threats) Analysis

Strengths: What you do better than the competition

Opportunities: Trends, changes, and characteristics of your market that may offer opportunities for your business now or in the future

Weaknesses: Things that the competition does better than you

Threats: Trends and changes associated with your market that may present your business with problems either now or in the future

This SWOT analysis form measures a business proposition or idea by assessing core issues. Most practices can apply the ideas developed here to understand their current position and help plan future initiatives.

(Political, Economic, Social, and Technological) analyses. A SWOT analysis measures a business proposition or idea. Long-range strategic planners often use SWOT analysis to assess core issues and develop a plan based on current perceptions (Table 1). Practices can also benefit by completing a SWOT analysis to evaluate a competitor.

A PEST analysis helps to measure the external macro-environment that affects all businesses. The most useful analysis for a dental practice will be the social and technological analysis portion. The social section is where patients' and referrers' demographics, class structure, education, culture, and attitudes about healthcare are considered. Technological analysis looks at recent technological developments, their impact on the value-chain structure, cost, and efficiency. For example, should you consider purchasing or leasing a cone beam computed tomography scanner, panoramic device, or refer patients needing advanced evaluation to a center with these capabilities? PEST analysis allows for proactive marketing and business development assessment.

SETTING GOALS

Goals are plain language statements that describe priorities or actions to be accomplished. Practices should have a number of goals, each describing a desired result toward which your efforts should be directed. Goals set priorities for management and staff and establish measurement parameters for evaluating success. Goals serve to keep an organization focused on success and away from activities that tend to distract and drain resources. If the goals are accomplished, then the business should be a success.

Practice goals are generally derived from mission statements and describe how the mission will be accomplished, while mission statements describe exactly what needs to be accomplished. A goal should be simple, clearly written, state the conditions that will exist if the goal is accomplished, and set action-oriented tasks that you want to accomplish in 1 to 3 years. Some business goals will have a 1-year time frame, while others may have longer or shorter time frame. It is not unusual for a practice to have a mix of business goals starting and

ending at different times. Most importantly, a goal needs to be achievable and challenge the people responsible for its accomplishment.

As more employees understand and commit to your vision for the practice, it is the job of leadership to continually reaffirm it through every available channel of communication, such as staff meetings, or when conversing with co-therapists, and so on. According to Lionel Urwick's¹¹ classic *Harvard Business Review* article, 1956, "There is nothing which rots morale more quickly and more completely than...the feeling that those in authority do not know their own minds." Once the plan is created, be ready to change it. Strategic plans are dynamic, living documents that are not a once-a-year project, but can be modified repeatedly as it needs warrant. Strategic planning is one of the key activities that forces organizations to focus on the right priorities to foster growth. In the end, all strategic planning models are goal-based and rely on clearly defined, understood, and communicated action steps. A strategy is not useful, however, if it is not realized. A Fortune Magazine study has shown that 7 out of 10 CEOs fail because of poor execution, not because of bad strategy.¹²

PRACTICE MODELS

Unlike the practice of medicine, which is becoming increasingly complex and business-like, Marjorie Jeffcoat,¹³ the Morton Amsterdam Dean at the School of Dental Medicine, University of Pennsylvania, says that "dentistry has remained a profession dominated by small, independent practices." In fact, Kathleen Roth, president of the American Dental Association (ADA), in a 2007 address to the Small Business Committee of the U.S. Congress, reported that over 90% of practicing dentists are in the private sector and 85% of those practitioners operate independent solo practices.¹⁴ But the need to investigate organizational alternatives is becoming more urgent with the expectation that there will be a sea change in the way health care is organized and funded in the future. While dentists may continue to practice independently, other dental practice models will show strong growth and evolve as business entities.

Armstrong et al.¹⁵ have postulated that some practices adhere to the “service factory model,” where low cost and standardization predominates, delivering consistent but standardized service. Conversely, other practices act as “service theaters,” or niche practices, where a select clientele undergo premium-priced procedures that are individualized and scripted for maximum effect. Patients choose this type of practice if price is no object. They want a high-tech approach, presented with personal attention in an office that rivals the ambiance of a fine hotel. Employees are not just hired here; they are trained to serve as members of a team that values a high-touch, patient-centered experience.

Other attempts to categorize practice models have been proposed by the Dental Trade Alliance (DTA). Jeffery Lavers,¹⁶ Marketing Director of 3M ESPE, says that continual change in the dental marketplace is certain and will be influenced by demographics, technology, disease patterns, patient behavior, and service choices and dental workforce. Providers of dental care, for example, will be reduced from their current level of 130,000 full-time equivalent practicing U.S. dentists by more women providers practicing fewer hours and lower numbers of dental school graduates than in the past. These factors and an associated increase in the U.S. population will continue to decrease the dentist/population ratio.

The DTA has proposed the following emerging practice models, which it predicts will provide over 60% of all dental services by 2010 (reproduced by permission of the DTA):

Ready Access Model—High-process standardization, convenience-oriented, highly flexible operating systems, focused on a dynamic “retail” service experience

Tech Station Model—High level of technical resources, procedural leading edge, “gee-whiz” experience backed by relatively high-touch patient communication

Small Group Model—Well-integrated staff with broad range of scope, seamless teamwork of staff geared to provide service efficiency and throughput

Cosmetic Center Model—A variation on the conventional practice with heavy emphasis on elective care in personal aesthetics and restorative services

Super Norm Model—Emphasis on high-touch, service-intensive patient experience, customer

intimacy, and high-margin work with demanding patients

Armstrong’s service theater approach is similar to the “super-norm model” proposed by the DTA’s description of emerging practice models, with an emphasis on a customer-centered approach that treats demanding patients and produces high-margin work. Practice models will continue to evolve, and some practices will incorporate elements of several business forms. One practice model may use technology while also providing cosmetic procedures based on personal aesthetics and high-end customer service. What does all of this have to do with your endodontic practice? Simply put, running a successful practice requires a powerful vision of where you want to go.

Starting a new practice, associating with an established endodontic practice, or choosing a hybrid format is the first of many decisions that every endodontist will have to make when beginning his or her career. What follows is a short primer on the risks and benefits of three employment options.

NEW PRACTICE

What are the benefits of starting your own practice? You will have complete autonomy in setting practice policies and making decisions. Every decision, that is, the selection of particular equipment and designing treatment protocols, as well as the selection of employees, will be yours to make. When it is your business, you dictate the way things are done. The scheduling of employee and your own vacations is at your discretion. Then there is personal fulfillment. Owning and running your own business can be more satisfying than working for someone else, and many practitioners enjoy the respect they earn from their peers for having the courage to go out on their own. When you own your own practice, you may have to forgo a regular paycheck, but the upside earnings potential may be greater than any other alternative. If these aspects have strong appeal, then starting your own practice should be considered.

There are formidable risks to starting your own practice, and a careful analysis is critical. As a sole practitioner, you must spend the time to research all decisions yourself or engage advisors to assist you in this process. Solo practice will require an emergency coverage arrangement with another practitioner when you are out of town. You will have no immediate peer consultation to explore the treatment of difficult cases. And you will face a greater risk of losing your investment. Although relatively rare, some practitioners just cannot earn sufficient income to remain

profitable. This may occur as a result of choosing a poor location, competing unsuccessfully with established neighboring practices, or assuming too much debt. Finally, opening your own business can come at a high personal cost. It will take a lot of energy and personal sacrifice to get going, likely necessitating working at night and on weekends, infringing on personal time.

ASSOCIATE-EMPLOYEE OR ASSOCIATE-INDEPENDENT CONTRACTOR

For a recent graduate with little or no prior practice experience, the benefits afforded by having a transitional period with an established practice can be priceless. Serving as an associate-employee allows the new practitioner to assume the reputation of the other member(s) of the practice, and by inference, more quickly establish a good professional reputation of his or her own. Other benefits include practice ownership opportunities, no initial financial investment, immediate patient flow, peer clinical consultation, shared emergency coverage, and the freedom to move easily to another locale if a change is desired.

Risks of the associate-employee and associate-independent contractor path include the lack of total control over the practice, loss of individuality, and the legal constraint of practicing with a restrictive covenant. A restrictive covenant is a contractual agreement usually between an associate and his or her employer that prevents the associate from practicing in a certain geographic area for a specified time period after termination of employment. These agreements are used by employers to protect their investment in start-up costs associated with bringing on an associate and their referral network from competition. Most contracts will include a restrictive covenant, also known as a non-compete agreement. Generally, courts have held that restrictive covenants are enforceable, but not in all states or under all conditions, so get good legal advice.

Associate-independent contractors are independent practitioners who provide services to a dental practice on a contractual basis. This form of practice must be carefully structured to remain in compliance with Internal Revenue Service (IRS) guidelines. Under current IRS rules, the practice owner cannot control both the means of work and the results of the independent contractor's efforts. No benefits, retirement plans, or employment taxes are paid by the practice for the associate-independent contractor. Additionally, the practice owner cannot furnish supplies, equipment and instruments, impose safety precautions, plan

work to be done, control office hours, or assume liability stemming from the independent contractor's performance. The associate-independent contractor relationship must be properly constructed to avoid incurring significant taxes, interest charges, and penalties. This is the province of an attorney with experience in such transactions.

HYBRID

A hybrid form of employment may include any combination of the following part-time schemes: (1) serving as an associate-employee or associate-independent contractor in an established endodontic practice, (2) starting your own practice, and (3) serving as an independent contractor in one or more general dentists offices. The latter will not likely result in a stable long-term practice situation, and should be viewed as a temporary solution, at best. The value of this arrangement is that it can serve as an interim step that can financially sustain the new endodontist until he or she builds a referral base.

Winning Management Practices

Forming and operating an endodontic practice is a complex and nuanced undertaking. The notion that we are simply a profession and not also a business seeking financial success is to miss the opportunity to generate fair compensation for your knowledge and professional skills. Generating a healthy revenue stream is the only way to ensure that you can continue to provide the most advanced care available. In fact, Joe Blaes, editor of *Dental Economics*, states that "it is impossible for you to stay in practice without a reasonable profit."¹⁷ How do you learn the basics of practice profitability? By studying other businesses to gain insights about operations management and best practices.

What really works in the business world? In the landmark Evergreen Project, 50 leading academics, led by William Joyce, Professor of Strategy and Organizational Theory at Dartmouth College's Tuck School of Business, and Nitin Nohria, the Richard P. Chapman Professor of Business Administration at the Harvard Business School,¹⁸ looked at 40 narrowly defined industries with \$100 million to \$6 billion in gross revenue and determined that winning companies adopted four primary management practices and two of four secondary management practices. Adapting this scheme to endodontic practice, the following sections summarize the study's findings:

PRIMARY MANAGEMENT PRACTICES

1. Strategy: Develop a step-wise plan to clarify your individual situation and develop a program to achieve future goals:
 - a. A clear value proposition: What patients and referrers want most are *results* and *process quality*. That the endodontic treatment works and the patient can maintain their dentition and the treatment meets or exceeds the specifications of the referring doctor is only the “results” part of the equation. “Process quality” measures how the patient was treated. This is the experiential piece, and endodontic treatment is usually defined by patients in these terms. At the end of the day, when patients ask the question “How was I treated?” they are actually assessing process quality. Remember, there is no reasonable way for patients to easily understand the five points of the technical side of treatment.
 - b. “Outside-In”: To put this concept in perspective for our profession, it means understanding what your patients and referring doctors want and creating systems to satisfy those needs, from their perspective. Finding out exactly what patients and referrers deeply value and how to deliver it with passion is the holy grail of practice excellence.
 - c. Continually measure and refine: Practice metrics can be an important indicator of your success. Understanding the referral process, measuring new patient referrals, and tracking “fading referrals” are examples of ways to measure the success of your efforts (Sidebar 1).

MEASURING CUSTOMER DEFECTIONS

In today’s competitive marketplace, success in a referral-based business like endodontics is all about building relationships. According to Frederick Reichheld,¹⁰⁵ a business consultant and author of *The Loyalty Effect*, a business invests in customers, and premature customer (e.g., referring doctor) defections will ultimately result in diminished profitability.

Reducing defections (also referred to as “fading referrals”) begins with measuring the rate of defection. According to Reichheld,¹⁰⁶ in another article in the *Harvard Business Review*, “customer defection is one of the most illuminating metrics in business.” Some defections are normal in any business and in rare cases they can even be welcomed. A percentage of referring doctors will never be loyal and can even diminish morale and increase stress if they continue to send patients. But, such welcomed defections are few and far between. In most instances, it is important to preserve and encourage continued referrals. So, what action should you take if a referral begins to fade? The best approach is to contact the individual who has stopped making referrals and find out why. Always avoid getting defensive, practice active listening, and no matter what you hear, thank them for their time and candor. You may not get these referrers back in the fold, but you may learn how to keep others from defecting in the future.

Once you lose a referrer, replacing him or her will not be easy nor inexpensive. In fact, Reichheld’s survey of 100 companies in 24 industries found that longer customer retention led to increased profits. No surprise here. Many companies make the mistake of not even keeping track of customer defections because they are unaware of the cost to replace them. And many business owners find that customer defections are hard to track, especially when referrals are based on business cycles and sometimes involve only partial defections. Measuring defections can be unpleasant and remedial action is often difficult to accomplish. Even so, it is important to quantify such defections and set goals to improve those relationships.

Measuring referrals is a necessary part of operating a referral-based practice. Look for practice management software that analyzes referral trends within a given time period. It should take just a few mouse clicks to get the information. Some industries report that reducing defections “by as little as five points... can double profits,”¹⁰⁶ and monitoring the “fading referral” to measure declining business will yield valuable insights that need to be addressed immediately.

The most profitable companies champion customers, recognizing that the longer a company keeps its customers, the more successful it will be. Loyal customers result in more profits, because loyal customers buy more, take less of a company’s resources and are willing to pay a price premium. Why? Because they do not want to start with new people either. Best of all, loyal referrers and patients are more likely to refer new patients.

What you do best	“Stop”	“Go”
What you do not do best	“Stop”	“Go with Partners”
	What your patients do not value	What your patients value

The Focusing Matrix demonstrates the convergence of what you do best and what your patients and referring doctors value most. For example, take one-visit endodontic procedures. These are valued by your patients and referrers and are more efficient for your office to perform. Put them in the “Go” category. If a procedure falls in the “Stop” category, consider a change.

- d. **Keep focused:** Understand your core business and focus on the convergence of what you do best and most profitably with what your patients really want. Consider a focusing matrix showing the relationship between what you do best and what your patient’s value most (Table 2). When the two converge, you have a winner!
2. **Execution:** Deliver products and services that consistently meet patient expectations. Every business tries to set their customer’s expectations. This research project has demonstrated that consistently satisfying customer expectations is far more important than exceeding expectations in one or more areas and falling below the grade in another. The customer will judge and remember the worst performing parameter or interaction, and his or her negative experience will overshadow any exceptional service provided. Another way to improve is to eliminate waste and increase productivity by constantly evaluating operations and making changes that improve the bottom line.
 3. **Culture:** Inspire to do your best. Every office employee looks to the doctor(s) and office administrators for leadership. We must continually refine and measure our care and motivate the members of our office team to strive for excellence. Rewarding achievement with acknowledgment and remuneration based on performance will create a fulfilling workplace.
 4. **Structure:** Simplify. Placing the best employee(s) close to the customer is another way top businesses achieve outstanding results. While most businesses promote the highest achievers to the next level in a vertically structured organization, this action usually takes the best and brightest and moves them away from the customers who

interact with the company. So consider this action carefully when reorganizing your staff. Keeping the vertical structure will simplify administration and will allow the staff with the best people skills to stay closest to those they serve.

SECONDARY MANAGEMENT PRACTICES

The Evergreen study also found a correlation between any two of the following four secondary attributes:

1. **Talent:** The value of developing and keeping great employees cannot be underestimated; most winning companies reward exemplary employees to keep them motivated. These rewards can take many forms, among them salary, benefits, vacation, and probably most importantly a safe and inspiring working environment that drives personal achievement.
2. **Innovation:** Advanced services and technologies are critical to your success. Working with sophisticated practice management software, advanced communications between the office and co-therapists, and treatment technologies such as microscopes and digital radiographic are increasingly important and expected.
3. **Leadership:** Trust and confidence in top leadership is one of the single most reliable predictors of employee satisfaction. Leaders help employees understand the organization’s overall business strategy and how they can contribute to achieving key business objectives. Sharing information and communicating about performance in a small office environment by non-professional HR managers/doctors can be challenging. To improve overall performance, rewarding individual employees and managers for leadership and creativity is a must.
4. **Mergers and partnerships:** Partnering with another practice to maximize the value of diverse talents is often overlooked in cottage industries and small businesses. Strategic alliances and mergers of individual practices to provide better coverage and economies of scale can produce benefits. This can take the form of an alliance between several endodontic practices or the combining of an endodontic practice with a periodontal practice, and so on. Establishing a solo group where two or more endodontists practice in the same facility with shared common areas and administration but separate practice entities is another possibility to economize and protect against the consequences of disability or death.

How to Get Started

Opening a new office for the practice of endodontics will require many months of planning. The project should begin with identifying your objectives. Do you want to establish a boutique or niche practice or a more traditional practice? Will you accept insurance assignment or participate with a preferred provider network or health maintenance organization? To succeed, you will need to make sure your practice will be appropriate to the needs and expectations of your community.

Begin by creating a business plan, develop a timeline, and establish an office location that will accommodate the unique requirements of an endodontic practice. Because endodontic offices require special planning, the time needed for construction and installation will far exceed the time and expense required for a typical non-healthcare facility. Ranking variables like location, parking, home-office travel times, amenities, and proximity to other medical and dental practitioners are necessary parts of the decision-making process. To get this right, you will need the services of an attorney, accountant, banker, commercial real estate broker, architect, interior designer, dental equipment supplier(s), and computer and telephone system engineers.

FIRST THINGS FIRST: CREATING A BUSINESS PLAN

The two essential elements of a good business plan are a winning vision and a clear path to profitability. To borrow money, carefully design the plan to “sell” your vision to a skeptical bank loan officer. The business plan should include the following:

1. A persuasive introduction to describe your planned practice, including features and benefits, and a request for funds.
2. A statement of the purpose.
3. A detailed description of how an endodontic practice works, office location overview, whether you will have employees, and who will provide your equipment and supplies.
4. An analysis of your market demographics (who are your patients?).
5. An evaluation of your main competitors.
6. A description of your brand strategy and how you will use marketing to drive your brand to top-of-mind-status (see “Branding: Enabling Your Practice Success”).
7. A resume setting forth your educational and professional accomplishments.

8. Detailed financial information, including your best estimates of start-up costs, revenues and expenses, and your ability to make a profit.

Help in designing a business plan is available from the U.S. Small Business Administration (SBA) and online software guides like Business Plan Pro (Palo Alto Software, Eugene, OR). Focus on creating a polished plan that can be presented to several bankers and their loan boards for consideration. The better it looks, the more likely you will get a favorable loan offer. If you are self-financing, concentrate on financial projections, because the cost of services, sales revenue, and profit will all figure prominently in how much you will have to invest. Remember that starting a new professional business will require money to market the practice. Very few offices today, especially in crowded urban markets, can just hang out a shingle and expect to be busy. Good planning requires making educated guesses about income and spending, based on the following projections:

1. A break-even analysis to determine if you will make money:
 - a. Projected collections
 - b. Fixed and variable costs (estimate)
 - c. Gross profit
 - d. Break-even revenue
2. A start-up cost estimate to evaluate the amount of money needed just to open the door on the first day of practice.
3. A profit-and-loss analysis to refine the month-to-month projection of profits for the first year of practice.
4. A cash flow projection to ensure that even if your business is profitable, there is enough money on hand to operate from month to month.

No business plan would be complete without consideration of what business structure the practice will take. Keep in mind that this decision will affect your personal liability as well as the amount of tax you and your organization will pay. Whether you choose a “C” or “S” corporation, a limited liability company (LLC), limited liability partnership (LLP), general partnership, or sole proprietorship, your attorney and accountant will need to provide advice.

CHOOSING AN OFFICE LOCATION

Choosing where to practice is one of the most important decisions a new practitioner will make. Family considerations, personal preferences, weather, career opportunities for your spouse, and lifestyle issues are

among some of the considerations that should govern your decision. Establishing a successful endodontic practice will require a location that will provide enough new patients to support the practice's expenses and result in the best opportunity for you to utilize your skills. Because the number of dentists in postdoctoral endodontic programs continues to increase faster than any other dental specialty,¹⁹ practice location will prove to be a key predictor of success. Studies by Wright,²⁰ and Solomon and Glickman,²¹ using sophisticated statistical analysis, clearly establish the relationship between the location of general dentists and the location of endodontic offices. Because endodontic practice is referral-based, the proximity of a referral network, followed by adequate population and other criteria such as socio-economic characteristics, are all variables that will affect the economics of your practice.

The economic potential of your proposed office location should be appraised to determine its professional desirability. People living in similar neighborhoods generally exhibit similar lifestyle and spending profiles. One of the easiest ways to learn about your clientele is to understand their geodemographical classifications. These data, available from vendors like Business Information Solutions (ESRI BIS, an internationally recognized provider of information services), will allow analysis of clinic site locations by creating a visual depiction of data which is spatially referenced to the earth, also known as geographic information systems (GIS) mapping. GIS-generated information will greatly improve your business planning and allow you to base location and growth decisions on the best available information. A new type of classification introduced by ESRI BIS, called the "Community Tapestry" segmentation system, provides an accurate, detailed description of America's neighborhoods. U.S. residential areas are divided into 65 segments based on demographic variables such as age, income, home value, occupation, household type, education, and other consumer behavior characteristics. ESRI BIS offers market surveys that provide a detailed look at data within various radii around a given geographical address. This is called a "Market Profile Report" and is based on the updated U.S. Census, including 5-year projections. Reports can also be ordered with specific filters, such as a plot of all general and specialty practices in the zones of interest. You can find them on the Web at <http://www.esribis.com>. Also, ESRI BIS offers a free Web-based lookup of demographic data based on ZIP codes, but ZIP codes will not provide adequate specificity for making a final decision.

Further analysis can be performed by purchasing a list from your state dental society in Excel format, and

then using a program such as Microsoft MapPoint to plot the data. Of course, there is no guarantee of success with any particular location, but a poor choice may lead to economic hardship. It is critical that you create a comprehensive plan to assure that your proposed site is architecturally and financially sound. Plan on specifying about 400 to 500 square feet per operatory in your new office.²²

According to Gregory L. Morgan,²³ Managing Director of Sperry Van Ness – Morgan Realty Advisors, specify your geographic parameters, space requirements, parking availability, modes of access, and street exposure if applicable. Then engage an experienced commercial real estate leasing professional to canvas your prospective area and match your requirements with properties using real estate databases, brokerage relationships, publications, and the Internet. Comparing the economics and qualitative differences between properties and market information is where a commercial real estate leasing professional will provide essential guidance. Hopefully, you will have several options to review, creating a competitive atmosphere where multiple landlords are competing for your business. As you will learn early on, the effective rent can be based on one of several formulas, and extending these costs over many years can add up to a significant difference. Even if you are especially focused on one of these locations, it is important to go through the exercise of requesting proposals from several property owners and managers. Some landlords will offer concessions in areas where others will not, helping you to identify the most important considerations for your business: property location, economics, and functionality. Analyzing the proposals will then help you request aggressive but fair economic concessions from the finalists based on what other competing landlords have offered.

The next step is to decide on the number of operatories and what supporting facilities will be required. Engage an architect or dental office designer to draw basic floor plans and confirm that adequate plumbing and electrical infrastructure needs are met. Now, with several lease proposals in hand, you should meet with a real estate attorney for further analysis.

According to leasing attorney Charles J. Levin,²⁴ some of the attributes of a successful commercial lease are summarized as follows: (1) lease terms and conditions are expressed in a complete written lease with no oral agreements and understandings; (2) all contingencies are considered and resolved; (3) lease terms and conditions are aligned with your needs; (4) the leased premises suits your needs; (5) you have protected yourself from operating expense charges that are not customary and

you understand what to expect with those that are passed through; (6) there are no defects like possible noise, odor, vibration, or other similar problems; (7) you have warranties protecting you from issues such as zoning, water quality, mold, asbestos, Americans with Disability Act (AwDA), and so on; (8) you have thoroughly reviewed the build-out letter with your architect and contractor and included all necessary details in the lease; (9) you have expressly excluded certain types of objectionable tenants from being in the building or on your floor (e.g., music school, barbecue restaurant, and social security office); (10) you have flexibility to renew, expand, and terminate; (11) you have option to purchase, if appropriate; (12) other tenants have no major complaints; (13) you have looked into the future and considered all of the possibilities with respect to issues such as fire and casualty, condemnation, changes in governmental requirements, assignment and subletting, and the many other issues that can arise; and (14) you, your commercial real estate leasing professional, attorney, and architect have all reviewed your office selection. Lastly, create a ticker file in your office management software as a reminder of notification dates memorialized in your lease.

Levin further emphasizes the importance of you being engaged in all aspects of the negotiations and that you understand the significance of each and every provision of the lease as it is being negotiated. It is a mistake to hand the lease to your attorney for negotiation and expect that your interests are being protected without your involvement. There are many aspects of the lease that combine both business and legal issues that will have a profound effect upon the success of the practice. The selection of an experienced commercial real estate leasing professional and real estate attorney cannot be overemphasized because of the complex and nuanced nature of leasing space and the long-term and potentially devastating implications of getting it wrong.

Once the lease is executed, the next step is contacting the telephone company to obtain a telephone number and secure a listing in the local phone directory. Many telephone providers will allow you to select a unique telephone number without charge or for a small fee. Generally, it is only necessary to secure one number, which will serve as your main trunk line. Additional numbers can be secured at a later time for use with multi-line phone systems, to avoid paying for reserving hidden numbers prior to the opening of the office. Today, most offices will have a choice between several trunk line providers and systems, such as copper wire or fiber optic. Use of Internet phone services over fiber-optic connections, such as Voice over IP, is

becoming more popular, and packaged with Internet connectivity and television services, may prove a viable alternative to traditional service.

After securing a telephone number and phone book listing, order the practice management software and a computer workstation which will become the front desk system. Once setup, this workstation can be located off-site to configure your practice management software and allow training of new employees. Every endodontic practice, including a de novo practice, must have practice management software to manage appointments, prescriptions, reports, and other communications with referrers, not to mention the financial aspects of treatment and insurance.

CREATING A WINNING OFFICE DESIGN

Although building a new office from an empty shell is a daunting challenge, it provides the opportunity to set up the office to your specifications, within budget and space constraints. A key element to insuring success is the early involvement of your design team—and the design team starts with your architect or dental design firm. Try to choose an architect who is familiar with the design of medical facilities, the AwDA (Americans with Disabilities Act)²⁵ standards, hygiene requirements, and your local building codes. By helping you define the building project, architects can provide meaningful guidance for the contractor and other construction professionals. They can conduct site studies, help secure planning and zoning approvals, perform a variety of other pre-design tasks. Evaluate for handicapped patients, transportation, parking, and general convenience. When experienced architects are involved at the earliest planning stage, they gain opportunities to understand your business, develop creative solutions, and propose ways to reduce costs. The long-term result is a facility that adds to the productivity and image of the practice. Specialty architects who design just dental or health-care facilities are also an excellent option, and the more endodontic offices they have designed, the better probability that all details will be considered. The American Institute of Architects²⁶ provides good resources on their Web site and lists numerous standard agreement forms that can be tailored to the types of services that are required.

Steven Covey's²⁷ maxim "begin with the end in mind," plays a large part in creating your desired outcome. What do you want your office to look like? How will patients and referring doctors be best served? Of course, ownership of your space in either a condominium or a stand-alone building that you

are purchasing or building will require special considerations.

After the plans are approved by the building owner, your architect and/or dental designer will be responsible for meeting with you and any interested contractors to explain the scope of the project and solicit a quote for construction. The following architectural drawings and specifications will need to be available: (1) site plan; (2) demolition plan, if applicable; (3) reflected ceiling plan; (4) mechanical plan, for example, smoke/fire detectors and fire annunciators, sprinkler system, heating, and cooling; (5) electrical plan, for example, power, telephone, and computer installation; (6) plumbing plan; (7) millwork; and (8) finish schedule, for example, flooring, wall coverings, and paint. The contractor will generally be responsible for getting approval from local building officials to begin construction.

Designing the office for new and even future technologies will require some coordination between the various planners of your space. The wires and cables must be installed and integrated for the practice management system, digital radiography, entertainment, power, fire and smoke annunciators, security systems, and climatic systems.

Design Aesthetics

According to Schmitt and Simonson,²⁸ “aesthetics is one of the major satisfiers in consumers’ experiential worlds.” They state that intangibles like experiences become key selling points when services are perceived as the same across an industry.

How can Starbucks charge over \$4 for a cup of coffee? It is because they provide experiences that customers can see, hear, touch, and feel—experiences that add value and allow for premium pricing. In the same way, your practice will become identified with certain traits that create a practice image, requiring “a careful mapping of a strategic vision to create sensory stimuli and communications that evoke that vision – that instantiate the identity”.²⁹ It is important to establish a style that is consistent throughout everything your practice does, from your Web site, to your brochure, to the design of the office interior. Bloch,³⁰ in his research to conceptualize consumer reactions to a product’s design, says there are three basic consumer responses, namely, “cognitive, affective and behavioral”. He goes on to state that product form—or in this case office aesthetics—influences behavioral responses through cognitive and affective responses and are based on individual tastes and preferences.

Research in the organizational sciences has shown a direct relationship between office design and impression management. The physical environment will convey social messages to your patients. Consider designing with positive visual impact, such as added accent lighting, dry-wall soffits in key areas, upgraded ceilings, an enhanced level of detail and color balance, pleasant artwork and furnishings, and fabrics to further establish your desired image. Keep in mind that some businesses, such as Starbucks, have left the traditional marketing to their competitors, differentiating themselves through the inviting “look” of their hip aesthetic that evokes a satisfying experience.³⁰ Some of the “don’ts” when it comes to office design are creating physiological barriers, that is, sliding glass enclosures between patients and the patient coordinator, showcasing your hobbies; unclean, inexpensive, or misarranged furniture; and off-putting signs in the reception area [a big no-no, with the exception of a Health Insurance Portability and Accountability Act (HIPAA) notice, if applicable]. Signs that tell patients about office policies, in general, are unwelcome reminders of what your office personnel should have advised either verbally, or in the office’s literature or Web site in the first place.

Branding: Enabling Your Practice Success

Dental practice begins as a journey after dental school with little or no training in the business aspects of practice. Unfortunately, talent and education alone are not enough to ensure success in our increasingly competitive healthcare marketplace. Getting and keeping patients in our endodontic practices will undoubtedly become more challenging, especially in mature urban settings. In order to develop long-term, directed growth, we must learn to manage our practice building efforts through trial and error, intuition, reading, continuing education, and use of management consultancies.

Before we address the ins and outs of practice operations, we should first explore the case for concern, the meaning of branding, and ultimately how to build a brand-driven culture within your organization. At the end of the day, building you brand in a way that energizes all referrers, patients, vendors, and employees must become the mantra of your operational strategy.

THE CASE FOR INCREASED CONCERN

In the United States, we are facing many new challenges in private endodontic practice. Endodontics is one of the smaller clinical specialties in dentistry, with about

4,000 practicing clinicians in 2007, and a population to endodontist ratio of about 75,000 individuals per endodontist. However, with our population projected at 340 million in 2035, and with endodontists graduating and leaving practice at approximately the same rate as today, we are projected to have approximately 6,580 active clinicians or a population to endodontist ratio of 54,270 individuals per endodontist. At current graduation rates, the number of dentists completing endodontic residency programs has been increasing faster than the number of general practitioners, and as a consequence, the practitioner to endodontist ratio has also been declining. The vast majority of endodontists practice in the Northeast and West Coast areas, and if misdistribution trends continue, the number of over-served areas will continue to increase with resultant case-load challenges. Other factors, such as the higher relative failure rates in restorative materials like resins, general dentist busyness, and increased productivity among all practitioners will continue to be some of the issues affecting the profession.³¹ A report by the DTA concluded that up to 40% of all practices are not reaching their full production. By the year 2010, it has been postulated that less than 40% of all dental care will be provided by non-owner doctors rather than more traditional practice models.³² The competitive landscape will continue to change, according to Eric Solomon,³³ Professor of Public Health Sciences at the Baylor College of Dentistry, in his *Dental Economics* article “The Future of Dentistry.” He predicts that the number of specialists in dentistry will increase from the current level of 20% to 27% by the year 2020,” leading to an increasingly competitive marketplace for the new specialist. The days of opening a new office in a major metropolitan area and instantly generating a sustainable financial model are becoming increasingly rare.

Increasing competition, demographic shifts, market saturation, bunching of endodontic practices in already crowded urban centers, insurance company control, and an insidious lack of customer loyalty will always challenge endodontic practices in the most desirable markets. Central to meeting these challenges is creating a brand identity that consistently conveys our special skills to referring doctors and patients. What follows is a summary of branding basics, with an emphasis on the connection between best business practices and the dental profession.

UNDERSTANDING YOUR BRAND

What is a brand? A brand is simply a *promise*—the expectations that exist in each customer’s mind about a product or service. According to John Hagel,³⁴ a

business strategy consultant, in the past, a brand used to say, “If you buy this product or buy from my company, you can rely on me because of the attributes attached to the brand.” He goes on to state that we are seeing “a new kind of branding emerge, a much more customer-centric branding, where the promise is, ‘I know you as an individual customer better than anyone else, and you can trust me to assemble the right products or services to meet your individual needs.’” Brands are imbedded in our minds and used in our daily lives, like “FedEx that photo to San Francisco.” Your brand is your personality; brands are the reason that companies exist, and they are based on multiple experiences over time. These experiences, from the patient intake process through treatment and post-treatment interactions, need to be delivered with consistency and be perceived as unequalled relative to the competition. In short, your patient’s and referrer’s experiences need to result in deep, trust-based relationships which generate loyalty. Your brand should reflect a high level of education, proficiency, and confidence that you are offering the best care.

While brands speak to the mind, brand identity or brandmark is the sensory expression of a brand. You can touch it, hear it, feel it, and it increases the customer’s consciousness and builds loyalty. Your brandmark can include a name, design, or symbol that visually represents the value of your practice beyond its functional purpose. The velocity of life in the future will inevitably demand that brands leverage the power of symbols. Whether it is a photograph, mark, graphic, or typographical image, which can be as simple as the practice name written in an artful font, symbols can trigger recall and stimulate emotion. A brand identity helps to manage perceptions of your practice and differentiates it from other practices.

Offices must deliver their services to create value that relies on understanding results and process quality from the referrer’s and patient’s perspective. When it comes to understanding your clients, according to Marty Neumeier,³⁵ a branding consultant, “Brand is not what you say it is. It is what they say it is.” Although branding is a simple concept, it is not that easy to accomplish. It takes a long-term commitment and hard work.

In the early 1990s, brands were a series of marketing tactics like the advertising icons made famous by Nike, Alka Seltzer, and even KFC. Brands now have strategic importance, brands result in deep, trust-based relationships which in turn garners customer’s loyalty. Products and services need to be delivered with consistently high level of quality and value, perceived to be unparalleled relative to the competition.

Adopting this brand-driven approach, “where making the brand the central focus of the organization clarifies what is ‘on-brand and what is off-brand’”.³⁶ Then the entire organization needs to adopt this brand-driven approach to guide critical business decisions as well as determine appropriate staff behaviors. Building a brand-based culture is simply not a quick fix program. It requires a solid dedication to the organization’s brand vision and an understanding that branding cannot be overemphasized an overall strategy.

As we learned in the beginning of this section, a brand is a promise that defines a patients’ value proposition that both their treatment and their experience will be as expected or better than expected. “It has meaning, prestige, and presence, and it helps confirm what is expected”.³⁷ The treatment performed must be unrivaled and the patient and referrer experience must be unequalled. According to Prophets 2002 Best Practices Study,³⁸ there are three main goals of any branding strategy: (1) increasing customer loyalty, (2) differentiating your organization from the competition, and (3) establishing market leadership. Let us look at each of these goals and how they affect practice success.

1. Increasing customer loyalty: A classic study by Xerox in the 1990s (Figure 1) looked at satisfaction and found that highly satisfied customers were six times more likely to repurchase a Xerox product than a merely satisfied customer.³⁹ This means that every highly satisfied patient will demonstrate repeat behavior and require much less effort on your part to maintain their loyalty than patients who are just along for the ride. Even more important, a patient who repeats their behavior is much more likely to continue repeating it, becoming more profitable as time goes on. For example, it takes the average credit card company 3 to 4 years of marketing effort to attract a new customer, or 7 to 10 times the cost of merely maintaining an existing customer. An increase in customer loyalty of just 2% will equal the equivalent of a 10% cost reduction program, and an increase of 5% in loyal customers can deliver 95% greater profitability over the lifetime of that customer.⁴⁰ Even more striking is that 50% of customers will try a new product or service from a preferred brand because of the implied endorsement, credibility, and trust.⁴¹ According to Robinette et al.⁴² of Hallmark Cards, Inc, “increased customer loyalty is the single most important driver of long-term profit-

Customer Satisfaction Index

Figure 1 Customer Satisfaction Index. In this typical customer satisfaction index, completely satisfied customers, rated 5, were six times more likely to repurchase a product or service over the next 18 months than just merely satisfied customers, rated 4.⁴⁰

ability.” If we look at the lifetime value (LTV) of a top-tier referring doctor whose career spans 35 years, revenue generated will easily exceed \$1.5 million. While calculating LTV is complex because of varying costs to acquire and maintain each customer, there is no doubt that looking at the “customer back” will allow formulation of strategies for each customer segment. Customer loyalty rules!

2. Differentiating your organization from the competition: If a customer cannot tell the difference between your service and another, they will buy on price. A practice needs to invest in the things that highlight a unique benefit to the customer and deliver it with skill and finesse, like a concierge at a fine hotel. Identify and build on the qualities or characteristics which make your practice distinctive.⁴³ Every customer, whether purchasing a car, hospital services, or endodontic care usually has a choice. Your job is to wind up in the referrers’ final consideration set and then be chosen because of your unique capabilities. It can range from a high-tech approach using a Web based patient intake process to digital radiography and microscopic imaging to non-surgical revision therapy to diagnosing a difficult case. Remember that technology implementation costs money, so do not market your practice as the best in town and then price it low, because you are sending a mixed message and wasting some of your marketing dollars. Learn what characteristics

make your office distinctive. If you are going to be a brand, you must be inexorably focused on what you do that adds value.

3. Establishing market leadership: First and foremost, communicate that you are a specialist. Make sure that patients understand that you have undergone extensive post-graduate training. Use verbal and written communication to focus attention on continually improving outcomes with the latest science by using evidence-based treatment that leads to a painless procedure with the highest level of success possible. Reveal the hidden by using models, drawings, and microscopic/radiographic imaging to increase the patient's understanding of the procedure. For example, drawing a scaled diagram for each patient at the end of their visit will demonstrate your special skills. Be sure to let patients know that treatment you perform through the microscope is reflected through a mirror, so that every hand movement is reversed. Use technology to create a value proposition for all stakeholders—defined by modern management science as everyone with an interest in what the organization does, such as clients, employees, and vendors. Demonstrate your proficiency both singly and as a team, reaffirm the patient's choice of endodontic treatment over extraction by addressing the benefits of decreasing dental disease to improve overall health, show sensitivity to patient's mental and physical comfort, provide impeccable service, and offer superb facilities.⁴⁴

One of the best ways to establish market leadership is to use state-of-the-art technology to create value in the referrer's and patient's mind that they can see and understand. Every patient treatment communication should reflect your technological competence. Digital radiographs and photographic images along with cogent narratives of treatment should reflect your commitment to the latest technology and help operationalize your brand. Performing a state-of-the-art procedure and then communicating the results by sending a film-based image and a few handwritten notes misses the opportunity to maximize your image as technologically sophisticated. This leads us to the next section about how to develop brand-building programs that are the most cost efficient, effective, and credible.

There are many ways to help define a brand. Volunteerism and community outreach programs are valuable ways to “give back” and also help your stakeholders understand your brand philosophy. The list of opportunities to partner with other profes-

sionals or community organizations is endless. Here are a few examples: (1) teaching at a dental school, (2) getting involved in philanthropic and civic organizations, (3) providing continuing education, (4) sponsoring a blood drive with the American Red Cross (Sidebar 2), and (5) partnering with another dental office to benefit a community program like a soup kitchen, food bank, and so on.

USING TECHNOLOGY TO OPERATIONALIZE YOUR BRAND

Although all endodontic practices provide basic specialty services to patients and referring doctors, it is the value-added services that can help differentiate your practice from competing practices. Research continues to link business success and professional achievement with developing long-term appeal and credibility. And adopting proven technologies is one of the most visible and reliable ways to create a positive impression and to continually engage patients, referrers, and staff, to say nothing of the clinical advantages.

Patients expect a high-tech approach to treatment. In fact, the National Health Information Infrastructure (NHII) is establishing a national electronic information network for health care. The NHII proposes to implement a computer-based patient record for most Americans by 2014.⁴⁵ So how will your practice measure up? With the expanding use of technology in every aspect of life, patients expect their healthcare encounters to include the newest technologies. Use of the Internet to improve patient intake, receiving electronic receipt of patient pre-treatment radiographs and information, digital radiography, computerized charting, microscopes with imaging capability, instant communication of your treatment reports by email, online pharmacology information at the chairside, and music and entertainment options are all ways that your office can project a technologically advanced practice image. The list goes on and on, but the importance of differentiating your practice cannot be overestimated, and one of the best ways is with useful and visible technology.

“A brand strategy is a statement of the brand's sustainable competitive advantage, usually consisting of a demographic and psychographic description of the intended customers and the benefits they get from the brand.”⁴⁶ A brand-driven approach will create customer loyalty that will ultimately translate into a competitive advantage and increased profitability. Modern management science defines everyone with

OFFICE DESIGN

Appealing to consumer needs has defined marketing for the past one hundred years. According to Abraham Maslow¹⁰⁷ in his book *Motivation and Personality*, once basic consumer needs like survival and safety are satisfied, higher order needs like experiential and aesthetic needs become increasingly important. A simplified version of his thesis depicts a pyramid with experiential and aesthetic needs at the top, which leads to the false conclusion that aesthetics is a luxury that humans care about only when they are wealthy. To the contrary, Virginia Postrel,¹⁰⁸ in her book *The Substance of Style*, states that “aesthetics is not a luxury, but a universal human desire.” She contends that humans do not wait for all of their lower order needs to be satisfied before wanting aesthetic environments and products. She goes on to say that “there is no pyramid of needs, where each layer depends on what we already have,” but rather we make important decisions every day based on our sensory experiences. These experiences are based on the precept that appearance counts and that aesthetic value is real and gaining even more importance in the twenty-first century. According to Postrel, we have entered the “Age of Aesthetics” when beauty and style are found everywhere in market economies. Simply put, increasingly sophisticated consumers demand “an enticing, stimulating, diverse and beautiful world.”¹⁰⁹ To this end, a coordinated and appropriate office aesthetic is important, and color, texture, sounds, lighting, and artwork will all lead to an identity that will satisfy patients experiential and aesthetic needs.

Creating positive attitudes and beliefs about your organization and its services will be influenced by how you deal with your brand identity. The overall impression of your practice will often depend on the management of the themes inherent in individual identity elements that must be coordinated and designed to convey your brand characteristics.¹¹⁰ Themes are an expression of your organization’s core values or mission and are typically created by graphic designers, interior designers, architects, and marketing experts.

The level of finishes you choose should follow a consistent design theme and may include (1) lighting accent fixtures; (2) dry-wall soffits and upgraded ceilings; (3) color balanced walls and carpets; (4) coordinated artwork and furnishings; and (5) harmonized vinyl, fabrics, and custom finishes. Items that may cause negative visual impact include (1) showcasing your outside interests; (2) inexpensive furnishings and artwork; (3) unclean and misarranged furniture; and (4) signage that gives information that could be reasonably explained by the office staff. I hate reception area signs!

When designing or renovating your office, strongly consider what the patient sees and design with them in mind. An office design that resonates with patients is an important factor in establishing a patient’s trust and helps them measure the quality of your treatment. Design themes should be repeated and coordinated to express a close association that increases recall and puts your practice in “top-of-mind status.”

an interest in what the organization does, such as clients, employees, and vendors are called stakeholders. And each interaction with a stakeholder must be understood and prioritized along the entire treatment cycle.

How important are employees to the branding process? The success of any branding strategy depends on engaging employees around your brand in a way that encourages ownership of the brand. We have all experienced the exceptional employee who understands the brand’s unique character and communicates it to all of the practice’s patients, for example, patients, referring doctors, and fellow staff members. Employees who are engaged around the brand confirm that the patient, referrer, and the brand are the things to focus on. It facilitates recruiting and reten-

tion of employees and improves morale, aligning each team member with your brand promise. All employees need to think, speak, and behave in ways that create the kind of patient and referring doctor experience that has lasting impact. Assimilating your brand among the employees of your organization will ensure that all employees understand and embrace your brand and can translate this into actionable behavior. This way employees become brand advocates that understand how his or her impact can affect satisfaction and ultimately loyalty.

EMPLOYEE MOTIVATION AND MORALE

Every business relies on its organizational values to deliver on its brand promise. Employee attitudes and

retention rely on a cohesive and upbeat culture. In order to develop brand advocates among all of your employees, your practice must first generate excitement about what it does. If each employee understands the benefits of modern endodontic treatment, it will reinforce their choice of employment. It can foster a sense of belonging to a profession they are passionately proud of. Employees need a leader who clearly understands the mission of the practice and can communicate his or her vision to each employee, patient, and referring doctor.

Brand-driven behaviors are enhanced by establishing a strong brand-based culture that is constantly fed and nurtured. It is crucial that your brand commitment is evident from the top down. If employees think that the practice leadership believes brand building is a priority, they will embrace it with the same passion. Each endodontist in the practice must communicate their endorsement of the practices' brand vision so that every employee experiences appropriate modeling at every level of stakeholder interaction. Without leadership support and willingness to lead by example, the old Russian proverb "the fish always stinks from the head downwards," will resonate loudly.

Successful brand strategies require a clearly articulated vision of what your organization's brand stands for and how to link it to your overall business strategy. For example, if employees are to bring the brand to life, a strategic foundation must be established. One important first step is to establish well-defined roles for your most important asset—your employees. The notion that your patient coordinator can just answer the phone, assign appointment times, and have customers fill out forms in the reception area will not lead to a patient-centered practice model that will generate a loyal following. There needs to be a conversation between the patient, referring doctor's office, and your staff that is welcoming, informative, and nurturing. It is clear from the work of Silversen and the Werthlen Group that the better prepared a patient is before treatment, the more positive their treatment experience will be.⁴⁷ Of course, our treatment must conform to the best available practices of the day, but also must provide the key satisfiers of the patient experience. In Bernick's⁴⁸ *Harvard Business Review* article about corporate culture, Alberto-Culver was able to boost sales 50% by creating a more customer-centered approach. It embraced a management culture that listened to its employees, celebrating events like birthdays and anniversaries, and creating passionate advocates of their brand. Without brand advocates, your practice will just muddle along, reducing the likelihood of reaching your desired future.

BECOMING A LEARNING ORGANIZATION

When you go to a barber shop or a salon to get a haircut, you tell the barber or hair stylist exactly how you want your hair done. After a few visits to the same person, he or she will probably know just how to shampoo, cut and, blow-dry your hair. You have invested time and energy to tell them how you want it, and they will have likewise invested in learning your preferences. In fact, the more you tell them about what you want, the more likely you will revisit the same hair stylist, because, after all, you have invested in them to create a mutual relationship. We have all experienced this kind of service and will tend to frequent the same establishment time and again because they have established a learning relationship. If you were to switch to another barber or stylist, you would have to make that investment all over again. According to Pine et al.⁴⁹ in an article in the *Harvard Business Review*, customers "want exactly what they want – when, where and how they want it." And a company that aspires to give customers exactly what they want must establish a learning relationship that ensures that all stakeholders collaborate. Developing learning relationships with referrers is critically important. The more you know about how they want it (new patients sent right over for consultation, one-visit treatment whenever possible, etc.), the greater chance that this referrer will continue to use your services. If you think about the cost of replacing one referrer with another, consider their lifetime value (LTV). LTV is the sum of the stream of profits attributable to this referrer. Take the average value of referrals in a year and multiply it by the projected number of years you intend to practice and you will see how important each referrer is to the bottom line.

New paradigms of patient care are emerging as the relationship between oral disease and systemic health become clearer. Developing a learning relationship with physicians is an emerging area that can enhance your professional image with non-dental sources of referral. In order to continually differentiate your practice, consider practice-building strategies that incorporate the latest research in endodontics or health care in general. Liaising with other healthcare providers is a good way to promote improved health and communicate your brand identity. Study clubs, continuing education opportunities, one-on-one meetings, Web sites, and publications can create valuable brand advocates.

BRAND ASSIMILATION: PUTTING THE PROGRAM INTO ACTION

The most successful organizations divide brand assimilation into three phases: strategic development, foundation building, and implementation. First, develop a strategic

plan that defines the scope and objectives of your program so that the right people and systems are identified to carry out your program. The second phase is foundation building, the process of aligning all employees around the central theme of your branding initiative through office workshops and reading. This is where each employee segment (e.g., chairside assistants and patient coordinators) learns about your brand initiatives and their role in communicating your message. The idea here is to guide behaviors that foster participation and allow all employees to understand the benefits of your key objectives. Implementation, the final phase, is where a range of tactics are employed to create key materials and talk about successes that will change employee behavior throughout the practice. As always, it is important to monitor the responses to your program and make changes as necessary.

Establishing a brand assimilation program will lead to a number of changes, but at what cost? How do you measure success? The first hurdle is to make sure that your employees understand your brand initiative. They have to be invested in developing significant relationships with your patients. When your employees assimilate your brand, you can begin to implement an action plan that markets your brand. One effective program can be an orientation luncheon for a referring office. Have all of the referrer's office staff join your staff for a catered luncheon, conduct a brief office tour, and present a short program to let them know how you welcome new patients and how good communication between your offices can build patient confidence. The practice should strive to highlight the ways that both practices can work together.

Changes in organizational culture do not happen quickly. It takes a considerable amount of leadership and vision to promote meaningful changes to employee behavior. But the payoff will be a strong brand that will resonate with patients and referrers and help excite employees. This will ultimately result in increased loyalty.

While the detailed application of these disciplines is beyond the scope of this chapter, it is instructive to look at the relationship between providing services and recognizing the link between loyalty and profitability. The service-profit chain provides just such a model for operating in the medical environment. This is where leadership develops a dedicated team that provides superb service to patients that go on to develop loyalty to your organization.

When customers are highly loyal, there are minimal considerations of other brands. In the Xerox study quoted earlier, a survey of 430,000 customers revealed that highly satisfied customers were six times more likely to repurchase a Xerox product than merely

satisfied customers.⁵⁰ What is the take-home from this study? Simply put, the key to business success is to create as many loyal referrers and patients as possible. Then to market your practice in a way that not only maintains your most loyal referrers and patients, but attempts to increase their ranks by "marketing below the gold." In other words, spend the bulk of your energy and precious marketing dollars taking a *merely* satisfied referrer and elevate them to the *extremely* satisfied category.

What are the benefits of loyalty? Patients will recommend your office to others. Hearing about how great your brand is from someone else will clearly be much more effective than self-promotion. Loyal patients are more accepting of new services, will say "no" to substitutes, and will pay a premium price for you to treat them. According to Passikoff,⁵¹ over 50% of customers would pay a premium of 20 to 25% before they would switch to another brand. The benefits of developing loyal patients cannot be overemphasized. It takes 7 to 10 times the cost to gain a new customer than to keep an existing customer. So do whatever it takes to retain your current patients. Remember that a service needs to do what is expected, as expected, for as long as expected throughout the customer experience.

Build on what differentiates you from the competition. If a patient cannot tell the difference between one service and another, they will buy on price. A practice needs to invest in the things that highlight a unique benefit to the patient and referrer and deliver it with skill and finesse, like a concierge does in a fine hotel. After all, patients and referrers really want just two things: *results* and *process quality*. The results part of the equation applies to a great diagnosis or root canal procedure, where the patient feels that he or she received caring service and state-of-the-art care and the referrer feels confident to complete their restoration. Process quality is how the referrer and patient were treated. Was the patient seen on a timely basis? Was the referral handled seamlessly? Was their treatment compassionate, respectful, and safe? Did the procedure make the referring clinician seem like everyone was on the same team?

Today's consumers⁵² are increasingly brand-centric, and developing a brand identity is an important element in differentiating your services.⁵² The problem is how to get started so that you can deliver your brand across every touchpoint and every stakeholder. Begin by formulating a brand strategy that creates visibility and recognition, unaided recall, top-of-mind status, deep customer relationships, and build differentiation.

Does this seem impossible? Collins and Porras⁵³ ask the question of how to use words that are not meaningless. All McDonald's corporate strategies are still guided by Ray Crock, McDonald's late founder's acronym, QSVC (Quality, Service, Cleanliness, and Value). Social psychology research indicates that when people publicly espouse a particular point of view, they become more likely to behave in a manner consistent with that point of view, even if they did not previously hold that belief. "Passion is a pretty fool proof test of whether a value is a core value," says Mike Moser,⁵⁴ an advertising and marketing expert. "It will help you include your heart in the decision-making process instead of just your head. Passion is what creates an emotional connection that transcends ads, public relations, brochures, or any other crafted messages that a company puts out."

The brand–customer relationship remains one of the most underleveraged and yet potentially powerful ways to drive sustainable, profitable, and long-term value back to your practice. First, determine your practice's core values. "Visionary companies tend to have only a few core values, usually 3 to 6...only a few values can be truly core values so fundamental and deeply held" that they will rarely change.⁵⁵

Every office has a personality, so maximizing the benefits of your practice by showing genuine warmth and sincere concern for the patient's comfort are part of a thoughtful brand approach. Simple things like offering a warm, moist towel after treatment, providing appropriate music or video entertainment, and always using the most current technology are critical to establishing your brand personality.⁵⁶ Always make sure your brand personality is appropriate for your audience. Is it predominately male or female, blue collar, white collar, or service workers? Demographic studies have shown that endodontic patients are 60% female, average 48 years old, with 69% older than 40 years old.⁵⁷

BRAND TOUCHPOINT OVERVIEW

Like most world-class businesses, the best endodontic practices operate with a clear vision to ensure peak performance. Just like an Olympic hurdler who mentally previews his or her performance before an event, from leaving the starting block to breaking the finish line, each element in the patient's visit must be carefully planned to ensure that patients feel they are in right place. Every staff member contributes to a successful visit by interacting with patients in a professional and caring way. It is useful here to visualize the patient and referring doctor experience as a conti-

num that begins with the introduction of endodontic therapy and only ends when the patient no longer needs your services. Dividing these interactions into three brand life-cycle stages, pre-treatment, treatment, and post-treatment procedures, each interaction can be choreographed to create a value chain that consistently fulfills the patient's clinical and experiential needs. These steps are really brand touchpoints, or the different ways your services interact with patients, referrers, and fellow staff members. The members of your staff have to serve as brand ambassadors, and each interaction with patients and referring doctors must be consistent to ensure the best experience.

In order to be truly successful, every functional area in your organization must be responsible for bringing the brand promise to life. There must be total alignment between your organization and your brand strategy, so that you control the critical interactions your patients and referrers, or stakeholders, have with your brand. What are all the touchpoints that exist between your brand and a current or potential stakeholder? How can you create a brand-driven organization? Outlined below are 10 brand touchpoints commonly found in endodontic practices. Please note that only 5 of the 10 involve the practitioner, and only one of these involves the practitioner alone. The importance of selecting an outstanding staff and taking control of all patient and referring doctor touchpoints cannot be overemphasized.

1. Patient is informed that they need endodontic treatment: The process begins when the patient is advised that he or she needs an endodontic consultation. Providing each referrer with a kit that contains your office brochure, referral forms, appointment cards, business reply envelopes, and Web site information will help introduce patients to your practice. According to Jack Silversin,⁵⁸ in his American Association of Endodontists-funded study to learn about the endodontist–patient relationship, the more your patients know about their treatment in advance, the better their treatment experience will be.
2. Patient calls for their first appointment: When a new patient calls for an appointment, complete a written telephone intake form or software-based pre-registration form, and set up an initial appointment. The telephone intake form should be designed with a sequenced set of questions in order to get efficiently critical information and document that all pre-treatment instructions were given.

Telephones are an essential part of the new patient experience, so make sure that proper telephone etiquette

is practiced at all times. According to Albert Mehrabian,⁵⁹ a pioneer in communications research, there are three elements to any face-to-face communication: words, tone of voice, and body language. When it comes to feelings and attitudes, approximately 7% of meaning is in the words that are spoken, 38% of meaning is paralinguistic (the way that the words are said, like smiling on the phone), and 55% of meaning is in facial expression. The telephone creates an immediate communication gap because facial expression is not apparent, so the words and paralinguistic attributes take on added importance.

New patients should be queried about their status, because patients in pain and/or swelling are interested in immediate treatment and will generally accept scheduling at the convenience of the office. These patients will ideally need to be appointed the same day they call. Patients who have no discomfort or mild discomfort will generally be interested in convenience.

There are several methods available to provide pre-treatment information. Invite new patients to view your office Web site, where they can complete a secure patient registration and health history form. Web sites are necessary, if not a necessity, in today's healthcare environment. According to Harris Interactive, in a poll of 1,015 US adults conducted in 2005, 72% search the Internet for health-related information.⁶⁰ Almost 58% report looking for information often search the Internet for health topics and only 14% say that they hardly ever search health topics. Even more remarkable, 85% of those who have ever searched the Internet for health-related information did so in the last month of the study, and now averages seven searches each month per patient. What does this mean to the endodontic practitioner? Today, patients expect to meet their prospective practitioner on the Internet. Mailing, faxing, or emailing a "welcome kit" to patients with a welcome letter, brochure, procedure explanation, doctor biography, financial policy, registration, health history form, and map are also valuable ways to streamline new patient intake. Creating a Web site to provide patient education opportunities, contact information, and referral materials will further enhance pre-treatment preparation and provide the most convenient and cost-effective solution. While society is becoming more accustomed to automation and the advantages it provides, "dentists must be careful not to allow technology to interfere with the relationship between patient and doctor and the patient and staff."⁶¹

If the office must meet the requirements of HIPAA, all online transactions, as well as the office network, must be secure. If the office uses a wireless network, appropriate security measures are required.⁶²

3. Patient arrives for first visit: When patients arrive for their initial visit, be prepared and give them a warm and sincere welcome. Patients can complete their registration on a reception area computer kiosk connected to the practice's network or the Internet, or fill out paper-based forms and view educational materials while in the reception area. This is the time for scanning any film-based radiographs or appending digitally transmitted images into your radiographic database, if applicable. Some endodontic software can allow front office personnel to indicate the patient's status from their arrival at the office and transitioning through treatment and finally discharge. Besides depicting the status of each patient in the office, recording the chair time for each type of procedure will allow create metrics that can be used to measure profitability.
4. Patient is escorted to operator: Escorting patients to the operator is an opportunity to connect staff and patient. Employee name badges and a policy of each staff member introducing himself or herself to the patient by name should be practiced at all times. Also, chance encounters in the office where a patient is within five feet should prompt a "hello" greeting.

When the patient is seated in the dental chair, the patient's individual record should appear on the chair-side computer screen in the operator, maintaining HIPAA compliance, and assuring the patient that your efforts will be focused on them. Once seated, the assistant should confirm that the patient has followed all pre-treatment instructions, including their antibiotic pre-medication regimen if any, other pre-treatment medications, and have eaten breakfast or lunch to ensure a normal blood glucose level, whichever is appropriate. Of course, staff should confirm that all prescribed medications have been taken on schedule, and if sedation is contemplated, an escort is present to accompany the patient after treatment completion. This is the time for your staff to tell the patient what comes next and set their expectations for their visit. Assuring that their comfort is of utmost importance, offering a blanket or pillow, describing what treatment will be performed, length of the visit, and so on are all important. Acknowledge and reassure the patient that his or her concerns will be addressed. This is also the time to project a safe practice image. Sanitize your hands in front of the patient or let them know you are leaving the operator to wash. Wear proper clothing and limit masks, gloves, and other protective gear to the clinical areas of the office. It is incumbent on the endodontic practitioner to convey a sense of safety throughout each visit.⁶³

This is the time for the dental auxiliary to record the chief complaint, history of present illness, medical history and review all current medications. Once the general area of interest is determined, the auxiliary should expose dental radiographs, record photographic images, take vital signs, answer questions, and, most importantly, comfort the patient. Each staff member should be dressed and groomed appropriately, scripted for this interaction, with the best answers to commonly asked questions to promote consistency and accuracy. Of course, all medications should be recorded in the patient's database so new prescriptions can be automatically checked for advised interactions and cautions.

5. Doctor consults with patient: After introduction by the dental assistant, you should establish eye contact, make sure the patient is comfortable, listen attentively without interrupting, and according to MaryJo Ludwig⁶⁴ Clinical Faculty, Department of Family Medicine at the University of Washington Hospital, "acknowledge and legitimize feelings, explain and reassure during examinations, and ask explicitly if there are other areas of concern." First impressions are important, and your first contact with the patient is no exception. Psychiatrists Leonard and Natalie Zunin,⁶⁵ stated in their book "Contact: The First Four Minutes," that, on average, there is only a short moment in time, a 4-minute window, "to grab someone's attention and establish credibility and rapport." These first impressions demonstrate our compassion, care, intelligence, attention to detail, and pride. Be sure to limit the time you spend with the computer at the expense of eye contact and personal interaction with the patient. Once the patient's dental needs and intake data are reviewed, the initial oral exam is completed, a discussion and informed consent can take place. According to Peter Sfikas,⁶⁶ chief legal counsel of the ADA, the ADA's Code of Professional Conduct requires dentists to "inform patients of proposed treatment and any reasonable alternatives in a manner that allows the patient to become involved in the treatment decision." Every dentist should understand the requirements of their state practice laws with regard to informed consent. In this regard, states differ greatly. In Pennsylvania, for example, a court ruling held that orthograde endodontic treatment was a surgical procedure requiring written informed consent, while treatment considered non-surgical in nature does not require informed consent. Conversely, courts in New Jersey require dentists to provide informed consent even for non-invasive procedures. Also, a patient's refusal of recommended treatment should be documented in writing to ensure that the patient comprehends the possible consequences of refusing treatment. After the discussion and informed consent processes are completed, any additional pre-operative issues should be addressed. Any patient who has not eaten a timely meal and will receive local anesthetic should receive an appropriate nutrient supplement to avoid syncope from low blood glucose levels. Ensure[®] and Glucerna[®] are lactose-free drinks designed for occasional meal replacement and intended for non-diabetic and diabetic patients, respectively. If non-steroidal anti-inflammatory drugs or antibiotics are indicated, they can be dispensed at this time.
6. Doctor treats patient: Every effort should be made to include the patient in the treatment process. Confirm that all of the patient's questions are answered. Then treatment can be initiated along with documentation of the visit. If digital scheduling is available, patients can be reappointed while still in the operatory and their insurance information can be sent to the office financial coordinator via the network or directly to the insurance company, if the office LAN integrates with the Internet.
7. Doctor discharges patient: Once the treatment is completed, the final 4 minutes should focus on the patient and their post-operative instructions. Communicate that you are a specialist by drawing a scaled diagram for each patient at the end of their visit that explains the intricacy of your procedures. Use technology to create a value proposition for all patients. In the end, be sure to take every opportunity to complement the patient on their cooperative attitude. Medications can now be dispensed, as necessary, and prescriptions selected and sent to the printer.
8. Patient is escorted to front desk: Patients are then escorted to the office departure station and reintroduced by their escorting assistant to the patient coordinator. Sit-down departure stations at the front desk will serve to increase patient comfort and to better accommodate disabled patients. In some endodontic offices, advanced practice management software will allow the clinician or assisting staff to forward all pertinent billing statements and post-operative instructions to the front desk computer with a few mouse clicks.
9. Patient is checked out: Once the patient is brought to the departure station, they are asked the "1, 2, 3 questions": (1) The patient coordinator asks the

patient how they are feeling; (2) Next, the patient receives customized instructions, which outline their post-operative instructions and an explanation of check-up recommendations. Patients are then appointed for their next visit and receive any prescriptions and a patient satisfaction survey with a business reply form centered on the reverse side for mailing convenience; (3) Lastly, patients are asked to satisfy their financial obligation.

A business reply permit can be obtained from your local post office at a nominal cost. Patients can either fill out the form immediately (highest response rate) or return it by mail. If patients are invited to fill out the form in the office, a box should be available for the completed survey. Because people often feel awkward expressing their real views, this anonymity will improve compliance.

Measuring patient satisfaction will provide two main benefits: (1) it will allow patients to vent about issues that will ultimately affect their loyalty and their likelihood to return for additional treatment, and (2) surveys present valuable feedback about what really works and what doesn't. All too often, we are providing what we want to and not what the patient deeply values. In a recent 2-year examination linking customer satisfaction with purchasing behavior, and ultimately with company growth, Reichheld⁶⁷ concluded that the likelihood of a customer recommending your services to a colleague or friend was directly related to increased growth.

Patient treatment reports and other correspondence can be created by the front desk or assisting staff, reviewed by the practitioner, and then transmitted to a printer and/or email client for distribution to referrers. It is important for the patient to list all of their co-therapists during registration, so they will automatically receive the final treatment reports.

10. Doctor telephones patient in evening: The last touchpoint is the evening phone call by the practitioner to the patient. The value of this call cannot be overemphasized, as it is one of the most appreciated services reported by patients on their satisfaction surveys.

Remember that patients want to be treated in a clean and welcoming office environment. They evaluate your office on a continual basis, and educating your patients about the safety precautions you take will add value. Always assure patients that their comfort and safety are major objectives of their treatment. Try to explain the procedure, with permission, to the patient in terms they can understand. Use every opportunity to further establish your technological

leadership by making them a partner in their treatment. The relevance of your brand involves reverse thinking. You need to "move out of your world and into theirs."⁶⁸ It is not what you are selling; it is what they are buying, that counts!

DEVELOPING A CULTURE OF EXCELLENCE AROUND YOUR BRAND

The operation of the practice can be managed by asking a key question: How can I be excellent? And the answer is by designing systems that allow you to do the job right the first time. Creating a strategy to achieve success requires five basic steps, each dependent on the preceding step to accomplish your goals.

1. Step 1: Identify which patients you really want. Begin with a clear understanding of who your patients are and which ones you want to serve.
2. Step 2: Identify what your targeted referrers and patients deeply value. All purchasers of services or products want *results* and *process quality*. Finishing treatment with a pain-free and fully functioning tooth is the results part. And having a positive experience where respect, timeliness, courtesy and treatment with all needs (in the mind of the patient or referrer) met on a consistent basis is the process quality part of the equation.
3. Step 3: Develop a "customer-centered focus." Learn to manage the convergence between what your patients deeply value and the things that you do best. This means that the core procedures are performed in a caring and expert manner. Focus on the routine procedures that lend themselves to the highest levels of success with the most profit.
4. Step 4: Make "creating a customer-centered focus" your mission. Your mission is your "compass" in an increasingly challenging practice environment. This means understanding your mission and how each stakeholder will support and interact with the mission. Everyone needs a program that they can own, but be ready to change on a routine basis.
5. Step 5: Create an organization-wide obsession with your mission. To become consistent and successful, communicate your mission to your staff, your referring doctors, and patients.⁶⁹ In fact, brands demand consistency. According to Straine and Straine,⁷⁰ "If your receptionist is rude, if your office manager is unhelpful when a patient needs financing, if your policies are always changing, the negative impact on your brand" will destroy your efforts to achieve clinical excellence.

“QUALITY IN FACT” AND “QUALITY IN KIND”

Another important concept that will help the empathize with patients and referring doctors is the concept of treatment quality as viewed from the patient perspective. In a look at quality, former Malcolm Baldrige Award examiner Patrick Townsend⁷¹ defines *quality in fact* as goods or services that measure up to the specifications of the provider. For example, when an endodontic procedure is completed, does it meet all of the desired specifications as defined by the practitioner? Are all of the canals identified, cleaned, shaped, and obturated to completely seal the root canal system? If so, then the procedure meets the specifications of the provider and satisfies the criteria of a satisfactory case. But that is only half of the story. The other half is defined by the authors as *quality in kind*, or the way that the patient perceives the procedure—from their viewpoint. For patients, a successful visit will hinge on how the patient was treated, because the success of the procedure will be judged on the subjective quality as the patient sees it, or the experiential aspects of their visit. And do not short change the importance of the physical environment of the office. If the office looks tired, patients will respond in kind, because patients will “judge the book by its cover.” There is no way for most customers to even begin to assess the quality of the endodontic treatment they receive, they can only judge by how they were treated, the appearance of the office, and other non-technical aspects of their treatment. Take a quick mental journey through your office, reception area, front desk area, hallways, sterilization area, and operatories. Do they reflect your intended practice image? Are they modern, clean, efficient, organized, and calm? Does it send the message that your practice is up-to-date? Pay attention to the details—your patients and referrers are. Remember, you do not get a second chance to make a great first impression.

UNDERSTANDING SATISFACTION

A typical business customer satisfaction index is shown in Figure 1. If the satisfied and completely satisfied patients total 81%, should the directors of this company be content? Should a business concentrate its resources on increasing the satisfaction of the very dissatisfied patients or try to raise the merely satisfied customer to a completely satisfied level?

Studies have shown that it is far cheaper to raise the customer with a satisfaction index of from between 3.5 and 4.5 to a 5 than move a very dissatisfied customer

to a higher level.⁷² Many businesses spend a disproportionate amount of resources on a small percentage of customers who are almost impossible to please. Pursuing these customers also may hurt company morale and will disparage the company to other potential patients.

What impact will this have on an endodontic practice? Referring doctors and patients who enjoy complete satisfaction with your services are more likely to be loyal “apostles” of the office than those who are just satisfied.

Professor James Hasket⁷³ of the Harvard Business School, in his ground-breaking research on the “satisfaction-loyalty link,” states that “if employee performance and loyalty is good within an organization, then that organization’s customers will be more likely to repurchase a product or service.” One way to measure the satisfaction of your referring doctors and customers is to use a satisfaction survey. This tool, outlined in more detail above, can point out areas that you can improve, such as front desk operations, office hours, parking, and so on.

Once you have identified areas that need corrective action, be prepared to create an action plan to fix the problem. Remember, a problem exists if a referring doctor or a patient perceives a problem. Problems can be fixed and loyalty maintained if the problem is fixed quickly. It has been shown that 95% of customers will repurchase a product or service if the problem is fixed on the spot, and 78% of customers will repurchase if the problem is fixed within 24 hours.

Every patient and referring doctor should receive the basic elements they expect, like a professionally performed and technologically advanced procedure. Everyone receives the basic support services that include instructions, assistance with financial arrangements, and insurance filing. Everyone gets the basic recovery help that includes an apology for an appointment delay or correction of a billing error. But only certain referrers will get extraordinary services that excel in meeting their personal preference that make the service seem customized. An example of the extraordinary services you might provide to a core referrer might be treating a patient for his or her convenience on a Saturday for non-emergent treatment when you normally do not conduct business on a weekend.

PATIENT SATISFACTION SURVEYS

Patient questionnaires seek explicit information that can be analyzed and trended over time. Patient opinion surveys can help determine satisfaction with office personnel, procedures, or other aspects of the practice which may ultimately affect patient and

referring doctor loyalty. Opinion surveys can be customized to fit the needs of each practice and allow customers to vent if there are problems.

Several options are available, each of which can be integrated into broader Total Quality Management (TQM) initiatives or performance assessment strategies. Surveys can be short in-office questionnaires, with each patient filling out a form while in the office, or longer take-home questionnaires. Anonymity may prompt patients to be more honest with their feedback. If identity is disclosed, the surveys can include call-backs to patients after they have returned home. They can even involve focus groups to investigate very specific questions about programs, services, and staff. Other forms of surveys include mail and email surveys, sent to a random selection of patients. These survey channels may give the patient more time to complete the survey, which may result in a more in-depth response.

The most personal way to conduct a satisfaction survey is in person or by telephone. You can have a staff member or research professional perform the survey. Patients can more easily elaborate on their responses, but these types of surveys can be expensive.

In recent research published by Press Ganey Associates⁷⁴ to evaluate healthcare satisfaction, patients rated the courtesy, friendliness, and professionalism of the dental assistant as more important than that of the dentist! Infection control and cleanliness was rated second. While the dentist's skill was important, the dentist's attention to patient anxiety and concerns were directly related to patient loyalty and their potential to refer other patients. Patients also rated the amount of time spent with a patient and explanation of treatment options as important indicators of practice quality.

Installation of a bulletin board at your office to allow clinicians and staff to read each survey is an easy way to share comments and build a consensus. Many surveys reinforce employee behavior, especially if they mention a staff member by name. Each survey is an opportunity for your organization to improve.

CREATING A WEB SITE, STATIONARY, AND BROCHURE

One of the most often neglected parts of an office branding program is the production of Internet resources and coordinated office publications. Internet technology is advancing at a record pace. In every field, including dentistry, entrepreneurs are using it to devise new and better ways to develop business and lower costs. To ensure brand awareness in the

future, endodontists must acknowledge the enormous potential of this technology and develop sound strategies for harnessing all its capabilities. In the larger context, an Internet site can be part of your overall identity management program that ties together all marketing materials to communicate your practices vision. Using a professional design firm to create your Web site, stationary, and brochures will ensure a coordinated look that will be more powerful than unmatched pieces. Internet technology can enable your practice to broaden the scope of patient relations and increase communications with patients, referring doctors, and study clubs. Over the last few years, the Internet has become a unique medium for the endodontist to promote innovative and technically sophisticated treatment.

Getting started on a Web site can be a challenging because there is a tendency to keep changing, and the possibilities are virtually limitless. Here are some pointers to help you get started:

1. The best way to begin is to visit other medical and dental provider's Web sites. Learn how to navigate their site, what elements are required and if you want to include programs with more high-end graphic effects. Simple is better, but patients and referring doctors will want to see some "eye candy" and learn on each visit. Video segments featuring you and your staff are becoming more commonplace as video technology over the Internet improves.
2. Decide on your goals. Is it to generate referrals via Internet search engines, develop links to sites that market dentists, or serve as a resource for your patients and referring doctors?
3. Work with Web site professionals to create a design for your site. Remember that the design of the site should complement the image you are trying to project. Also, consider employing search engine optimization techniques to make your site more prominent.
4. Outline your proposed site and create a storyboard that includes navigation possibilities for your audience. Design every page on a separate piece of paper and test your ideas with friends, selected patients, and referring doctors.
5. Choose a Uniform Resource Locator (URL) so that Internet address can be easily remembered and entered in a browser with a minimum of effort and confusion. The URL should tie into your desired image.
6. Then just fill in the blanks with copy, photographs, and an appealing style that projects your vision. Keep it fresh. If you want repeat visitors,

continually update the site and make sure your links are relevant and functional.

Human Resources

Organizational success in endodontic practice requires a high-performance staff.⁷⁵ After all, your employees are your brand. They must understand what your brand stands for and how to deliver on your brand promise. Pfeffer and Veiga⁷⁶ observe that “there is a substantial and rapidly expanding body of evidence, some of it quite methodologically sophisticated, that speaks to the strong connection between how firms manage their people and the economic results achieved.” Exactly how important is marinating a well-trained and dedicated staff? Recent studies looked at 968 firms representing all major industries and found that just a 7% decrease in employee turnover resulted in a per employee increase of \$27,044 more in sales and \$18,641 more in market value.⁷⁷ It is clear that any business, including an endodontic practice, can benefit by adopting employee-related best practices to ensure financial success and ultimately clinical excellence.

According to Pfeffer and Veiga,⁷⁸ the most important elements of a successful HR management program are (1) providing long-term job security to assure that employee efforts will be rewarded; (2) recruiting and hiring the right people from the beginning; (3) creating self-managed project teams of peers to increase their sense of responsibility and accountability; (4) providing high compensation that is contingent on performance; (5) investing in extensive training for all employees; (6) reducing status differences between employees to improve idea generation from all employees; and (7) teaching information sharing to create a high-trust organization that allows inclusiveness.

JOB DESCRIPTION

The largest cost items for most endodontic practices is employee wages and benefits.⁷⁹ The plethora of regulations, such as equal employment opportunity (EEO) legislation enacted by local, state, and federal governments, has made job analysis a mandatory part of HR management. One of the most useful products of comprehensive job analysis is the job description, an Americans with Disability Act (AwDA) compliant narrative of the major responsibilities and duties associated with each job. While most job descriptions are limited to a single type of service or project, many endodontic offices require the use of cross-functional team members to complete certain tasks or to fill-in for a vacationing employee.

A good starting point is to consult O*NET, a US Department of Labor (DOL)-sponsored comprehensive source for continually updated information on occupational characteristics. Based on the most current version of the Standard Occupational Classification System, each O*NET occupational title and code includes descriptors for skills, abilities, knowledge, tasks, work activities, work context, experience levels required, job interests, and work values.⁸⁰ A partial sample of O*NET’s listed tasks, knowledge, and abilities section for dental assistants (code 31-9091.00) are summarized in Table 3.

THE STANDARD OPERATING PROCEDURE

Often overlooked but extremely valuable, the standard operating procedure (SOP) is a written practices and procedures reference, which is designed to ensure that key procedures are performed in a safe and compliant manner. The SOP is typically written by the current job holder and edited by the practice administrator.⁸¹ SOPs force employees to think through a procedure

Table 3 Tasks, Knowledge, and Ability Tasks

Importance	Category	Tasks
99 	Core	Prepare patient, sterilize and disinfect instruments, set up instrument trays, prepare materials, and assist dentist during dental procedures
92 	Core	Expose dental diagnostic X-rays (certification may be required)
90 	Core	Record treatment information in patient records
88 	Core	Take and record medical and dental histories and vital signs of patients
88 	Core	Provide post-operative instructions prescribed by dentist
87 	Core	Assist dentist in management of medical and dental emergencies
77 	Core	Instruct patients in oral hygiene and plaque control programs
79 	Supplemental	Apply protective coating of fluoride to teeth
76 	Supplemental	Schedule appointments, prepare bills and receive payment for dental services, complete insurance forms, and maintain records, manually or using computer
Importance	Knowledge	
87 	Medicine and Dentistry—Knowledge of the information and techniques needed to diagnose and treat human injuries, diseases, and deformities. This includes symptoms, treatment alternatives, drug properties and interactions, and preventive healthcare measures	
73 	Customer and Personal Service—Knowledge of principles and processes for providing customer and personal services. This includes customer needs assessment, meeting quality standards for services, and evaluation of customer satisfaction	
64 	English Language—Knowledge of the structure and content of the English language including the meaning and spelling of words, rules of composition, and grammar	
59 	Clerical—Knowledge of administrative and clerical procedures and systems such as word processing, managing files and records, stenography and transcription, designing forms, and other office procedures and terminology	
51 	Chemistry—Knowledge of the chemical composition, structure, and properties of substances and of the chemical processes and transformations that they undergo. This includes uses of chemicals and their interactions, danger signs, production techniques, and disposal methods	
42 	Computers and Electronics—Knowledge of circuit boards, processors, chips, electronic equipment, and computer hardware and software, including applications and programming	
40 	Psychology—Knowledge of human behavior and performance; individual differences in ability, personality, and interests; learning and motivation; psychological research methods; and the assessment and treatment of behavioral and affective disorders	
40 	Public Safety and Security—Knowledge of relevant equipment, policies, procedures, and strategies to promote effective local, state, or national security operations for the protection of people, data, property, and institutions	
36 	Mechanical—Knowledge of machines and tools, including their designs, uses, repair, and maintenance	
Importance	Ability	
78 	Oral Expression—The ability to communicate information and ideas in speaking so others will understand	
75 	Oral Comprehension—The ability to listen to and understand information and ideas presented through spoken words and sentences	
72 	Near Vision—The ability to see details at close range (within a few feet of the observer)	
72 	Written Expression—The ability to communicate information and ideas in writing so others will understand	
66 	Information Ordering—The ability to arrange things or actions in a certain order or pattern according to a specific rule or set of rules (e.g., patterns of numbers, letters, words, pictures, and mathematical operations)	
66 	Speech Clarity—The ability to speak clearly so others can understand you	
62 	Arm-Hand Steadiness—The ability to keep your hand and arm steady while moving your arm or while holding your arm and hand in one position	
60 	Speech Recognition—The ability to identify and understand the speech of another person	
56 	Finger Dexterity—The ability to make precisely coordinated movements of the fingers of one or both hands to grasp, manipulate, or assemble very small objects	
56 	Problem Sensitivity—The ability to tell when something is wrong or is likely to go wrong. It does not involve solving the problem, only recognizing there is a problem	
56 	Selective Attention—The ability to concentrate on a task over a period of time without being distracted	
56 	Written Comprehension—The ability to read and understand information and ideas presented in writing	
53 	Flexibility of Closure—The ability to identify or detect a known pattern (a figure, object, word, or sound) that is hidden in other distracting material	
53 	Manual Dexterity—The ability to quickly move your hand, your hand together with your arm, or your two hands to grasp, manipulate, or assemble objects	

Table 3 continued on page 1499

Table 3 continued from page 1498

53		Time Sharing—The ability to shift back and forth between two or more activities or sources of information (such as speech, sounds, touch, or other sources)
50		Category Flexibility — The ability to generate or use different sets of rules for combining or grouping things in different ways
50		Control Precision—The ability to quickly and repeatedly adjust the controls of a machine or a vehicle to exact positions
50		Deductive Reasoning—The ability to apply general rules to specific problems to produce answers that make sense

National wage and employment trends

Category	Occupation information
Employment (2004)	267,000 employees
Projected growth (2004–2014)	■■■ Much faster than average (36+ %)
Projected need (2004–2014)	189,000 additional employees

A partial list of the tasks, knowledge, and ability associated with dental assisting is reproduced above. Adapted from O*NET Web site <http://online.onetcenter.org/link/details/31-9091.00>, accessed May 1, 2007. O*NET is a service of the U.S. Department of Labor and acts as a comprehensive source of ranked descriptors for more than 900 occupations.

step by step and are in themselves useful training tools. More complex tasks lend themselves to the SOP structure for training new employees and modifying procedures to improve efficiency and safety. While SOPs work well for procedures that require safety and standardization, they may limit creativity where imagination is warranted. The best approach is to be concise and make the document as dynamic as possible. SOPs should be easily accessible to all employees via the practice's computer network and at a minimum should be updated on an annual basis.

Each SOP should have a header with the title, original issue date, revision dates, number of pages, the author of the SOP, and “approved by” signature plus the following basic elements (Table 4):

1. Desired outcome
2. Definitions
3. Measurement
4. General information
5. Step-by-step procedure with identification of critical information
6. Attachments and forms to be used, if any

CREATING THE EMPLOYEE HANDBOOK

Employee handbooks help to establish the employer's expectations and can prevent misunderstandings that may reduce the risk of litigation. Because most employees want to be successful, they will generally welcome a description of expectations, procedures for obtaining a promotion or raise, policies on dress, leave requests, work hours, disciplinary issues, and other important guidelines. The process involved in creating a handbook can also help you think through and establish your own unique policies. To aid in the process, consider getting

professional advice from your attorney, accountant, or a personnel advisory firm, so that personnel procedures are documented before contentious issues arise. Personnel advisory firms can provide comprehensive and cost-effective help and implementation, providing excellent handbooks, supporting resource manuals, and technical assistance. The ADA also sells a hand-book resource manual with step-by-step guidance.

Courts generally view both verbal and written policies as a contract. However, unwritten policies may pose more risk than written policies, because verbal policies either can be implied or given by someone with no authority. Written handbooks help avoid conflict by reducing the chances of a dispute between you and employee, especially in the most litigious areas of firing and discipline. It is critical that your handbook is properly vetted by knowledgeable advisors, because, as Peter Sfikas,⁸² ADA general council notes, courts “have determined that manuals, handbooks and booklets can create implied employment contracts, subjecting the employer and employee to additional terms and conditions of employment.” In the interest of both the employer and the employee, written handbooks that clearly state the policies of the practice serve to minimize the risk of litigation, and well-drafted disclaimers may help to maintain the “at will” status of employees. Generally, a clear statement at the beginning of the handbook stating that the handbook is not a contract and that the policies therein can change at any time without advanced notice will provide some measure of protection.

According to the U.S. SBA,⁸³ an employee handbook should include the following:

1. Overview of practice philosophy and history
2. Equal opportunity statement that hiring, promotion, pay, and benefits are not related to employee's

Table 4 Standard Operating Procedures: Computers

Desired Outcome: All computer equipment in the Practice will operate efficiently to create and store all radiographic and visible light images, clinical charts, patient financial transactions, appointments, protected health information (PHI), and other materials related to the Practice. Patient confidentiality will be maintained in accordance with the Practice's current Health Insurance Portability, and Accountability Act (HIPAA) Manual and office policies.

Definitions: Information technology (IT) refers to the use of computers and computer software to manage office information.

Measurement: Evaluation of internal and external customer satisfaction by "Employee Evaluation of Office" and "Patient Satisfaction Survey." Internal customers will experience infrequent computer down time, undergo adequate training, and use programs that do the intended job right the first time.

Introduction: All computer systems in the office are critical to the success of the Practice. The Practice stores all clinical and administrative data on the office computer system. Therefore, the Practice's computers and networks are to be used for Practice-related work only.

No expectation of privacy: In the course of operation and maintenance activities, use of computers and networks may be monitored to ensure the continuing effectiveness and integrity of the Practice's IT resources. Email, Web logs and data, and other files created or received while using the Practice's computers are neither private nor confidential. The Practice reserves the right to access and disclose all messages sent by its computers and networks, as well as any data created, received, or stored on them.

Computer security and access to files and email: Although the Practice intends to convey no expectation of privacy, its business communications must be protected from unauthorized access. At no time may any employee remove or transfer any data to computers outside of the office by any means, including disks, jump-drives, CD-ROMs, or the Internet for any reason.

Employees are not to give any computer information to anyone on the telephone who calls our office without specific permission from Dr. Levin or Dr. Lee. The only exception is our IT services company.

No disks, CD-ROMs, or other material of any kind can be brought from the home of an employee and placed on the Practice's computer systems at any time.

Patient confidentiality: see HIPAA Manual and office policies as published periodically.

Internet use: No employee is allowed to use the computer system for personal use at any time.

Web: When using the Web, only the approved Internet browser is permitted. Approved sites include only those directly related to the business of the Practice.

Email: Only MS Outlook, Google, and Yahoo are approved for email use. Any email messages generated or viewed at the office are the property of the Practice.

Virus protection: We use McAfee Enterprise virus protection, which automatically updates all of our workstations every night via the McAfee Web site and our LAN. All computers will be running McAfee virus protection at all times. This will protect our system from virus destruction and other potentially harmful computer intrusions. Confirm that this software is active at start-up and remains active at all times.

Firewall protection: We are protected from hackers through our Internet switch called WatchGuard "Firebox." Make sure this equipment is on at all times.

Backup: We use a tape backup system, located in the server. Each business day, a numbered tape is placed in the server and noted on the "Backup Log" by the operator's initials. Every Friday, the cleaning tape is placed in the tape drive, allowed to complete one cycle that takes approximately 1 minute, and is removed from the drive. On Monday, the Friday night tape is placed on Dr. Levin's laptop bag for off-site storage.

Passwords: Each employee will be issued a discrete user name and password to log into EndoVision. As there are nine levels of security, some codes will not allow every user to perform all tasks.

SQL: EndoVision (EV) and Schick (CDR) use their own database engines that reside on the server. This SQL database software must be active on the server to allow workstation access to EV and CDR. Both of these SQL database engines will be running on the "Taskbar" of the server. If you cannot login from any workstation for either EV or CDR, check the server to see if their individual SQL database engines (icons in the taskbar) are active.

PC software and hardware controls: Users may not download, purchase, or install software or hardware on office computers unless it is approved by Dr. Levin or Dr. Lee. Copyrighted and licensed materials may not be used on a PC or the Internet unless legally owned or otherwise in compliance with intellectual property laws.

Critical information is italicized.

- race, color, religion, sex, age, disability, or national origin.
3. Work hours should be defined, including time for lunch and conditions that could require late hours, such as treating after-hours emergencies.
4. Wage policies should include general information about when paychecks will be issued, how and when promotions are handled, classification of part-time, full-time, and on-call employees, overtime, loans, and leaves without pay.
5. The performance review section should describe how and when employees will be evaluated; unscheduled evaluations may be made at any time to advise employees of unsatisfactory work.
6. Paid holidays and all types of leave, including family (maternity, adoption, and elder care), medical, dental, funeral, personal, jury, and military should be listed.
7. A termination section should inform employees about causes that will trigger firing, including criminal activity, insubordination, absenteeism, and poor work performance.
8. All forms should be included, such as sample requests for vacation, medical leave, hepatitis vaccination declination, and so on.

9. Acknowledgement of receipt and reading of handbook by employees should be required by the practice and kept in the employee's personnel folder or other secure location.

Employee handbooks should be written by a lawyer specializing in employment law or by consultants who provide HR advice. A poorly written handbook may contain legal pitfalls that can lead to litigation. The following suggestions may help avoid some common errors:

1. A statement that conforms to your state's "employment-at-will" doctrine, which specifies that employment can be terminated at any time, for any reason, or no reason at all, will generally provide some measure of protection against successful litigation. Good advice here is critical, because construction of the document, obtaining written acknowledgement by the employee, public policy exceptions, situations where an expressed or implied employment contract exists, and "situations where an implicit duty of good faith exists in the employment relationship" can lead to confusion and ultimately to litigation.⁸⁴
2. Announcing a "probationary period" of employment may wrongly imply that employees are entitled to continuing employment after the probation period is over.
3. Employee manuals should not include benefit plan documents, but simply point employees toward other documentation.
4. Do not outline specific pre-firing procedures, because courts have held employers liable for "wrongful termination when those steps were not followed."⁸⁵
5. Generally, paychecks must be paid within a specified time limit, so be sure to specify these guidelines in accordance with local wage and hour laws.
6. Ensure that employees sign an acknowledgement that they have received, read, and agreed to the provisions of the handbook. Otherwise, an employee may claim that he or she never received the manual.
7. Limitations on employee-employee communications about wages or benefits are not allowed.

The employee handbook should be a positive tool for promoting better communication and improving morale. Be sure to review the handbook at least annually to be sure it is consistent with office policies. Also, annualizing employee performance reviews, raises and updating state and federal withholding forms to

coincide with the date of hire for each employee, will help improve compliance by the practice.

EMPLOYEE SELECTION CRITERIA

What are the predictors of the best job performance? In an article reviewing 85 years of the practical and theoretical implications of personnel psychology, researchers Schmidt and Hunter⁸⁶ have shown that, on average, intelligence or general mental ability (GMA) is the most useful primary personnel measure for hiring decisions when compared to all other attributes, including conscientiousness. The positive economic effects of assessing an applicant's intelligence and hiring only the top performers cannot be overestimated. Furthermore, this study states that performance in a skilled job will benefit more from a higher GMA than performance in a semi-skilled job. It turns out that people with a high GMA scientifically correlate with conscientiousness, agreeableness, and emotional stability.⁸⁷ Other studies have demonstrated that while intelligence is the best single predictor of performance, screening employees for how well their values fit with their employer's values (value fit) is also a predictor of employee satisfaction and retention. However, when interdependent tasks were measured against non-interdependent tasks, value fit predicted only better citizenship behaviors, not higher performance.⁸⁸

Of course, the success of your practice will depend, in part, on the people you hire. Ritz-Carlton hotels use an elaborate system for assessing job candidates, and the qualities the company believes are crucial to its success. When Paul Hemp,⁸⁹ a senior editor at the *Harvard Business Review*, spent a week at the hotel as a room-service waiter, he went through the new employee interview to see if he was the kind of candidate the Ritz was looking for. He said that "even after fudging my answers to a few questions, I got only ten points out of a possible fifteen in the composite hospitality assessment." The interviewer told Hemp that a score of 10 was not bad, but they wanted someone with a score of 12. He later found that just taking care of his sister in a time of need was not an extraordinary example of caring, but if he had given her his house for a month, he would have earned a higher score. Using scientifically based criteria, the Ritz has managed to reduce its annual employee turnover from the industry average of 55 to 28%!

Surveys that rank the importance of pay is another area of interest for the endodontic practice. Research has shown that self-reports of pay significance are likely to "underestimate its importance due to norms

that view money as a somewhat crass source of motivation.”⁹⁰ But money speaks, and getting the right combination of remuneration and benefits will positively impact your practice.

However, be certain to have any pre-employment exams or surveys thoroughly reviewed by an attorney or HR consultancy in order to ensure that it does not unintentionally skew results that disfavor applicants based on their protected EEO classes.

HIRING THE BEST PERSON FOR THE JOB

The hiring process should begin only after creating a set of job descriptions and an employee handbook. Once these documents are created, the next step is placing a job announcement in the print or online media or contracting with an employment agency. Typically, the Internet will produce same-day results and can be placed free of charge or on fee-based sites. An example of a job announcement for a Patient Coordinator written for Craig’s List, a popular online listing service follows:

Dental specialty office has immediate opening for a Patient Coordinator with a friendly attitude. If you share our vision of a customer-centered focus with a high-tech approach, this is the job for you! We are looking for someone who is a team player and enthusiastic (someone who likes to smile). You will need excellent telephone and customer service skills. Proficiency with MS Word and Excel is required. Responsibilities include answering the phones, scheduling, and welcoming new patients, billing, and organizing practice promotion activities.

This position requires some schedule flexibility as patient appointments may occasionally extend the workday. Our usual hours of operation are Monday to Friday 8:15 am until 5:15 pm. Employee handbook and complete benefits package including medical and parking await the right candidate. Please email your resume without attachments (cut and paste into body of email).

When candidates respond to the job announcement, a pre-interview screening of the applications by the person in charge of personnel can help in choosing the best qualified candidates. Ideally, the screener should review the applications for basic objective criteria and reject those that do not possess the minimum education, experience, or skills set. Having a formal intermediary step in the screening process may help insulate against litigation because it will interject an objectively neutral perspective into the hiring process that can mitigate any claims of bias.

It may also be helpful for you to conduct brief telephone interview with each of the remaining candidates. Asking a few open-ended questions like “Tell me about your recent job experience” may help to identify those applicants you deem worthy of further consideration and will provide an opportunity for the candidate to ask questions to determine whether they believe the job is right for them. After a positive phone conversation, invite the candidate for a face-to-face interview.

Have a job application form ready for the new candidate and make sure it includes appropriate language authorizing reference checks. Notifying the candidate of your intention to check references gives the candidate time to alert contacts to expect your inquiry. If you want to know what the prospective employee is really like, contacting his or her former employers may be the best way to find out. Many companies check references as the final part of their hiring process, and sometimes extend job offers with the condition that references check out. Using a reference request form with a waiver signed by the prospective hire is a good way to safely get the information. Try contacting former employers et al. at more than one company, if possible, to get the broadest picture of the candidate. It is best to restrict questions to those that relate to education, training, experience, qualifications, job performance, professional conduct, and reason for termination.

Check with your attorney or HR consultancy to make sure that you are in compliance with state employment laws. To ensure that the information exchanged is from a legitimate former employer, try using fax or mail to verify the information. To help make the process a little less litigious, many states have enacted legislation providing some immunity from civil liability for providing information about the employee. Also, many employers have their own policies regarding reference checks on current and former employees that restrict the information they divulge to position title and dates of employment. If you encounter such a response, do not automatically assume that the applicant had a negative employment experience with their previous employer.

The purpose of the initial interview is to form an impression of how the candidate will fit into the practice culture, confirm his or her technical skills, and narrow down the field of applicants. Keep a record of the conversation, with each question and answer documented for future reference. Always meet candidates at your office during regular business hours with other staff on premises during the entire meeting to preclude any chance of allegations of

inappropriate behavior. Unfortunately, many interviewers are improperly trained or uninterested in meeting with applicants. Nonetheless, endodontic practices, like other small businesses, need to adhere to good hiring practices or hire employees through employment agencies. Because many questions can open the door to non-job-related information that may be illegal, try to formulate behavioral questions guided by the job description. Having this list of questions ready will ensure that you get the precise information you need every time. Examples of good questions to ask are the following:

1. Tell me about a time when your teamwork with a co-worker helped you meet a patient's needs.
2. Give me an example of a mistake you made while carrying out your job duties. What happened? How did you correct the mistake?
3. Tell me the procedures used for sterilizing a treatment setup.
4. What steps do you take to ensure patient and operator safety when working with a patient?

Asking the right questions allows you to control the interview and helps to make certain that the interview is legally compliant.⁹¹ It is important that you ask the same questions for each candidate during the hiring process to ensure that each applicant is treated equally.

Remember that there are areas where caution should be used in making pre-employment inquiries. Whether asked on an application form or in an interview, the EEO Commission and state Departments of Labor will consider some questions as evidence of discrimination, unless the employer is able to show that the inquiries are job-related or that there is a documented business-related necessity for asking the question. Partial list of subject areas to avoid during interviews:⁹²

1. Arrest records
2. Garnishment records
3. Marital status
4. Child-care provisions
5. Contraceptive practices
6. Pregnancy and future childbearing plans
7. Physical or mental disabilities
8. Age, height, and weight
9. Nationality, race, or ancestry
10. Other areas of potential discrimination include certain limiting physical requirements, availability for weekend work, appearance standards, and fluency of the English language

Always avoid asking about the applicant's immigration or citizenship status. Although it will be necessary for the applicant to establish that they are lawfully permitted work in the United States, questions regarding the specific immigration status of the applicant can give rise to national origin discrimination claims. It is permissible to ask the applicant the yes or no question "are you lawfully permitted to work in the United States?"

Interviewers should avoid any assurances related to job security. Assuring the interviewee that they will "have their job for as long as they do a good job" is fraught with risk. If the applicant accepts the job and 6 months later is laid off, a breach of contract claim could be filed, where the employee asserts that he or she cannot be terminated unless they did not do a good job.

Once an offer of employment has been extended and the candidate has accepted the offer, a welcome packet of office information should be presented. This packet can include a welcome letter, employee handbook, a listing of compensation and benefits, employee roster, hepatitis vaccination verification or declination form (if applicable), health insurance application, payment options, retirement plans (if applicable), and any other information deemed important for the new employee. In addition, federal and state withholding forms, along with the Department of Homeland Security, U.S. Citizenship and Immigration Services' Employment Eligibility Verification form must be completed within 3 business days of the employment commencement date.⁹³

POSTING OF EMPLOYEE NOTICES

The US DOL⁹⁴ and all states including the District of Columbia require that notices be provided to employees and/or posted in the workplace where employees can readily observe them.⁹⁵ Designating a wall area in the employee locker room or break room will provide an ideal place for a bulletin board to post periodic notices to staff and federal and state posters. DOL provides free electronic and printed copies of these required notices and posters at the "elaws® Poster Advisor" on the DOL Web site.⁹⁶ State posting requirements can be determined by contacting your state DOL through the links page located on the DOL Web site. In addition, some states, like California, require distribution of pamphlets, such as the State Disability Insurance and Paid Family Leave pamphlets, to employees under certain circumstances.⁹⁷

EMPLOYEE BENEFIT AND SALARY ADMINISTRATION

Compliance with statutory wage and hour requirements is one of the areas that endodontic practices may find confusing, that is, hourly versus salaried compensation or complying with wage and hour requirements for staff travel to and attendance at continuing education meetings. Be sure to check with your HR advisors to determine the best policy.

Many practices use outside services for payroll processing and tax filing (i.e., W-2 and 1099 annual filing), reducing the chance of errors and incorrect filing of federal and state taxes. According to a recent study, the average small business that “ran payroll in-house and filed and paid quarterly taxes manually spent more than 250 hours away from customers... doing these tasks.”⁹⁸ Offering direct deposit of wages to each employee’s own bank account is an additional way to improve security and encourage staff members to maintain individual privacy and avoid salary comparisons. Direct deposit has the added advantage of ensuring that wages are available to employees as quickly as possible. No one benefits by stressed-out staff members leaving the office during the business day to deposit their payroll checks. Check your state wage and hour laws to determine if you can require direct deposit before mandating this service. Some new endodontic practice management software even includes timesheets with biometric fingerprint identification technology.

Additional information is available from the American Dental Assistants Association, ADA, Dental Assisting National Board, Inc. and the DOL, Bureau of Labor Statistics, on the national estimates for dental assistant wages, including industry and metropolitan area profiles for this occupation (Table 5).

There are several important laws governing salary and benefits compensation packages. The Fair Labor Standards Act (FLSA), the Employee Retirement Income Security Act (ERISA), and the (HIPAA) impose a myriad of complicated rules and regulations governing retirement plans, health insurance, cafeteria plans, and other benefits of employment. It is important that you seek guidance from a plan benefits advisor and attorney or HR consultant in deciding how to structure your employee salary and benefits packages.

TERMINATION

Few practice owners or managers want to face the emotionally charged process of firing people. Terminating employees in a way that preserves their dignity while preventing costly mistakes will benefit both the employee and the practice. The actual termination process will stay in everyone’s mind for a long time and speak volumes about the practice. At best, a successful termination can make the employee a friend of the practice and in the worst scenario can result in a costly legal process. A termination will also affect co-workers if not handled properly, even if the employee is not well liked. Remember that in most jurisdictions, employees have the right to claim unemployment benefits which will often raise the practice’s tax rate. The burden of proof is almost always on the practice to prove the reason for the separation in unemployment claims cases.

Even after carefully vetting new employees, he or she may not meet your expectations or may even act illegally. As soon as performance or discipline problems become apparent, start documenting your communications with the employee in question. Before terminating an employee, review your

Table 5 Dental Assistant Wages

Employment	Employment RSE	Mean Hourly Wage	Mean Annual Wage	Wage RSE	
270,720 Percentile wage estimates for this occupation	1.3%	\$14.41	\$29,970	0.6%	
Percentile	10%	25%	50% (Median)	75%	90%
Hourly Wage	\$9.46	\$11.53	\$14.19	\$16.92	\$20.21
Annual Wage	\$19,680	\$23,980	\$29,520	\$35,190	\$42,030
Employment estimate and mean wage estimates for all categories of dental assistants, (31-9091) for May 2005 (Adapted from http://www.bls.gov/oes/current/oes319091.htm , accessed March 2, 2007). According to the Dental Assisting National Board, certified dental assistants earn higher wages than those who are not certified (Adapted from http://www.dentalassisting.com , accessed March 2, 2007).					

employment offer letters, company policies, handbooks, and performance reviews to assure compliance with the practice's policies. If an employee performance review was conducted, exercising special care will help reduce the chances of litigation in the following situations: (1) when firing someone who has filed prior complaints about harassment or Occupational Safety and Health Act (OSHA) violations; (2) is older than 40 and covered by the Age Discrimination in Employment Act (ADEA); (3) is a member of a minority group because of race, color, gender, religion, or national origin; (4) has an employment contract; (5) has been promised job security or long tenure; and (6) if you are laying off more than one employee at once. In all cases, every employee must be treated even-handedly.

In determining whether to discipline or terminate an employee, it may be helpful to consider various factors to preserve objectivity. Consider the following:

1. The nature and seriousness of the offense and its relation to the employee's duties, position, and responsibilities, including whether the offense was intentional, technical, inadvertent, malicious, for personal gain, or was frequently repeated.
2. The employee's job level and type of employment, including supervisory or fiduciary role and contacts with customers.
3. The employee's past disciplinary record.
4. The employee's past work record, including length of service, performance on the job, ability to get along with fellow workers, and dependability.
5. The effect of the offense upon the employee's ability to perform at a satisfactory level and its effect upon supervisors' confidence in the employee's work ability to perform assigned duties.
6. Consistency of the penalty with those imposed upon other employees for the same or similar offenses.
7. The notoriety of the offense or its impact upon the reputation of the practice.
8. The clarity with which the employee was on notice of any rules that were violated in committing the offense or had been warned about the conduct in question.
9. The potential for the employee's rehabilitation.
10. Mitigating circumstances surrounding the offense such as unusual job tensions, personality problems, mental impairment, harassment, or bad faith, malice or provocation on the part of others involved in the matter.
11. The adequacy and effectiveness of alternative sanctions to deter such conduct in the future by the employee or others.

Although this list is not complete, it is a good starting point to consider when dealing with employee misconduct.

In sensitive firing situations or if terminating an employee is new to you, consult with an experienced employment lawyer or labor advisor ahead of time to prepare what to say, understand state laws that govern termination, and have all paperwork, salary checks, and severance pay ready to give to the employee. Always keep all discussions confidential and document the termination to aid in future communications with any state or federal agencies. Be prepared to answer the employee's questions about their schedule, severance pay, references, what will co-workers be told, medical and other insurance benefits, keys and security cards, profit sharing plan, if any, and eligibility for unemployment insurance.

Conducting an exit interview is another way to improve the work environment for the practice. Exit interviews should be conducted separately from the termination meeting and in small practices can be a simple survey to be mailed back or a phone conversation. Explain that the purpose of the interview is to gather information about the employee's experience at the practice and how it treats employees. Be sure to set the right tone, stay objective, and listen without providing opinions or becoming defensive.

EMPLOYMENT LAW

Many dentists assume that as they are practicing in an "at-will" state, they can discharge employees at anytime without problems. In certain circumstances, other issues can supersede the "at-will" prerogative, like violating an employee's civil rights. For example, the practice cannot discriminate against an employee who belongs to a protected class, where issues regarding age, sex, race, color, religion, disability, or national origin may play a role. Get the advice of legal council or your HR advisory firm if you plan to discharge an employee whose dismissal may trigger other issues.

It is best to administer your employment practices in a fair, equal, and consistent manner by counseling and documenting disciplinary and performance problems in written form. Include specific comments (i.e., reason for counseling, nature of disciplinary action, corrective action expected, consequences of non-compliance, and employee and employer comments) that are dated and signed by the administrator, employee, and a neutral witness, if possible. Never include an employee's co-workers or peers in the termination process.⁹⁹

The following suggestions may help avoid common legal pitfalls

1. Maintain two types of personnel files for each employee, regular and confidential. The I-9 form should be kept in the confidential file and should not be given to anyone for inspection without legal advice. The I-9 form should be kept for 3 years from date of hire or 1 year from termination, whichever is longer.
2. Have an established protocol to follow when an employee or former employee or their attorney asks to review his or her personnel file.
3. Have a signed employment handbook with each employee.
4. Prohibiting employees from talking about their wages or benefits is not allowed under the National Labor Relations Act which specifies the right of employees at all workplaces, unionized or not, to engage in collective bargaining.
5. To protect the privacy of employees, keep all employee files locked or off-site. Records in many states can only be disposed of by destruction, modification, or other reasonable action to protect personal information.⁹⁹
6. Employee records must be maintained on the following schedule.¹⁰⁰ OSHA: OSHA requires that records of job-related injuries and illnesses be kept for 5 years. Employers are also required to fill out and post an annual summary. Any exposure to toxic substances and blood-borne pathogens along with any records related to medical exams must be retained for 30 years after termination of employment. FLSA: Under the FLSA, the record-keeping requirements are 3 years to cover both supplementary basic records and payroll records. Civil Rights Act of 1964, Title VII, ADEA and the Americans with Disabilities Act (AwDA): Under the Civil Rights Act of 1964, Title VII, and the AwDA, employers with at least 15 employees must retain applications and other personnel records relating to hires, rehires, tests used in employment, promotion, transfers, demotions, selection for training, layoff, recall, terminations of discharge, for 1 year from making the record or taking the personnel action. The ADEA requires the retention of the same records for 1 year for employers with 20 or more employees. Title VII and the AwDA require that basic employee demographic data, pay rates, and weekly compensation records be retained for at least 1 year.
7. Family and Medical Leave Act (FMLA): The FMLA requires the retention of certain records

for 3 years with respect to payroll and demographic information as well as information related to the individual employee's leave of absence.

8. IRS: IRS rules require keeping copies of employment tax records (Social Security documents) for 4 years after the due date of the tax. If a claimant files a claim, the retention period should extend for 4 years after the date of the filing. (26 CFR 31.6001).

Other employment law issues to be aware of include the following:

1. The Uniformed Services Employment and Reemployment Rights Act (USERRA): USERRA requires employers to hold available the position of employees who are active reservists called for duty. This includes short-term assignments for training which may only require a few days of leave, or long-term active duty in times of conflict. Additional guidance may be found at the DOL Web site at <http://www.dol.gov/elaws/userra.htm>.
2. The Pregnancy Discrimination Act: An amendment to Title VII of the Civil Rights Act of 1964, the Pregnancy Discrimination Act prohibits an employer from treating an employee who becomes pregnant differently than any other employee with a serious medical condition. For example, if your practice grants extended leave (either paid or unpaid) to an employee recovering from a heart attack, you must grant the same consideration to a pregnant employee. Keep in mind, that pregnant employees may also have additional rights under the Family Medical Leave Act.
3. Sexual Harassment: It is imperative that your practice have a strongly worded written policy stating that sexual harassment will not be tolerated. It should include a provision that employees who report sexual harassment will not be retaliated against and notify them of a confidential process for reporting any instances of harassment. You should take prompt and remedial action in addressing any allegations of harassment including investigating the claims, separating the person who reported the harassment from the alleged harasser, and taking any necessary disciplinary actions. For more information, please refer to the U.S. Equal Employment Opportunities Commission (EEOC) guidance at <http://www.eeoc.gov/policy/docs/harassment.html>.
4. Local Laws: Local laws may expand or modify Federal employment statutes, so it is necessary that

you consult with an attorney or HR consultancy to become aware of any additional requirements. For example, some jurisdictions also prohibit discrimination on the bases of sexual orientation and/or political affiliation.

CONFIDENTIALITY AND NON-COMPETITION COVENANTS

Some employers require employees to sign non-compete covenants and confidentiality clauses. Generally, non-compete covenants with administrative or clerical staff will be held invalid. Some firms may legitimately enter into non-compete clauses with associates or other professional staff within their practice so long as they are for a limited duration (1 or 2 years); not overly restrictive (limited to a specialty practice and not the entire medical or dental profession); and of a limited geographic scope (a few mile radius of the current practice location). Keep in mind state laws and professional ethics rules may bar any non-compete covenants.

Contrary to covenants not to compete, confidentiality clauses can be enforced so long as they pertain to proprietary procedures or information and patient medical information. Consult with an attorney if you are considering either covenant.

EMPLOYMENT LIABILITY PRACTICES INSURANCE

Liability arising from employment practices continues an upward trend that shows no signs of abating. Unlike comprehensive general liability (CGL) policies, which insure against claims for tangible damages, for example, property damage, employment practices liability insurance (EPLI) insures against claims arising from employment practices. CGL policies differ from EPLI policies by excluding intentional acts and bodily injury that might occur while working. Also, CGL policies cover claims made while the policy is in effect, even if the claim is brought years later, whereas EPLI will cover only claims made during the coverage period or claims that the employer knew about or should have known about during the coverage period.

Many EPLI policies include wording that requires the insurance carrier to defend the employer against claims, even if the deductible has not been met. However, these clauses allow the carrier to choose the attorney who will defend the employer against the claim. Some policies also contain a provision that allows the carrier to settle the case, and if the employer rejects the settlement offer, the carrier can limit its liability to the amount offered in settlement

or require arbitration. Before purchasing coverage, carefully review limitations and exclusions to make sure the policy fits your needs, as follows: (1) find out what is covered in addition to wrongful termination, harassment, and discrimination, such as invasion of privacy, negligent supervision, and hiring issues; (2) check to see if the policy will cover claims made by current part-time or temporary employees, independent contractors, and the EEOC; (3) confirm that you can choose your legal defense team; and (4) choose a carrier that has a solid track record in the field.

WORKERS' COMPENSATION

Workers' compensation provides wage replacement benefits, medical treatment, vocational rehabilitation, and other benefits to certain workers or their dependents that experience work-related injury or an occupationally related disease. Workers' compensation claims can be minimized by ensuring a safe workplace and making sure employees are capable of performing their jobs before they are hired. Employers cannot ask about a prospective employee's Workers' compensation history before a job offer is made.

Whenever a work-related injury occurs, make sure that an accident report is completed and a notification is provided to your Workers' compensation insurance provider. Any work-related injury that occurs over a period of time, like carpal tunnel syndrome or hearing loss, must be reported by the employee as soon as he or she learns that it is work-related.

STAFF MEETINGS AND PEAK PERFORMANCE

As the U.S. demographic picture continues to change, and the population/dentist ratio exacerbates health-care manpower shortages, especially in rural and underserved areas, there has never been a greater need for the dental team to work more efficiently. Dental practices must not only "provide optimum patient care, but also must operate as a profit-making business"¹⁰¹ to ensure the ability to upgrade facilities and acquire new technologies and training

Along with hiring the right people, using meetings to enhance peak performance and improve service quality are the hallmarks of a well run office. The "morning huddle," a 10- to 15-minute briefing, facilitated by the patient coordinator, is a valuable way to keep up-to-date on patients, procedures, scheduling, upcoming events, and miscellaneous matters. As a group, determining the best place to schedule emergency patients and share suggestions about how to fill

appointment openings will improve efficiency and reduce stress. The agenda should include a brief review of production and collections from the previous day, expected for the current day, and the month, along with some time to discuss operational issues that need attention. Try to end on a positive note, adding a birthday or anniversary acknowledgement, a joke or a complement.¹⁰²

Regular staff meetings are another way that practices stay ahead. Start by creating a file for staff to place suggestions and complaints between meetings (a word processing file accessible to all computers on the network will be helpful). Make the meetings a safe environment for all to be heard, take minutes, and create a written action plan that gets reviewed in 48 hours to measure progress.¹⁰³ Hotel chains like the Ritz-Carlton, home of legendary customer service excellence and two-time winner of the Malcolm Baldrige Award, have pioneered many innovations in customer service. Believing that employees are one of the keys to success, the Ritz-Carlton hotels “win the hearts and minds of its employees by making them feel part of a proud heritage.”¹⁰⁴ Success in dental practice, and any profession for that matter, involves the construction of organizational processes and capabilities necessary to achieve performance through people delivering results and process quality.

Lastly, and all too often, organizations reach their goals and start planning new initiatives while forgetting to celebrate their accomplishments. Take time to acknowledge practice accomplishments by scheduling events, sending letters of praise, and giving out bonuses that say “Thank You!”
